product lifecycle

Steven Klepper
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The product life cycle connotes the idea that, comparable to humans and other organisms, new industries evolve through distinct and predictable stages. When industries are young, they are subject to high product innovation, rapid output growth, a build-up in the number of producers, and flux in firm market shares. As industries age, product innovation gives way to process innovation, output growth declines, the number of producers goes through a shakeout, and firm market shares stabilize. Evidence supporting this characterization is discussed and three alternative theoretical accounts of it are reviewed.

Keywords

innovation; market share; product life cycle

Article

The product life cycle (PLC) connotes the idea that industries evolve through distinct and predictable cycles, similar to the way humans and other organisms pass through distinct stages in their lives. Originally, the idea of a PLC was proposed in the marketing literature (Levitt, 1965). Subsequently it became a rallying point for how a number of disciplines view the evolution of new industries, especially ones with rich opportunities for product and process innovation.

Typically, three stages of evolution are distinguished in the PLC (see Williamson, 1975, pp. 215–16; Clark, 1985; and Drew, 1987, for prototypical depictions). In the first stage, uncertainty about user tastes and the means to satisfy them is high, product design is primitive, unspecialized machinery is used in production, and the volume of production is low. Many firms enter and compete on the basis of product innovation, offering different variants of the industry's product. In the next stage, output growth is high, the design of the product begins to stabilize, product innovation declines, specialized machinery is substituted for labour, and the production process becomes more refined. Entry slows and exit exceeds entry, leading to a shakeout of producers. In the final stage, the industry becomes mature. Output growth
slows, product innovation becomes less significant, diversity in product offerings declines, firm market
shares stabilize, entry remains low and the number of firms may continue to decline, and management,
marketing and manufacturing techniques become more refined. The firms that are left in the market
disproportionately tend to be those that entered early.

Industries

This conceptualization of the PLC has been heavily influenced by the history of the US automobile
industry, which is summarized in Klepper and Simons (1997). Commercial production of automobiles in
the United States began in 1895. By 1904 annual sales were only 22,800 cars, but from 1909 to 1919 the
average annual growth in the number of automobiles sold was 25.8 per cent, and well over a million cars
were sold in 1919. Subsequently annual growth slowed to 11.5 per cent through 1929 and then declined
to lower levels after the Second World War and the recovery from the Great Depression. Entry initially
was slow but then rose steadily through 1907, when it peaked at 82 firms. Two years later the number of
firms peaked at 272. Subsequently entry declined precipitously, the number of firms steadily fell, and by
1941 only nine firms were left in the industry. Counts of product and process innovations indicate that
product innovation peaked early in 1905 but process innovation increased steadily into the 1930s, with
innovations such as the moving assembly line revolutionizing the production process. Firm market
shares initially fluctuated greatly, but after 1910 the industry was dominated by Ford and General
Motors. Based on data for 1895–1966 (Klepper, 2002), early entry provided a decided advantage.
Thirteen of the 219 entrants from 1895 to 1904 survived at least 30 years, as against 3 of the 271
entrants from 1905 to 1909 and none of the subsequent 275 entrants from 1910 through 1966.
The shakeout of producers in automobiles was extreme, but Klepper and Simons (1997) document
similarly severe shakeouts in tyres, television receivers and penicillin. All experienced rapid initial
output growth that subsided over time. All experienced considerable entry that eventually became
negligible, after which the number of firms declined for many years. In all three products firm market
shares stabilized over time and the long-term survival rate was decidedly greater for earlier entrants
(Klepper, 2002). The record of innovation in the three products is less well documented than in autos
(Klepper and Simons, 1997). Trends in product and process innovation in tyres were similar to autos. In
televisions there were only two major product innovations, both of which occurred early, but labour
productivity grew steadily, suggesting no decline over time in process innovation. In penicillin process
preceded product innovation, but this was largely due to a government-orchestrated war effort to reduce
the cost of production of penicillin rather than market forces.
These three products were part of a larger sample of 46 new products studied by Gort and Klepper
(1982) and later by Klepper and Graddy (1990), Agarwal and Gort (1996), and Agarwal (1998). The
products were typically characterized by high initial growth in output that declined over time.
Pronounced shakeouts were common in a majority of the 46 products. Agarwal and Gort (1996) found
that early entrants had greater survival rates, although this was also true of very late entrants. No
systematic evidence was compiled on product and process innovation, but Agarwal's (1998) findings
suggest that products subject to greater technological change were more likely to experience shakeouts.
Numerous theories have been proposed to explain ‘excessive entry’ and shakeouts, but three stand out in their emphasis on technological change and thus their ability to address all aspects of the PLC. Jovanovic and MacDonald (1994) develop a model of a new industry that is created by a major invention. Initially firms enter to develop the invention until expected profits are driven to zero. Subsequently another major invention occurs that opens up the possibility of an increase in the minimum efficient scale of production. It may induce immediate entry, but entrants are at a disadvantage relative to incumbents in developing the invention because of their lack of experience. Successful innovators expand their output to the new minimum efficient scale, pushing down the price of the product until non-innovators are forced to exit, which triggers a shakeout.

Utterback and Suarez (1993) envision that firms enter a new industry based on innovative designs for the industry's product. Eventually consumers and producers coalesce around a particular design for the industry's product that becomes a de facto product standard known as a dominant design. Product innovation is limited to incremental improvements in the dominant design, which makes entry more difficult. Process innovation increases because firms become less fearful that product innovation will make investments in the production process obsolete. Firms less successful at process innovation, which tend to be later entrants with less experience, exit. Coupled with the decline in entry, this gives rise to a shakeout.

Klepper (1996) develops a model of the evolution of a new industry in which firm growth is costly and firm size conditions the returns from process R&D. This imparts a competitive advantage to earlier entrants. Over time, entry and incumbent expansion causes industry output to rise and price to fall. Eventually this renders entry unprofitable and it ceases. Continued decreases in price compromise the profitability of the latest entrants, forcing them to exit, giving rise to a steady decline in the number of producers. As incumbents expand, they increase their expenditures on process R&D, causing a rise in process relative to product innovation. Firm price–cost margins also get compressed, which diminishes the incentives of firms to grow, causing firm market shares to become more stable and industry output growth to decline.

Testing of alternative accounts of the PLC is in its incipiency. Klepper and Simons (2005) found that in autos, tyres, televisions and penicillin, innovation was dominated by the leading firms and was a key determinant of firm survival, as predicted by all three theories. During the shakeouts in the four products, exit rates of early and late entrants generally did not converge, which is not consistent with the first two theories.

Variations

Not all technologically progressive industries follow the PLC (Klepper, 1997). Notably, some industries have not experienced any sign of a shakeout after 35 years and show no sign of the decline in entry that is characteristic of shakeout industries. Two examples that were in Gort and Klepper's (1982) sample of 46 new products are styrene, which is a petrochemical, and lasers. In both industries firms have ended up specializing either vertically (styrene) or horizontally (lasers). In other industries, technological developments led to turnover in the leading firms, undermining the advantages of early entry. This occurred in the disk drive industry before it went through a shakeout (Christensen, 1993). It also
occurred in autos, tyres and televisions well after their shakeouts had begun, with long-time US leaders
displaced by Japanese and European firms that capitalized on small cars, radial tyres and the use of
semiconductors in televisions.
These examples make clear that the PLC is a composite that only describes the prototypical evolutionary
path followed by new industries. It will be an ongoing challenge to document systematic departures
from the PLC and to understand the forces that contribute to them. This process is just beginning.

Abstract

Traditionally, the production function was assumed to be additive and homogeneous. The constant elasticity of substitution (CES) production function adds flexibility by treating the elasticity of substitution as an unknown parameter, but retains the assumptions of additivity and homogeneity and imposes very stringent limitations on patterns of substitution. The dual formulation of production theory characterizes the production function by means of a dual representation such as a price or cost function, and generates explicit demand and supply functions as derivatives of the price or cost function.

Article

1 Introduction

The economic theory of production – as presented in such classic treatises as Hicks’s Value and Capital (1946) and Samuelson’s Foundations of Economic Analysis (1983) – is based on the maximization of profit, subject to a production function. The objective of this theory is to characterize demand and supply functions, using only the restrictions on producer behaviour that arise from optimization. The principal analytical tool employed for this purpose is the implicit function theorem.

The traditional approach to economic modelling of producer behaviour begins with the assumption that the production function is additive and homogeneous. Under these restrictions demand and supply functions can be derived explicitly from the production function and the necessary conditions for producer equilibrium. However, this approach has the disadvantage of imposing constraints on patterns of producer behaviour – thereby frustrating the objective of determining these patterns empirically.

The traditional approach was originated by Cobb and Douglas (1928) and was employed in empirical research by Douglas (1948, 1967, 1976) and his associates for almost two decades. The limitations of this approach were made strikingly apparent by Arrow, Chenery, Minhas and Solow (1961, henceforward ACMS), who pointed out that the Cobb–Douglas production function imposes a priori restrictions on patterns of substitution among inputs. In particular,
elasticities of substitution among all inputs must be equal to unity.
The constant elasticity of substitution (CES) production function introduced by ACMS adds flexibility to the traditional approach by treating the elasticity of substitution as an unknown parameter. However, the CES production function retains the assumptions of additivity and homogeneity and imposes very stringent limitations on patterns of substitution. McFadden (1963) and Uzawa (1962) have shown, essentially, that elasticities of substitution among all inputs must be the same.
The dual formulation of production theory has made it possible to overcome the limitations of the traditional approach to econometric modelling. This formulation was introduced by Hotelling (1932) and later revived and extended by Samuelson (1953, 1960) and Shephard (1953, 1970). The key features of the dual formulation are, first, to characterize the production function by means of a dual representation such as a price or cost function, and second, to generate explicit demand and supply functions as derivatives of the price or cost function.
Patterns of producer behaviour can be described most usefully in terms of the behaviour of the derivatives of demand and supply functions. For example, measures of substitution can be specified in terms of the response of demand patterns to changes in input prices. Similarly, measures of technical change can be specified in terms of the response of these patterns to changes in technology. The classic formulation of production theory at this level of specificity can be found in Hicks's *Theory of Wages* (1963).
Hicks (1963) introduced the elasticity of substitution as a measure of substitutability. The elasticity of substitution is the proportional change in the ratio of two inputs with respect to a proportional change in their relative price. Similarly, Hicks introduced the bias of technical change as a measure of the impact of changes in technology on patterns of demand for inputs. The bias of technical change is the response of the share of an input in the value of output to a change in the level of technology.
By treating measures of substitution and technical change as fixed parameters the system of demand and supply functions can be generated by integration. Provided that the resulting functions are themselves integrable, the underlying price or cost function can be obtained by a second integration. As we have already pointed out, Hicks's elasticity of substitution is unsatisfactory for this purpose, since it leads to arbitrary restrictions on patterns of producer behaviour. The introduction of a new measure of substitution, the share elasticity, by Christensen, Jorgenson and Lau (1971, 1973) and Samuelson (1973) has made it possible to overcome the limitations of parametric forms based on constant elasticities of substitution. Share elasticities, like biases of technical change, can be defined in terms of shares of inputs in the value of output. The share elasticity of a given input is the response of the share of that input to a proportional change in the price of an input.

2 Models of producer behaviour

The purpose of this section is to present the simplest form of the economic theory of production. We base this theory on a production function with constant returns to scale. Producer equilibrium implies the existence of a price function, giving the price of output as a function of the prices of inputs and the level of technology. The price function is dual to the production function and provides an alternative and equivalent description of technology.
An econometric model of producer behaviour takes the form of a system of simultaneous equations, determining the distributive shares of the inputs and the rate of technical change as functions of the input prices and the level of technology. Measures of substitution and technical change give the responses of the distributive shares and the rate of technical change to changes in prices and technology. To generate an econometric model of producer behaviour we treat these measures as unknown parameters to be estimated.
In order to present the theory of production we first require some notation. We denote the quantity of output by \( y \) and the quantities of \( J \) inputs by \( x_j (j = 1, 2, \ldots, J) \). Similarly, we denote the price of output by \( q \) and the prices of the \( J \) inputs by \( p_j (j = 1, 2, \ldots, J) \). We find it convenient to employ vector notation for the input quantities and prices:

\[
\mathbf{x} = (x_1, x_2, \ldots, x_J) \quad \text{vector of input quantities}.
\]
\[
\mathbf{p} = (p_1, p_2, \ldots, p_J) \quad \text{vector of input prices}.
\]
We assume that the technology can be represented by a production function, say \( F \), where:

\[
\gamma = F(x, t),
\]

(1)

and \( t \) is an index of the level of technology. In the analysis of time series data for a single producing unit the level of technology can be represented by time. In the analysis of cross-section data for different producing units the level of technology can be represented by one-zero dummy variables corresponding to the different units.

We can define the shares of inputs in the value of output by:

\[
v_j = \frac{p_j x_j}{\gamma}, \quad (j = 1, 2, \ldots, J).
\]

Under competitive markets for output and all inputs the necessary conditions for producer equilibrium are given by equalities between the share of each input in the value of output and the elasticity of output with respect to that input:

\[
\nu = \frac{\partial \ln \gamma(x, t)}{\partial \ln x},
\]

(2)

where:

\[
\nu = (\nu_1, \nu_2, \ldots, \nu_J) - \text{vector of value shares}, \quad \ln x = (\ln x_1, \ln x_2, \ldots, \ln x_J) - \text{vector of logarithms of input quantities}.
\]

Under constant returns to scale the elasticities and the value shares for all inputs sum to unity:

\[
i' \nu = i' \frac{\partial \ln \gamma}{\partial \ln x} = 1,
\]

where \( i \) is a vector of ones. The value of output is equal to the sum of the values of the inputs.

Finally, we can define the rate of technical change, say \( \nu_t \), as the rate of growth of the quantity of output holding all inputs constant:
It is important to note that this definition does not impose any restriction on patterns of substitution among inputs. Given the identity between the value of output and the value of all inputs and given equalities between the value share of each input and the elasticity of output with respect to that input, we can express the price of output as a function, say $Q$, of the prices of all inputs and the level of technology:

$$Q = Q(p, t).$$

We refer to this as the price function for the producing unit. The price function $Q$ is dual to the production function $F$ and provides an alternative and equivalent description of the technology of the producing unit. We can formalize this description in terms of the following properties of the price function:

1. (1) **Positivity.** The price function is positive for positive input prices.
2. (2) **Homogeneity.** The price function is homogeneous of degree one in the input prices.
3. (3) **Monotonicity.** The price function is increasing in the input prices.
4. (4) **Concavity.** The price function is concave in the input prices.

Given differentiability of the price function, we can express the value shares of all inputs as elasticities of the price function with respect to the input prices:

$$\nu = \frac{\partial \ln Q(p, t)}{\partial \ln p},$$

where:

$$\ln p = (\ln p_1, \ln p_2, \ldots, \ln p_l) - \text{vector of logarithms of input prices}.$$
Since the price function $Q$ is homogeneous of degree one in the input prices, the value shares and the rate of technical change are homogeneous of degree zero and the value shares sum to unity.

We have represented the value shares of all inputs and the rate of technical change as functions of the input prices and the level of technology. We can introduce measures of substitution and technical change to characterize these functions in detail. For this purpose we differentiate the logarithm of the price function twice with respect to the logarithms of input prices to obtain measures of substitution:

$\nu_{\ln p} = \frac{\partial \ln q(p, t)}{\partial p}.$

We refer to the measures of substitution (7) as *share elasticities*, since they give the response of the value shares of all inputs to proportional changes in the input prices. If a share elasticity is positive, the corresponding value share increases with the input price. If a share elasticity is negative, the value share decreases with the input price. Finally, if a share elasticity is zero, the value share is independent of the price.

Second, we can differentiate the logarithm of the price function twice with respect to the logarithms of input prices and the level of technology to obtain measures of technical change:

$u_{\ln p\ln t} = \frac{\partial^2 \ln q(p, t)}{\partial \ln p \partial \ln t} = \frac{\partial \nu(p, t)}{\partial \ln p}.$

We refer to these measures as *biases of technical change*. If a bias of technical change is positive, the corresponding value share increases with a change in the level of technology and we say that technical change is *input-using*. If a bias of technical change is negative, the value share decreases with a change in technology and technical change is *input-saving*. Finally, if a bias is zero, the value share is independent of technology; in this case we say that technical change is *neutral* (in the sense of Hicks).

Alternatively, the vector of biases of technical change $u_{\ln p \ln t}$ can be employed to derive the implications of changes in input prices for the rate of technical change. If a bias of technical change is positive, the rate of technical change decreases with the input price. If a bias is negative, the rate of technical change increases with the input price. Finally, if a bias is zero so that technical change is neutral, the rate of technical change is independent of the price.

To complete the description of technical change we can differentiate the logarithm of the price function twice with respect to the level of technology:

$u_{\ln t} = \frac{\partial^2 \ln q(p, t)}{\partial t^2} = -\frac{\partial \nu_t(p, t)}{\partial t}.$
We refer to this measure as the *deceleration* of technical change, since it is the negative of rate of change of the rate of technical change. If the deceleration is positive, negative, or zero, the rate of technical change is decreasing, increasing, or independent of the level of technology.

The matrix of second-order logarithmic derivatives of the logarithm of the price function \( Q \) must be symmetric. This matrix includes the matrix of share elasticities \( U_{pp} \), the vector of biases of technical changes \( u_{pt} \), and the deceleration of technical change \( u_{tt} \). Concavity of the price function in the input prices implies that the matrix of second-order derivatives, say \( H \), is nonpositive definite, so that the matrix \( U_{pp} + \nu' - \nu \) is nonpositive definite, where:

\[
\frac{1}{q} N \cdot H \cdot N = U_{pp} + \nu' - \nu;
\]
the price of output \( q \) is positive and the matrices \( N \) and \( V \) are diagonal:

\[
N = \begin{bmatrix}
p_1 & 0 & \ldots & 0 \\
0 & p_2 & \ldots & 0 \\
& & \ddots & \vdots \\
0 & 0 & \ldots & p_J
\end{bmatrix}, \quad V = \begin{bmatrix}
\nu_1 & 0 & \ldots & 0 \\
0 & \nu_2 & \ldots & 0 \\
& & \ddots & \vdots \\
0 & 0 & \ldots & \nu_J
\end{bmatrix}
\]

We can define substitution and complementarity of inputs in terms of the matrix of share elasticities \( U_{pp} \) and the vector of value shares \( \nu \). We say that two inputs are *substitutes* if the corresponding element of the matrix \( U_{pp} + \nu' - \nu \) is negative. Similarly, we say that two inputs are *complements* if the corresponding element of this matrix is positive. If the element of this matrix corresponding to the two inputs is zero, we say that the inputs are *independent*. The definition of substitution and complementarity is symmetric in the two inputs, reflecting the symmetry of the matrix \( U_{pp} + \nu' - \nu \). If there are only two inputs, nonpositive definiteness of this matrix implies that the inputs cannot be complements.

To generate an econometric model of producer behaviour a natural approach is to treat the measures of substitution and technical change as unknown parameters to be estimated. For this purpose we introduce the parameters:

\[
B_{pp} = U_{pp}, \quad B_{pt} = u_{pt}, \quad B_{tt} = u_{tt},
\]

(10)

where \( B_{pp} \) is a matrix of constant share elasticities, \( B_{pt} \) is a vector of constant biases of technical changes, and \( B_{tt} \) is a constant deceleration of technical change.

We can regard the matrix of share elasticities, the vector of biases of technical change, and the deceleration of technical
change as a system of second-order partial differential equations. We can integrate this system to obtain a system of first-order partial differential equations:

\[ v = \alpha_p + B_{pp} \ln p + \beta_{pt} t, \quad v_t = \alpha_t + \beta_{pt} \ln p + \beta_{tt} t, \]

(11)

where the parameters—\( \alpha_p, \alpha_t \)—are constants of integration.

To provide an interpretation of the parameters—\( \alpha_p, \alpha_t \)—we first normalize the input prices. We can set the prices equal to unity where the level of technology \( t \) is equal to zero. This represents a choice of origin for measuring the level of technology and a choice of scale for measuring the quantities and prices of inputs. The vector of parameters \( \alpha_p \) is the vector of value shares and the parameter \( \alpha_t \) is the negative of the rate of technical change where the level of technology \( t \) is zero.

Similarly, we can integrate the system of first-order partial differential equations (11) to obtain the price function:

\[ \ln p = \alpha_0 + \alpha_p \ln p + \alpha_t t + \frac{1}{2} \ln p \rightarrows B_{pp} \ln p + \ln p \rightarrows \beta_{pt} t + \frac{1}{2} \beta_{tt} t^2, \]

(12)

where the parameter \( \alpha_0 \) is a constant of integration. Normalizing the price of output so that it is equal to unity where \( t \) is zero, we can set this parameter equal to zero. This represents a choice of scale for measuring the quantity and price of output.

For the price function (12) the price of output is a transcendental or, more specifically, an exponential function of the logarithms of the input prices. We refer to this form as the \textit{transcendental logarithmic} price function or, more simply, the translog price function, indicating the role of the variables. We can also characterize this price function as the \textit{constant share elasticity} or CSE price function, indicating the role of the fixed parameters. In this representation the scalars—\( \alpha_t, \beta_{tt} \)—the vectors—\( \alpha_p, \beta_{pt} \)—and the matrix \( B_{pp} \) are constant parameters that reflect the underlying technology. Differences in levels of technology among time periods for a given producing unit or among producing units at a given point of time are represented by differences in the level of technology \( t \).

3 Economies of scale

In section 2 we have considered producer behaviour under constant returns to scale. In this section we consider producer behaviour under increasing returns to scale. Under increasing returns and competitive markets for output and all inputs, producer equilibrium is not defined by profit maximization, since no maximum of profit exists. However, in regulated industries the price of output is set by regulatory authority. Given demand for output as a function of the regulated price, the level of output is exogenous to the producing unit.

With output fixed from the point of view of the producer, necessary conditions for equilibrium can be derived from cost minimization. Where total cost is defined as the sum of expenditures on all inputs, the minimum value of cost can be expressed as a function of the level of output and the prices of all inputs. We refer to this function as the cost function. We have described the theory of production under constant returns to scale in terms of properties of the price function (3); similarly, we can describe the theory under increasing returns in terms of properties of the cost function.

Utilizing the notation of section 2, we can define total cost, say \( c \), as the sum of expenditures on all inputs:
\[ \tau = \sum_{j=1}^{J} p_j x_j. \]

We next define the shares of inputs in total cost by:

\[ v_j = \frac{p_j x_j}{\tau}, \quad (j = 1, 2, \ldots, J). \]

With output fixed from the point of view of the producing unit and competitive markets for all inputs, the necessary conditions for producer equilibrium are given by equalities between the shares of each input in total cost and the ratio of the elasticity of output with respect to that input and the sum of all such elasticities:

\[ v = \frac{\frac{\partial \ln v}{\partial \ln x}}{\frac{\partial \ln v}{\partial \ln x}}, \quad (13) \]

where \( i \) is a vector of ones and:

\[ v = (v_1, v_2, \ldots, v_J) - \text{vector of cost shares}. \]

Given the definition of total cost and the necessary conditions for producer equilibrium, we can express total cost, say \( c \), as a function of the prices of all inputs and the level of output:

\[ \tau = C(p, y). \quad (14) \]

We refer to this as the cost function. The cost function \( C \) is dual to the production function \( F \) and provides an alternative and equivalent description of the technology of the producing unit.

We can formalize the theory of production in terms of the following properties of the cost function:

1. (1) **Positivity.** The cost function is positive for positive input prices and a positive level of output.
2. (2) **Homogeneity.** The cost function is homogeneous of degree one in the input prices.
3. (3) **Monotonicity.** The cost function is increasing in the input prices and in the level of output.
4. (4) Concavity. The cost function is concave in the input prices.

Given differentiability of the cost function, we can express the cost shares of all inputs as elasticities of the cost function with respect to the input prices:

\[
\nu = \frac{\partial \ln c(p, y)}{\partial \ln p}.
\]

(15)

Since the cost function is increasing in the input prices, the cost shares must be non-negative. We can define an index of returns to scale as the elasticity of the cost function with respect to the level of output:

\[
\nu_y = \frac{\partial \ln c(p, y)}{\partial \ln y}.
\]

(16)

Following Frisch (1965), we can refer to this elasticity as the cost flexibility. The cost function is increasing in the level of output, so that the cost flexibility is positive. Since the cost function \( C \) is homogeneous of degree one in the input prices, the cost shares and the cost flexibility are homogeneous of degree zero and the cost shares sum to unity. The cost flexibility \( \nu_y \) is the reciprocal of the degree of returns to scale, defined as the elasticity of output with respect to a proportional increase in all inputs:

\[
\nu_y = \frac{1}{\nu_x}.
\]

(17)

If output increases more than in proportion to the increase in inputs, cost increases less than in proportion to the increase in output.

We have represented the cost shares of all inputs and the cost flexibility as functions of the input prices and the level of output. We can characterize these functions in terms of measures of substitution and economies of scale. We obtain share elasticities by differentiating the logarithm of the cost function twice with respect to the logarithms of input prices:

\[
U_{\ln p} = \frac{\partial^2 \ln c(p, y)}{\partial \ln p^2} = \frac{\partial \nu(p, y)}{\partial \ln p}.
\]

(18)

These measures of substitution give the response of the cost shares of all inputs to proportional changes in the input prices.
prices.
Second, we can differentiate the logarithm of the cost function twice with respect to the logarithms of the input prices and the level of output to obtain measures of economies of scale:

\[
\mu_{\ln p, \ln y} = \frac{\partial^2 \ln \mathcal{C}(p, y)}{\partial \ln p \partial \ln y} = \frac{\partial v_y(p, y)}{\partial \ln y} = \frac{\partial v_y(p, y)}{\partial \ln p}.
\]

We refer to these measures as *biases of scale*. The vector of biases of scale \( \mu_{\ln p, \ln y} \) can be employed to derive the implications of economies of scale for the relative distribution of total cost among inputs. Alternatively, this vector can be employed to derive the implications of changes in input prices for the cost flexibility. To complete the description of economies of scale we can differentiate the logarithm of the cost function twice with respect to the level of output:

\[
\mu_{\ln y} = \frac{\partial^2 \ln \mathcal{C}(p, y)}{\partial \ln y^2} = \frac{\partial v_y(p, y)}{\partial \ln y}.
\]

The matrix of second-order logarithmic derivatives of the logarithms of the cost function \( \mathcal{C} \) must be symmetric. This matrix includes the matrix of share elasticities \( U_{\ln p} \), the vector of biases of scale \( \mu_{\ln p, \ln y} \), and the derivative of the cost flexibility with respect to the logarithm of output \( \mu_{\ln y} \). Concavity of the cost function in the input prices implies that the matrix of second-order derivatives, say \( H \), is nonpositive definite, so that the matrix \( U_{\ln p} + \mu_{\ln y} - \mu_{\ln y} \) is nonpositive definite, where:

\[
\frac{1}{\mathcal{C}} N \cdot H \cdot N = U_{\ln p} + \mu_{\ln y} - \mu_{\ln y}.
\]

Total cost \( \mathcal{C} \) is positive and the diagonal matrices \( N \) and \( V \) are defined in terms of the input prices \( p \) and the cost shares \( v \), as in Section 2.
We say that the cost function \( \mathcal{C} \) is *homothetic* if and only if the cost function is separable in the prices of all \( J \) inputs \( \{p_1, p_2, \ldots, p_J\} \), so that:

\[
\mathcal{C} = \mathcal{C}[P(p_1, p_2, \ldots, p_J), y],
\]

where the function \( P \) is homogeneous of degree one and independent of the level of output \( y \). The cost function is homothetic if and only if the production function is *homothetic*, where:
\[ y = F(G(x_1, x_2, ..., x_l)), \]  
(22)

where the function \( G \) is homogeneous of degree one.

Since the cost function is homogeneous of degree one in the input prices, it is homogeneous of degree one in the function \( P \), which can be interpreted as the price index for a single aggregate input; the function \( G \) is the corresponding quantity index. Furthermore, the cost function can be represented as the product of the price index of aggregate input \( P \) and a function, say \( H \), of the level of output:

\[ \ell = P(p_1, p_2, ..., p_l) \cdot H(y). \]  
(23)

Under homotheticity, the cost flexibility \( \nu_y \) is independent of the input prices:

\[ \nu_y = \frac{\partial \ln H(y)}{\partial \ln y}. \]  
(24)

If the cost flexibility is also independent of the level of output, the cost function is homogeneous in the level of output and the production function is homogeneous in the quantity index of aggregate input \( G \). The degree of homogeneity of the production function is the degree of returns to scale and is equal to the reciprocal of the cost flexibility. Under constant returns to scale the degree of returns to scale and the cost flexibility are equal to unity.

We can generate an econometric model of cost and production by introducing the parameters:

\[ \theta_{pp} = \alpha_{pp}, \theta_{py} = \alpha_{py}, \theta_{yy} = \alpha_{yy}, \]  
(25)

where \( \theta_{pp} \) is a matrix of constant share elasticities, \( \theta_{py} \) is a vector of constant biases of scale, and \( \theta_{yy} \) is a constant derivative of the cost flexibility with respect to the logarithm of output. We can treat the matrix of constant parameters as a system of second-order partial differential equations, obtaining:

\[ \nu = \alpha_p + \theta_{pp} \ln p + \theta_{py} \ln y, \nu_y = \alpha_y + \theta_{py} \ln p + \theta_{yy} \ln y, \]  
(26)

where the parameters – \( \alpha_p, \alpha_y \) – are constants of integration.
We can integrate the system (26) to obtain the cost function:

\[
\ln c = \alpha_0 + \alpha p \ln p + \alpha y + \frac{1}{2} \ln p' \beta_{yy} \ln p + \ln p' \beta_{yp} y + \frac{1}{2} \beta_{yy} (\ln y)^2,
\]

(27)

where the parameter \( \alpha_0 \) is a constant of integration. We can refer to this form as the translog cost function, indicating the role of the variables, or the constant share elasticity (CSE) cost function, indicating the role of the parameters.

Under homotheticity the cost flexibility is independent of the input prices. A necessary and sufficient condition for homotheticity is given by:

\[
\beta_{yy} = 0;
\]

(28)

the vector of biases of scale is equal to zero. Under homogeneity the cost flexibility is also independent of output, so that:

\[
\beta_{yy} = 0;
\]

(29)

the derivative of the flexibility with respect to the logarithm of output is zero. Finally, under constant returns to scale, the cost flexibility is equal to unity; given the restrictions implied by homotheticity, constant returns requires:

\[
\alpha y = 1.
\]

(29)

4 Summary and conclusion

The econometric modelling of producer behaviour requires parametric forms for demand and supply functions. Patterns of production can be represented in terms of unknown parameters that specify the responses of demands and supplies to changes in prices, technology and scale. New measures of substitution, technical change and economies of scale have provided greater flexibility in the empirical determination of production patterns. These innovations have arisen from the dual formulation of the theory of production.

We can conclude by suggesting possible directions for future research. The primary focus of our discussion has been on the characterization of technology for individual producing units. Application of the results typically involves models for both demand and supply of a given commodity. The ultimate objective of econometric modelling of production is to construct general equilibrium models encompassing demands and supplies for a wide range of products and factors of production, along the lines suggested by Jorgenson (1983).

Our exposition of the theory of production has emphasized models where the econometric methodology has crystallized.
An important area for future research is the implementation of dynamic models of technology. These models are based on substitution possibilities among outputs and inputs at different points of time. The simplest intertemporal model of production is based on capital as a factor of production. This model is treated in a companion paper by Jorgenson (1986). A number of promising avenues for further investigation have been suggested in the literature on the theory of production summarized in the entry on vintages.

Article

A theory of profit should address itself to at least three questions – about the size (volume) of profit, its share in total income and about the rate of profit on capital invested. Each of these three issues (size, share, rate, hereafter) can be examined at three separate levels of aggregation, the firm, the industry or the economy.

Theories of profits of size, share or rate can be classified as to whether they treat profits as an equilibrium or as a disequilibrium phenomenon, and of course as to whether the equilibrium is a static or a dynamic one. Theories then deal with the role of profits, that is, the effects of the size, share or rate on other economic variables, and the source of profits, that is, the variables which cause profits to be what they are. An issue related to the cause of profits is the moral justification of the claimant to profits. This issue though prominent in the classical and Marxian economics, disappears in neoclassical economics with the triumph of the marginal productivity theory of distribution. But the issue reappeared during the controversy surrounding capital theory in the 1960s.

Before we go into these issues, we have to ask whether profit is a pure category in economics since a theory presumes the existence, in the abstract at least, of a definable category to which the theory is
addressed. With profits, there has been a frequent problem of conflating it with interest and rent. One class of theories have taken profits as synonymous with interest. Theories have failed to distinguish consistently between profits and interest as categories of non-labour income. Thus, theories for the existence of positive rates of interest are often thought of as theories of profit rate. The abstinence theory of profits, attributed to Nassau Senior, is as much a theory of interest as of profits. In early classical writing, in Adam Smith for example, profits and interest do not appear as separate income categories. Wages, rent and profits are the three divisions of total income. When the interest rate does make its separate appearance, it is as the limit to which the rate of profit can fall. The ambiguous relationship between the two reappears in the marginal productivity theory where the return to capital (real rental on capital) is not sufficiently distinguished from interest to be a separate category of income.

There are also other conventions which lead to a loose definition of profits. Profits are sometimes used as synonymous with all non-labour income, subsuming rent and interest incomes. This is very much a Marxian tradition which has come down into modern-day Cambridge growth theory via Kalecki’s theory of distribution. Alternatively, Marshallian theories subsume profits under a general category of quasi-rent. This leads to the further distinctions made between normal and supernormal profits or pure profits.

**Neoclassical theory**

In neoclassical theory, the competitive firm (the entrepreneur) maximizes the quantity of profits to decide the level of output and inputs. This gives the price equal marginal cost condition. In equilibrium, the size of profits is indeterminate as are the rate and share. In long-run competitive equilibrium of the industry (if such an equilibrium can be shown to exist) the firm has zero (actual or if there is uncertainty, expected) profits; price equals average cost and the output is produced at the lowest point of the U-shaped average cost curve. Thus, zero profit is an equilibrium condition and also a signal that output is produced under efficient conditions. This zero profit condition is often qualified by adding that this does not rule out ‘normal’ profits. This not only leaves normal profits indeterminate in size but could easily lead to the condition of zero profits being a tautology. In this paradigm, non-zero profits are an indication of (long-run) disequilibrium or of non-competitive conditions (for example, barriers to entry). A third alternative is that in the presence of uncertainty any observed non-zero profits may be the random deviation of actual from expected profits. The zero profit condition is best thought of not as a descriptive prediction but as a rule to check for consistency in any model that assumes competitive behaviour.

In terms of the rate of profit the condition for competitive equilibrium is that the rate of profit be equal in all activities (industries, sectors, and so on). Here again the rate of profit is itself indeterminate but it is the interindustrial differential in the rate which needs to be zero in equilibrium. Again in analogy with the size of profits, a persisting non-zero differential indicates either disequilibrium or imperfectly competitive elements.

Normal non-zero level of profits or persisting differential in a particular firm or industry can be reconciled with competitive equilibrium by an appeal to Marshall’s doctrine of quasi-rent. Ricardo’s theory of rent compels the marginal land to have zero rent but supramarginal lands to earn positive rent. Marshall extends this logic to other factor incomes with the doctrine of quasi-rent relying on restrictions on elasticity of factor supply in the particular case where differential rates of return or non-zero surplus incomes are found. Normal non-zero profits could then be a quasi-rent.
But if so, what is the factor of production whose income is profit (as quasi-rent)? This raises the contentious question of the moral and economic basis of profit as income. Is profit the return to capital or is it the remuneration of the capitalist as a manager/entrepreneur? Attempts to provide a justification for profits as income invoke the abstinence doctrine, or the ‘residual claimant’ argument in the 19th century. But abstinence could provide a theory of reward for savings, that is, a theory of the interest rate but not for a reward for capital unless all savers are also capitalists. The residual claimant theory, that is, profits are what is left over after every other input has been paid its due, is hardly a theory. It needs to be supplemented by a theory of how all other inputs are rewarded, that is, how the residual is determined. It was the achievement of J.B. Clark’s marginal productivity theory of distribution to provide such a link by an attempt to integrate production and distribution via the marginal principle. Clark’s theory claimed to explain distribution at each of the three levels of aggregation. The equating of the marginal value product of a factor to its unit price is a principle which treats labour and non-labour inputs symmetrically. In this theory, capital appears as equipment and its marginal revenue product is equated to its unit price. If one could further identify the profit per unit of capital with the unit price of capital, then the return to the capitalist (profits) is the reward of the productivity of capital (the rental for the factor). This brings profits in an analogous relation with rent. The capitalist is one who owns the factor of production capital. It is the structure of property rights as well as the productivity of capital which combine to make the owner of capital the recipient of its fruits.

In equilibrium, the price of the capital equipment will be the present value of its future net income stream. This is the contribution of Irving Fisher. Under certain restrictive assumptions – known future income stream, constant relative price of capital and constant and known discount factor – the real rental of capital is equal to the sum of the rate of discount (the rate of interest) and the rate of depreciation of the capital good. The presence of the rate of depreciation in the formula is required only in the case of a physical durable good. The rate of depreciation may of course not be constant but variable; worse, it could be endogenous and dependent on the forces determining the rental on capital (the rate of investment, for example). If, on the other hand, one were to take an infinitely lived capital good, that is, zero depreciation rate, then the real rate of return (the rate of profit) ‘degenerates’ to the rate of interest. In such a case an infinitely lived capital good becomes like a financial asset – a consol.

This illustrates the difficulty of separating profits from rent or interest. The problem here is that capital can be a physical good (a machine/a building), a financial asset (bond/consol) or an abstract attribute (human capital/skills). The marginal productivity notion relates to capital only when it is a material input to production. This is why the specification of the production function used to explain the rate of profit as arising from the marginal productivity of capital as factor becomes a contentious issue. Once capital is a physical good, its durability and heterogeneity entail an assumption of malleability if we wish to add up the disparate units of capital to arrive at an aggregate capital stock. This aggregate may be at the level of a firm, or an industry, but it is at the highest level of the economy that the problem is serious.

The need to have an aggregate measure arises from the practice of using an aggregate production function in terms of labour and capital, both assumed to be homogeneous aggregates. The use of the aggregate production function had begun in the 1920s and 1930s where on the one hand, Paul Douglas and Charles Cobb had used their well-known function to explain the constancy of the share of labour in total income (Cobb and Douglas, 1928; Douglas, 1948). Theorists such as Hicks, Harrod and Joan Robinson had also used the device of an aggregate production function to define various measures of technical progress which would reconcile the stylized facts of the constancy of the share labour, with a
rising real wage and a trendless rate of profit. Thus it was that technical progress measures such as Hicks-neutral, Harrod-neutral, and so on, were proposed as simple constructions to explain these stylized facts. The theorists’ work did not require the Cobb–Douglas form as such but the latter proved a convenient way for expressing these forms explicitly in econometric work in the 1950s when economic growth and technical progress engaged the attention of economists. It was Solow's work both in proving the stability of growth equilibrium and in measuring the contribution of technical progress to economic growth which generated the veneration of the Cobb–Douglas production function (Solow, 1956; 1957).

This use of the aggregate production function in neoclassical growth theory in the 1950s accomplished two things. It could link the rate of growth of the economy to the rate of profit; in some cases the two could be equal. At the same time, the Cobb–Douglas form could be used to link the rate of profit to the marginal productivity theory. Thus, a microeconomic firm theoretic proposition – the equality of marginal productivity and factor prices – could be exploited to explain macroeconomic magnitudes of factor shares and growth.

This brilliant device linking the marginal productivity theory of distribution with a macroeconomic growth theory soon ran into difficulties and unravelled itself. The capital theory (or Cambridge–Cambridge) controversy is dealt with elsewhere in this dictionary. For the purpose of this essay, it suffices to note that while the factor prices could be taken as given by the firm, they become endogenous at the macroeconomic level. The return to capital – the real rental or the profit rate – depends on the rate of investment. To explain the latter in terms of demand for capital in terms of factor–price substitution involves circular reasoning. Further, the existence of an aggregate capital stock presumes the prior existence of equilibrium prices for the heterogeneous capital goods comprising such an aggregate. The aggregate then cannot be used to ‘explain’ equilibrium profit rate. There seemed to be some insuperable logical problems in the notion of an aggregate capital stock. As an explanation of the profit rate, the macroeconomic theory of distribution proved to be a cul-de-sac.

An alternative treatment of the return to capital would be to abstract from such complications and treat capital as a commodity like any other. Using Debreu's very general definition of a commodity, new capital and old capital become different commodities, heterogeneous capital goods retain their differences and do not need to be aggregated. The task of the theory is then to show that a set of non-negative prices will clear markets for all the commodities. Given the facts of time and uncertainty we create dummy markets for contingent commodities. The price of the commodity ‘capital’ can then be determined for each time period and each state of nature.

But while the price of capital good can be determined by this method, it has no further link with profits. Profits in the Arrow–Debreu equilibrium are zero. Owners of capital goods will receive the price as their reward but this is not profit. Nor need the price of capital good have any specific connection with the rate of interest; as an intertemporal price the interest rate links the price of any commodity to that of its substitute available at a different date.

The Arrow–Debreu theory invokes a very stylized sort of uncertainty. Going back to a distinction made by Frank Knight between risk and uncertainty, it is risk rather than uncertainty which is involved in the Arrow–Debreu notion of contingent commodities. It assumes that states of nature can be described fully and the probabilities of various outcomes under different states of nature calculated in advance of determining the excess demand functions (or correspondences) for such contingent commodities. Such risk being previsible and insurable against, will yield only such return which cannot be arbitraged away. There can be no pure profit in such an equilibrium.
Classical theories of profit (Smith and Ricardo)

In classical economics profits are important as a quantity. Together with rent, they constitute the economic surplus, wages being the *faux frais* of production. The distribution of the surplus as between the owners of stock (capitalists) and the landlords becomes a central issue. This is because the two classes were presumed to have different propensities for productive consumption (accumulation). The division of surplus then had growth consequences.

The Physiocrats regarded land (nature) as the only source of surplus. Profits were only a recycled part of the *produit net*. Adam Smith could be read as regarding a surplus producing agriculture as a necessary but not the sole source of surplus, since productive labour was another source. The productivity of both land and labour depended on constant improvements in the manner of their utilization – agricultural practices and division of labour. Thus behind the ‘factors’ was the incessant propensity for progress – technical progress in the narrow sense as well as general innovations and improvements in practices. The size of profits is ambiguous in Smith as there are no clear rules about the division of the surplus between rent and profit. The rate of profit was expected by Smith to fall. The reason for this was not diminishing returns in agriculture, as it was to be for Ricardo. The division of labour and effects of trade could counter the limits imposed by the soil. It was however that the stock of profitable investment opportunities was limited within a country. Smith could see that the fabulous profits made by trading companies were shrinking as merchants began to compete. Profits on industrial activities were on the moderate side. Thus the falling rate of profit hypothesis emerges to recognize an empirical fact though Smith had no reason for believing that technical progress could not stave off the tendency indefinitely.

It is David Ricardo who relates profits and rent antagonistically and has a clear view of the rate of interest as defining the lower limit of the rate of profit. In Ricardo, there is the first rigorous attempt to define the rate of profit, as a pure number which will be free of problems of valuation. By defining a one-good economy, corn, inputs and outputs can be measured in the same commodity. This is done by defining the wage in terms of corn and any equipment as product of labour. Given these two assumptions, the profit rate is defined as the ratio of net surplus – output of corn less inputs defined in terms of corn – to the capital advanced also measured by the inputs defined in terms of corn. But given the conflict in the economy between rent and profits, how was rent to be accounted for?

Ricardo defined the marginal land as zero rent yielding land. Thus the pure rate of profit could be defined on the marginal land free of complications introduced by rent. If we then add that profit rates equalize everywhere, the rent yielding land does so by achieving a superior output–input ratio compared with the marginal land. The difference is rent. Rent is an unearned income accruing to the landlords as a result of the progress of accumulation and the growth of population.

Ricardo integrates the conflict between rent and profit with a theory of growth which gives an explanation of the falling rate of profit. The size of profit as shared out with rent, determines the rate of accumulation since capitalists have a high propensity to accumulate. As accumulation proceeds, there are diminishing returns to land as well as labour. If the real wage were to be taken as constant, then the surplus above wage shrinks due to diminishing productivity of labour. But at the same time, rents rise. Hence profit is squeezed out. The rate of profit falls with accumulation.

But on the zero rent land, profits are antagonistic to wages. Thus any tendency for wages to go up will reduce the rate of profit. The determinants of real wages were accumulation (demand for labour) and...
growth of population (supply of labour). The Malthusian mechanism to keep real wages constant worked at least in the long run. But even in the short run, although theoretically real wages could rise with the force of accumulation, the empirical facts of population growth since the 1780s and the potentially high participation rate of men, women and children, meant that for the period in which he was writing, Ricardo could easily assume rapid adjustment of the supply of labour to a rise in the real wage rate.

New classical theories of profit (Sraffa, von Neumann)

There are at least two directions in which Sraffa (1960) generalizes Ricardo. First he drops the single-good assumption but defines a standard commodity in terms of which the rate of profit is invariant to relative price changes. He also drops the assumption of a constant subsistence wage. By taking wages and profits as constituting surplus, that is, wages no longer being merely the costs of production but part of value added, the conflict between the rate of profit and the share of wages in total surplus is made explicit. The wage–profit frontier derived from the structure of the input–output information illustrates this conflict.

If we were to take Ricardo's choice of corn as the single good as a substantive and not merely a methodological device, one must attribute a large role to agriculture as the source of surplus. Ricardo is less explicit about the role of technical progress either in generating surplus or in staving off the effects of diminishing returns. By dropping land from the general model altogether as an essential input, Sraffa implicitly takes the technical conditions of production (the matrix of the input coefficients) as guaranteeing that a surplus exists. He does not however pursue the question of the disposal of profits, that is, accumulation.

In a parallel but independent work, von Neumann put forward a linear model of the economy with joint production, in which the timing of input and output was articulated. In this system, there are several processes available for producing a commodity but only those are chosen which at least yield a certain rate of surplus (say $g$) of the output above the inputs. Labour is one of the inputs. The converse of this proposition is that given the input and output prices, only those activities are chosen which yield the minimum rate of profit ($p$). If the linear system of production coefficients is indecomposable, from the duality of prices and quantities, it follows that $g = p$. If we now regard $g$ as the rate of growth between this year's inputs and next year's output, we have in von Neumann's model, an equality between the rates of growth and profit. All profits need to be accumulated and wages have to be at subsistence level. The classical lineaments of von Neumann's model are thus clear (von Neumann, 1945–6).

Von Neumann's system leaves the size and share of profits indeterminate while making its rate determinate. It is his device of defining the production process as jointly producing final output and one year older capital goods, that is, the joint production technology that has proved a fertile innovation. In one way this device avoids the problem of heterogeneity as well as of durability of capital. Each item of capital equipment can be defined as a separate commodity and can be given a one period length of life after which it becomes another commodity, albeit a one year older version of itself. The problems of measurement of capital which plague the neoclassical aggregate production function are thus avoided. Also a strict separation is made between price of capital goods and profits. Finally the source of profits is seen as the technology which permits growth.

Technological progress is not endogenized in neoclassical economics, nor in classical economics except in a loose sense in the grand design of Adam Smith. Von Neumann as well as Sraffa leaves the question
well alone. It is with Karl Marx that an ambitious model is attempted of a fully endogenous model of
growth, accumulation and technological progress.

Profits as exploitation (Marx)

Marx makes an explanation of the source of profits a central part of his theory. There are two ways of
understanding this central role of profit in Marx. The measure of economic surplus being labour in the
classical theory, an immediate question arose among certain socialist followers of Ricardo as to whether
labour was also the source of all surplus and hence should be its sole recipient. While this is not the case
in Smith or Ricardo, for Marx labour becomes a measure of value, and the source of surplus value.
Surplus value takes the money form of profits via the mediation of prices, which are formed on the basis
of values.

A second motivation of Marx's theory could be seen as extending Ricardo's critique of rent as an
unearned income to the category of profits. The scarcity of fertile land is not a natural but a social
phenomenon in Ricardo, caused by the progress of accumulation and population. Was the scarcity of
capital and the fact that it commanded a surplus equally social? Marx asked.

Marx's theory of profits is that profits are the money form of surplus value produced by labour in the
production process but appropriated by the owners of means of production. The capitalist advances
capital to buy labour and means of production. But what he buys is labour power, the capacity for work.
This is because the labour contract is a voluntary, ex ante agreement on the part of the labourer to work a
fixed period of time – the length of the working day in return for a wage. The wage is the exchange
value of the commodity labour power. The use value of the labour power is whatever productivity the
capitalist can extract from the worker during the working day. There is a gap between the use value and
exchange value of labour power but this gap cannot be seized by the sellers of labour power, but only by
the buyers. This is because the buyers of labour power, the capitalists, enjoy a class monopoly of
ownership of the means of production. Without finding a buyer for the labour power, the labourer cannot
reproduce himself, that is, he cannot survive for any length of time with his working capacity intact.
Thus, there is an asymmetry in the positions of the workers and the capitalists, as a result of a historical
process that has deprived workers of direct access to means of production.

The gap between use value and exchange value present in the case of labour power is not present in the
case of capital goods. These are bought and sold by capitalists and hence there is no scope for unrealized
gaps to exist for any length of time without being captured by the seller. This is why Marx called the
flow of input services from capital goods constant (c) capital, i.e. capital which had the same value in
the beginning as at the end of the production process. For labour, the flow of input services – the use
value realized – was made up of necessary labour measured by the exchange value, i.e. wage and surplus
labour which accrued to the capitalist. This is why labour was variable (v) capital, it changed value
between the time it was bought/paid for and the end of the production process.

The rate of profit, for Marx, was then the ratio of surplus value (s) to the sum of constant and variable
capitals (c + v); \[ \rho = s / (c + v) \]. All the three terms of the ratio are measured in labour time and are
commensurate. Thus, Marx also attempted to arrive at a measure of the rate of profit which would be
invariant to relative price changes. But, unlike Ricardo, he did not assume a single good economy. What
is needed is that the wage rate can be converted into labour values. The same has to be done about flow
of services emanating from the means of production. This requires that the production technology be of
a form which makes such conversion of goods into their labour values problem free.

The source of profits in Marx is the exploitation of labour by the capitalists, although it is subsumed that the technology is such as to yield a surplus, that is, a gap between the use value and exchange value of labour power. Positive surplus value is seen as a necessary and sufficient condition for profits to be positive (Okishio, 1963; Morishima, 1973). Profits are accumulated, and put into ever improving technology as a result of the competition among capitalists. It is in the constant search for higher profits, partly immanent and partly as a response to factors threatening the rate of profit, that the incessant improvement in technology takes place. Capitalists have to find better ways of increasing profits, by any means which can increase the gap between the exchange value and use value of labour power. They may do this by improving working methods (Taylorism), by extending hours of work without increasing the wage (absolute exploitation) or by investing in improved machinery (relative exploitation).

Marx in common with the classical economists also has a theory of the falling rate of profit. The progress of accumulation raises the wage rate and hence with a given technology lowers the ratio of surplus value to variable capital, that is, lowers the rate of surplus value \( (s/v) \). In order to stave off this danger, capitalists are compelled to use labour-replacing technology. This raises the organic composition of capital, that is, the share of constant capital in total capital \( [c/(c+v)] \). The rate of profit varies directly with the rate of exploitation and inversely with the organic composition of capital. In the pure theoretical model, Marx reasoned that the balance would be such that the rate of profit would fall. He also discussed a number of countervailing tendencies such as the growth of monopolies in particular and a high degree of concentration in the industrial structure which may arrest this tendency of the rate of profit to fall.

Accumulation in Marx proceeds incessantly but not at a constant or equilibrium rate. The search for higher profits drives accumulation and accumulation in turn increases surplus value by being embodied in better techniques. But accumulation acts on a labour force that ultimately even exhausts its reserve army and thus wages threaten to rise. On the other hand, markets have to be found for the larger quantities of goods being produced at prices which will yield a profit, that is, surplus value has to be realized in the market, not just extracted from labour. The result is that the accumulation process facing these two limits results in a cyclical growth pattern. This pattern yields cycles around a declining rate of profit.

Marx's attempt to obtain a pure (relative price invariant) measure of the rate of profit has been criticized mainly due to the problem of evaluating the different types of skilled labour used in production. Marx's theory requires that all types of labour be reducible to homogeneous labour. Such reduction cannot be made without a measure of relative value productivity of different types of labour, independently of their market rates of remuneration. Despite much ingenious work, this problem has proved intractable.

Another problem arises from the durability of capital. In a joint production formulation, it can be shown that positive surplus value is neither necessary nor sufficient for positive profits. The theoretical formulation has to be amended to rule out non-convexities which lead to the curiosum that negative surplus value can lead to positive profits (Steedman, 1976; Morishima, 1974). A third problem arises from the fact that an example of accumulation, with balanced growth and a constant rate of profit, was provided by Marx himself in his Scheme for Expanded Reproduction contradicting the necessity of cyclical accumulation or of a falling rate of profit.

**Profit as disequilibrium (Schumpeter, Keynes)**
Another ambitious attempt to combine profits and growth was made by Schumpeter. With Schumpeter, profits become a *disequilibrium* phenomenon. He advances a theory of the size of profits, especially the source of profits but none of either the rate or the share of profit. Schumpeter's theory is also the only one where there is a clear link between the monetary system that finances production and the real system that generates profits. Schumpeter's is also the only theory which makes the agency of the profit earner – the entrepreneur – an explicitly central part of the theory.

The source of profits is innovation. Innovations can comprise introduction of a new good, of a new method of production, the opening of a new market, discovery of a new source of supply of raw material, or the carrying out of a new organization of an industry. The economy is supposed to be in a state of stationary or steady-state equilibrium before the innovation occurs. An entrepreneur as a visionary innovates by launching a new product or a new technique, and so on. Such a new product may have a long gestation lag before it earns revenue and, as such, may be risky. Thus in the financing of innovations, credit plays an active role. Such credit will be excess to current goods supply and will cause inflation. Once the innovation appears on the market, the entrepreneur makes monopoly profits. The credit initially created can be liquidated out of profits but the innovation causes further ripples via backward and forward linkages as well as by attracting imitators. Innovations occurring singly or in a cluster set off a long wave, a Kondratieff cycle. In the rising phase, prices, profits and output rise. But eventually the monopoly profits are bid away by competitors and the system returns to equilibrium, with profits tending to zero.

The innovation process is discontinuous and disequilibrating. It is accompanied by a credit boom and a cyclical upturn. Innovations are unanticipated. The economy exists in cycles caused by innovations but tending towards an equilibrium of zero profits, once the innovation has spent itself. The history of capitalism was for Schumpeter made up of successive long waves caused by clusters of innovations. Thus for Schumpeter the source of profits is the superior productivity achieved by innovations but the agent of change is the entrepreneur. Neither the conventional industrialist nor labour generates profits. Profits are by nature abnormal, disequilibrium phenomena. They do not persist but dissipate in equilibrium.

Schumpeter thus reconciles a zero profit stationary equilibrium with observed facts of profits. But while the theory is an appealing one, it has lacked sufficient analytical detail to prove either a source of further developments in profit theory or a tool for empirical investigation.

While Schumpeter put forward a dynamic theory of the disequilibrium role of profits, his model is sparse in details. Keynes in his *Treatise on Money* also treats profits as disequilibrium and insists that national income calculations exclude profits. The emergence of profits as a disequilibrium category comes from the gap between savings and investment. The famous Fundamental Equations of the *Treatise* describe a two sector model with consumption goods and investment goods. For each sector, the price level is made up of unit labour cost and a disequilibrium item. For the consumption goods sector, this item consists of the cost of production of investment goods less savings. Following a similar procedure for the other sector and aggregating over the two sectors, Keynes gets the result that

\[ P = W + \pi \]  

(1)
\[ \pi = \frac{(I - S)}{Y}. \tag{2} \]

\( P \) is the overall price level, \( w \) earnings per unit of output (unit labour cost) and \( \pi \) is profit per unit of output, that is, the share of profit. This identity becomes an equation only because via the expenditure equations, profits per unit of output are derived as the gap between investment expenditure (\( I \)) and savings (\( s \)) both per unit of output (\( Y \)) as in equation (2). In equilibrium, Keynes expects \( \pi \) to be zero and \( w \) to include ‘normal’ profits or remuneration of non-labour inputs as well as labour. When profits are non-zero this is because of investment exceeding savings and in a Wicksellian process this gap drives profits to drive the gap wider still. This process is not sufficiently articulated due to the fact that Keynes concentrates on conditions for price stability rather than on disequilibrium dynamics.

**Post-Keynesian theories of profit and growth**

Kalecki's theory marks a bridge between Marxian and Keynesian traditions and is the seminal contribution to what is now called the Post-Keynesian or Cambridge theory of income distribution. Paradoxically its points of contact with the *Treatise on Money* have not been sufficiently brought out. Kalecki's route was via Rosa Luxemburg's critique of Marx's Schemes of Expanded Reproduction (SER). The SER is also a two-sector model but of a growing economy. It has a two goods/two class configuration which is similar to the Fundamental Equations of the *Treatise*. While Marx's formulation of the SER make the model an equilibrium one, Luxemburg was seeking to find roots of dynamic disequilibrium within it. There are several strands which Kalecki weaves into this story. Kalecki has a macroeconomic theory of pricing which yields a determinate share of profits in total output. He does this by exploiting the marginal revenue equals marginal cost conditions of equilibrium for the neoclassical firm. By then exploiting the simple idea that the ratio of price to marginal revenue departs from one to the extent that the price elasticity of demand is below infinity he connects price to marginal cost via the demand elasticity. Thus

\[ p = mc(1 + \eta^{-1}) \tag{3} \]

where \( mc \) is the marginal cost and \( \eta \) is the elasticity of demand. The coefficient \( (1 + \eta^{-1}) \) is called the degree of monopoly. To the extent that \( \eta^{-1} \) departs from zero, the firm is a monopolistic one.
This is a partial equilibrium, microtheoretic derivation of the \( \frac{p}{mc} \) ratio and its generalization to a macro-economic level has proved to contain problems (Mitra, 1954). The main problem is that if (3) is supposed to refer to a specific firm, its elasticity of demand is not a constant but a function of the firm's own and its rivals' strategies. A determinate and tractable aggregation procedure for many jointly dependent \( \frac{p}{mc} \) ratios is not possible. It has however been found possible and empirically fruitful to interpret pricing decision as a mark-up above average cost.

\[
p = (1 + k)ac
\]

(4)

where \( ac \) is average cost and \( k \) is the mark-up ratio. The similarity of (4) to Keynes's Fundamental Equation in (1) is striking, that is, \( \pi = \frac{k}{1 + k} \). But while (1) is an identity, (4) could be thought of as an equation where the profits come from producers' price setting behaviour.

But how are these profits sustained or in Marx's terminology realized? This is where the aggregate demand relations become important. It would be through the spending behaviour of the profit receivers that profits can be sustained. This was already clear in Keynes's invocation of the widow's cruse parable whereby a Wicksellian cumulative dynamic process can sustain growing profits as long as capitalists spend (that is, dis-save) while keeping up their investment expenditure. By starting with the Marxian SER, Kalecki was able to derive this as an equilibrium relation.

Kalecki's macroeconomic theory is best seen in terms of Kaldor's generalization. Kaldor takes the two class/two good model and integrates profits into a theory of growth and distribution. Let \( R \) be total profits (\( \equiv \pi Y \)) and \( W \) be the total wage bill (\( \equiv wL \)). Then

\[
Y = R + W
\]

(5)

\[
l = S = s_w W + s_c R.
\]

(6)

Equation (5) is a national income identity, whereas (6) combines the saving–investment equality with a decomposition of total savings into workers' savings (\( s_w W \)) and capitalists' savings (\( s_c R \)) with the \( s_c s_w \) being saving propensities and \( s_c > s_w \). From (5) and (6), we can derive
\[ R / \gamma = \pi = (s_c - s_w)^{-1}(l / \gamma) - s_w(s_c - s_w)^{-1} \]  
\[ (7a) \]

and

\[ R / K = \rho = (s_c - s_w)^{-1}(l / K) - s_w(s_c - s_w)^{-1}(\gamma / K). \]  
\[ (7b) \]

Equation (7a) gives the share of profits in terms of the investment income ratio and (7b) gives the rate of profits in terms of the rate of growth of capital stock \((I/K)\) and the output–capital ratio \((Y/K)\). To specialize the equation, set \(s_w = 0\), that is, assume workers do not save. Then

\[ \pi = s_c^{-1}(l / \gamma) \]  
\[ (8a) \]

\[ \rho = s_c^{-1}(l / K). \]  
\[ (8b) \]

These two equations show how the profit share is determined by the capitalists’ investment behaviour, i.e. capitalists determine their own profits. If we take the output–capital ratio to be a constant, then the rate of growth of income \((g)\) is equal to the rate of growth of capital stock \((I/K)\). Thus from (8b), we have

\[ \rho = s_c^{-1}g. \]  
\[ (9) \]
If we now put \( s_c = 1 \), we have the von Neumann result reproduced in the Kalecki–Kaldor models. The restriction that \( s_w = 0 \) is of course arbitrary and thus makes the result under (8b) somewhat unrealistic. Pasinetti (1962) generalized the Kaldor argument by allowing workers as well as capitalists to save and own capital. Thus total capital \( K \) could be held either by capitalists \( K_c \) or by workers \( K_w \) but since capitalists make output and investment decisions workers were assumed to have loaned \( K_w \) to capitalists. In terms of the distinction we made above, capital as productive equipment is \textit{controlled} by capitalists but capital as a financial asset is \textit{owned} by both workers and capitalists, and capitalists pay workers a rate of interest \( i \) on the loaned capital. Thus instead of (7a) and (7b), we get

\[
R / \gamma = \pi = (s_c - s_w)^{-1} \left[ \left( \frac{l}{\gamma} - s_w \right) + r(s_w s_c(l / K)^{-1} - s_w(\gamma / K)^{-1}) \right] \\
(9a)
\]

\[
R / \kappa = \rho = (s_c - s_w)^{-1} \left[ \left( \frac{l}{\kappa} - s_w(\gamma / K) \right) + r(s_w s_c(l / K)^{-1} - s_w) \right] \\
(9b)
\]

If we now put \( r = \varphi \), (9a) and (9b) degenerate to

\[
\pi = s_c^{-1}(l / K) \\
(10a)
\]

\[
\rho = s_c^{-1}(l / K) \\
(10b)
\]

The only condition needed for this result is that \((l - s_w)Y = 0\). But while (10b) is similar to (8b), now it is independent of whether \( s_w \) is zero or not.
The similarity of the Kalecki–Kaldor result to the von Neumann result, as we noted above, is striking. The Pasinetti result seems to reinforce it. It is a one-good model and hence problems of relative price or aggregation or measurement of capital which plague other theories are completely avoided here. It is also not clear as to whether causality proceeds from growth to profits or profits to growth. There is an implicit assumption that the economy must have adequate resources and technology to generate surplus but the source of the surplus is not clear. There is no specification of the production conditions and a neoclassical aggregate production function is deliberately avoided.

The Pasinetti result has been derived by an alternative route by Samuelson and Modigliani (1966) who do use a neoclassical aggregate production function. Their purpose was to point out that the Pasinetti result was a special case of a more general result and that a dual to Pasinetti’s theorem – an anti-Pasinetti theorem – could be derived from a slightly alternative formulation. All the assumptions of Pasinetti’s theory are retained except that profits and wages are now derived from the marginal productivity conditions and a constant return to scale, two factor production function.

Let the production function be

$$\bar{Y} = f(\bar{K}) \quad f' > 0, \quad f'' > 0.$$  \hspace{1cm} (11)

Here $\bar{Y} = Y / L$, $\bar{K} = K / L$, that is, output per worker and capital per worker. By the standard rules of marginal productivity theory we have that wage and rate of profit are determined as

$$\rho = f'(\bar{K}) \quad (12a)$$

$$w = f - \bar{K}f'(\bar{K}). \quad (12b)$$

In the production function, there is no distinction as to who owns the total capital stock – capitalists or workers. The savings augment the amount of capital owned by workers and capitalists,
The equilibrium condition in the Samuelson–Modigliani model is that the relative rates of growth of capital stock owned by workers and capitalists be the same, i.e. constancy of shares in productive wealth. This is not an obvious condition for equilibrium but it does have the dramatic consequence that in such an equilibrium (of balanced growth of $K_c$ and $K_w$), the rate of profit is independent of the saving propensity of the worker. If $n$ is the constant growth rate of the capital stock, we get from the above after some manipulation

\[
\dot{K}_c = s_c f'(K) K_c
\]  
(13a)

\[
\dot{S}_c = \dot{K}_w = s_w[\gamma - f'(K)K_c].
\]  
(13b)

\[
\dot{K}_w = s_w[f(K) - K_c f'(K)] - nK_w
\]  
(14a)

\[
\dot{K}_c = [s_c f'(K) - n]K_c.
\]  
(14b)

In steady state $\dot{K}_c = \dot{K}_w = 0$, so (15) gives

\[
\rho = f'(K) = n / s_c.
\]  
(15)

Thus, the Pasinetti result can be derived from a neoclassical logic. This should not be too surprising...
though much was made of this paradox at the time (Pasinetti, 1966; Kaldor, 1966). Neither a condition such as $\sigma = r$ (what we have called the degeneracy result) nor that $K_c/K_w$ is a constant tell us very much about the mechanisms by which an economy can arrive at such results. Our economic world is a world of many heterogeneous goods – capital as well as labour, of uncertainty, of financial constraints, of the persistent possibility of technical progress, of mergers and takeovers. There is in these models no decision making agency and time is eliminated in any meaningful sense since no \textit{ex ante} versus \textit{ex post} distinctions can be made. The Kalecki–Kaldor–Samuelson–Modigliani propositions are simple parables of pedagogic value no doubt but they do not tell us much about the origins or the role of profits in a modern economy.

**Behavioural theories of profit**

We can move in the final section of our essay to theories where the behavioural context is much more explicit. The neoclassical firm is a black box, where all the allocative rules could be followed by a computer which can be programmed to equate a derivative to a price. But the modern economy consists of corporations which operate in a world of financial markets and profits and are in this world both a signal of managerial performance and a facilitator for future expansion. It is this cluster of theories which supply the missing dimension in the theories hitherto surveyed.

**Entrepreneurial theories of profit**

In this cluster of theories, the level of aggregation is the firm and the agency of decision making is identified as the entrepreneur. It is assumed that the firm operates in a noncompetitive but stable environment where the entrepreneur has to form expectations about economic variables within his control as well as rivals’ strategies. The other set of variables is the macroeconomic one where entrepreneurs may hold similar short run expectations. The level of profit sustained by the firm will depend in the short run on macroeconomic factors, common to all firms but in the long run on the decisions to invest so as to keep rivals at bay (Keirstead, 1953).

Knight's definition of uncertainty and Keynes's view of the difficulty of rational calculus in forming long-run expectation have been synthesized by Shackle in a series of works (Shackle, 1954; 1969; 1970) which purport to relate investment and \textit{ex ante} profit in a decision theoretic framework. Shackle's decision theory is not however that of von Neumann–Morgenstern. He puts forward the notion of potential surprise and a surprise function relating the ‘size’ of potential surprise to the profit or loss attached to the project. Along with the surprise functions there is an ascendance function which relates the entrepreneur's engagement with a project given the size of gain or loss anticipated. Shackle then describes an optimizing exercise on the part of the entrepreneur, yielding optimal potential surprise. The size of gain or loss attached to the optimal potential surprise is then called primary focus gain or loss. The zero surprise (that is, certainty) equivalent of this primary gain is what Shackle calls profits. Profits are thus an \textit{ex ante} certainty equivalent measure of the likely gain of the optimally chosen investment project. This definition unlike all previous ones makes the subjective and \textit{ex ante} concept of profits clear. The problems with Shackle's theory are that it is determinedly resistant to aggregation even over individuals and while emphasizing the difficulty of using the calculus of subjective probability it
assumes that the surprise function and the ascendancy functions are continuous and differentiable enough to define a unique maximum. There is obviously a contradiction here. Mention should be made in this respect of Lamberton's work (Lamberton, 1965). Lamberton prefers a satisficing to a maximizing approach and explicitly introduces the entrepreneur's income–leisure (inactivity) trade-off as determining the choice of investment projects and the associated profit outcome. In later work, Lamberton rationalizes suboptimizing behaviour in terms of the costs of information gathering and processing. Entrepreneurial activity to maintain or enhance profits is triggered off subject to threshold effects.

A corporate theory of profit

Authors such as Keirstead and Shackle view the firm as a single-owner entity. Modern firms are not by and large individually owned. In terms of share of output, employment or sales, it is the corporation with team management and hierarchical command structures which is the dominant mode of firm organization. It is not surprising therefore that one class of theories deals with profits in the context of corporate or managerial behaviour. While in general Galbraith can be said to have made economists aware of the corporate form, corporate theories could be said to have benefited from the contribution of the behavioural theory of firm of Simon, Cyert and March, the hypothesis attributed to Baumol that firms maximized sales rather than profits and the notion due to Marris among others that growth of corporate size was the aim of managers of corporations (Baumol, 1967; Cyert and March, 1963; Galbraith, 1967; Marris, 1964; Simon, 1957). These various developments in industrial economics brought forth a view that managerial behaviour was growth oriented, that operating in monopolistic competitive environments managers could choose profits and growth combination subject to the constraint of external sources of finance. Wood (1975) presents the most complete theory in this respect. There are no details on the production side in his theory of profits. Profits arise from the need of the corporation to grow. The choice variables are the retention ratio, that is, the proportion of investment financed from external sources and the amount of liquid financial assets desired by the firm to be held as some relation of gross investment expenditure.

The firm is assumed to be facing a convex opportunity frontier between the profit share (profit margin as Wood calls it) and the growth rate of its sales revenue. Its desired (or target) values of the retention ratio (γ) the external finance ratio (λ) and the liquid financial holdings ratio (δ) give a simple relation between profit share (π) and the growth rate g. We have

\[ l + δl ≤ γR + λl. \]

(16)

In equation (16), the left-hand side represents the uses of funds and the right-hand side the sources of funds. A slight rearrangement gives us
\[ \frac{R}{Y} = \pi \geq \frac{1}{\gamma} \gamma^{-1} (1 + \delta - \lambda) \sigma g \]  
(17)

where \( g = \Delta Y / \gamma \), the growth rate of sales and \( \sigma = I / \Delta Y \) is investment to increase in output (or the incremental capital output) ratio. Now if one could accept that the coefficients \( \delta, \lambda \) and \( \gamma \) are fixed parameters and \( \sigma \) is also constant, then \( \pi \) and \( g \) are linearly related. The firm will start with a desired value of \( g \) and seek the appropriate \( \pi \) and by an iterative process arrive at a \( \pi, g \) combination which satisfies (17) as an equality rather than an inequity. This \( \pi, g \) combination will also be on the boundary of the opportunity frontier.

Wood's theory treats the corporation in isolation and with some control over its pricing and revenue situation. The presence of competing monopolistic firms is ignored here as in Kalecki's theory. But his theory does bring out the interrelationship between profits and the financing of investment. Note also that in (16) all the variable are in nominal terms. If the parameters \( \delta, \lambda \) and \( \gamma \) were identical across firms, we would aggregate (16) across firms. Since \( Y \) is sales revenue in nominal terms equation (17) would make sense at an aggregate level though it would be harder to swallow that \( \sigma \) would be a constant.

**Conclusion**

A satisfactory theory of profits is still elusive. For neoclassical economics, profit is a non problem and the only problem is to assign any observed net income above costs to the category of interest, quasi-rent or managerial wages for risk bearing. But problems persist for other theories as well. The classical theory neglects uncertainty and is vague about the microfoundations of profits. If von Neumann and Sraffa detail the technical conditions of production, neither uncertainty nor demand considerations figure prominently in their theories. Most theories, with the exception of the corporate theories and Schumpeter's, neglect the financial aspects of business operations. The firm is a black box in neoclassical theory whereas for Knight, Keynes and Shackle the individual decision maker's expectations are crucial to business behaviour. To allow for persistent positive profits in a dynamic equilibrium microeconomic model with subjective uncertainty and expectations with the possibility of technical substitution and technical change in production remains a challenge. If such a theory could be cast in terms to allow aggregation over firms to the level of the economy, the puzzle of profits would be solved.

progressive and regressive taxation

Original 1987 article by William Vickrey, revised by Efe A. Ok
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Progressive (resp. regressive) taxation refers to a taxation scheme in which the amount of tax paid as a proportion of the tax base rises (resp. declines) with that base. While progressive taxation has been justified in terms of the ‘principle of equal sacrifice’ and mitigating the inequality of market outcomes, no general political theory of income taxation provides theoretical support for the observed prevalence of progressive taxation schemes. Nor has the theory of optimal income (and consumption) taxation shed any light on the nature of progressive taxation, either normatively or positively.

Keywords

end-point theorem; equal sacrifice principle; equity–efficiency trade-off; income mobility; Jakobsson–Fellman Theorem; Lorenz curve; mixed strategy equilibrium; optimal taxation; progressive and regressive taxation; redistribution of income and wealth; Reynolds–Smolensky progressivity index; tax base; tax burden; tax incidence

Article

Progressive (resp. regressive) taxation refers to a taxation scheme (applied to a monetary base such as income, consumption, wealth and so on) in which the amount of tax paid as a proportion of the tax base rises (resp. declines) with that base. As such, characterizing taxes as progressive or regressive according to the relative degree to which they impose burdens on the wealthy and on the poor seems at first blush a fairly straightforward matter. Unfortunately, when one wishes to understand the nature of effective progressivity of a taxation scheme, and its redistributive properties thereof, and especially to compare the relative degree of progressivity or regressivity of alternative taxes, a number of problems arise. Before formalizing the notion of progressivity, we thus have a quick look at these issues.

Tax base
An important and often overlooked question is that of the base to which the tax burden is to be related. Usually the base is taken to be income, which in practice, whenever an attempt is made to produce actual figures, means some version of annual monetary income (which perforce includes salaries, interest and dividends, but which may or may not include capital gains). An alternative basis for evaluating progression would be consumption. This is not often used, and is subject to the same deficiencies as income as a result of omissions of non-monetary items such as imputed incomes from consumer durables (like owned homes).

**Tax burden**

There are various difficulties in determining the actual tax burden levied on a taxpayer. First, application of tax rates to incomes that fluctuate (due to, say, the stage of one's life cycle) makes this difficult to measure. As advocated by Vickrey (1947), it appears that some form of income averaging is needed (to serve as a proxy for the expected permanent incomes) but this has been found to be too complicated to administer in practice. Second, it is not obvious how to incorporate family size in the computation of tax burdens. Simply taking the aggregate would misclassify the larger and smaller units relative to their level of welfare or ability to pay, while taking a per capita measure overstates the importance of children relative to their needs. (See Pechman, 1987, pp. 78–133, for a careful discussion of these issues and other structural problems with tax assessment in general.) Third, the market mechanism often allows the tax burden to be passed from the taxpayer to other units in the economy, with the eventual consequence that the burden of taxes is not necessarily borne by those upon whom they are levied. In particular, the imposition of taxes on income or sales changes the budget sets of individuals, thereby altering equilibrium prices in the economy. The issue becomes particularly pressing in the case of corporate income tax, as tax incidence in this case varies widely according to fiscal, monetary or activity level changes that are associated with an alteration in the tax. For instance, a tax imposed on firms for hiring labour is more than likely to be ‘shifted’ to workers through lower wages and to consumers through higher prices, upon the adjustment of employment decisions on the part of the firms. In general, then, the ultimate distribution of the tax burden – the so-called *economic incidence* – is different from *statutory incidence*, that is, the initial distribution of tax liabilities. Unfortunately, it is a highly non-trivial matter, both empirically and theoretically, to determine precisely who bears the tax burden, and ultimately to what extent. It is thus not uncommon in practice to encounter discussions on tax progressivity that ignore tax incidence problems and concentrate instead simply on statutory incidence. (See Musgrave and Musgrave, 1989, chs 12 and 13, for an introductory account of tax incidence analysis, and Kotlikoff and Summers, 1989, and Atkinson, 1994, for advanced treatments.)

It is worth noting that the issues concerning the base and burden of taxes are integral to any sort of fiscal analysis, and are not particular to the analysis of tax progressivity. To flesh out the elements of the latter, therefore, we shall abstract from these difficulties in what follows and assume that a notion of monetary outcome, which we shall simply refer to as *income*, is determined as the arbiter of ability to pay. Moreover, for the most part we shall work under the (uncomfortable) supposition that the amount of tax charged on a given level of income corresponds to the actual tax burden of the taxpayer with that amount of income. At the very least, this will allow us to focus properly on certain facets of the *theory* of progressive taxation.
Progressive (regressive) tax functions

Formally speaking, a tax function is a right-differentiable and strictly increasing map \( T: \mathbb{R}_+ \to \mathbb{R}_+ \) such that \( T(0)=0 \) and \( T(x)<x \) for all \( x \in \mathbb{R}_++ \), and \( 0 < T'(x) < 1 \) for all \( x \in \mathbb{R}_+ \). (Here we denote the right-derivative of \( T \) by \( T' \).) This formulation maintains that (i) zero income earners do not pay any taxes; (ii) if a person earns positive income, the amount of taxes imposed on her must be less than her taxable income base; (iii) higher-income earners pay a higher level of tax than lower-income earners; and (iv) taxation is non-confiscatory in that the ranking of taxpayers by pre-tax income and post-tax income is the same. (We rule out here negative taxation to simplify our exposition, and view \( T \) as modelling a statutory tax scheme.) A tax function \( T \) is said to be progressive if the map \( x \mapsto \frac{T(x)}{x} \) is increasing on \( \mathbb{R}_++ \), that is, if the amount of income tax paid as a proportion of the tax base (say, income) rises with that base. In turn, \( T \) is regressive if \( x \mapsto \frac{T(x)}{x} \) is decreasing on \( \mathbb{R}_++ \). Finally, \( T \) is marginal-rate progressive (regressive) if the tax rate \( T' \) is itself an increasing (decreasing) function. In practice, statutory taxes on income and spendings are always progressive – in fact, they are almost always marginal-rate progressive – while payroll and sales taxes possess a flat statutory tax rate (but economic incidence analyses frequently reveal that such taxes are, effectively, regressive).

Normative basis for progressivity

The most well-known equity principle – advanced originally by John Stuart Mill – that provides a normative basis for progressive taxation is the principle of equal sacrifice. The modern formulation of this principle demands that there be a social norm, represented by a continuous, concave and strictly increasing (social) utility function \( U: \mathbb{R}_+ \to \mathbb{R}_+ \) relative to which the income tax \( T \) imposes equal sacrifice upon all taxpayers, that is,

\[
U(x) - U(x - T(x)) = \text{constant for all } x > 0
\]

(see Young, 1987; 1990; Ok, 1995). We may now ask: does a progressive, or a marginal-rate progressive, tax necessarily satisfy the principle of equal sacrifice? Conversely, does this principle necessitate progressivity?

The answers are, unfortunately, not very clear. First, the good news: it can be shown that a marginal-rate progressive tax function surely satisfies the principle of equal sacrifice. The bad news is that mere progressivity of a tax function is not enough for it to satisfy this principle (Mitra and Ok, 1997). To make matters worse, even for some non-progressive taxes \( T \) we can find a (social) utility function \( U \) that satisfy the properties above, that is, the principle of equal sacrifice need not imply, or be implied by, tax progressivity. At the very least, one needs to assume more about \( T \) and \( U \) to be able to relate these
principles more closely. For instance, if we demand that $U$ be differentiable (at least near the origin), then a piecewise linear tax function $T$ satisfies the principle of equal sacrifice (as we formulated above) \textit{if, and only if}, $T$ is marginal-rate progressive (Mitra and Ok, 1996). If one is prepared to accept this set-up, therefore, the principle of equal sacrifice can be thought of as characterizing marginal-rate progressivity of a (statutory) tax function, thereby necessitating its progressivity.

An additional caveat here is, of course, that this account ignores the disincentive effects of taxation. It is partial relief that Berliant and Gouveia (1993) have shown that, when the individual utility functions over income and leisure are additively separable, the link between the principle of equal sacrifice and progressivity would prevail even in the presence of such effects. Unfortunately, little is known about this matter in the (more realistic) non-separable case.

\textbf{Redistributive consequences of progressivity}

One of the traditional arguments for progressive taxation is that such schemes redress the highly inequalitarian outcomes of the market system, thereby acting as social insurance against inequality. As colourful as it may be, this argument needs to be formalized properly.

Let us first agree to model an income distribution as a continuous and increasing distribution function $F: \mathbb{R} \rightarrow [0, 1]$ with $F(0)=0$ and $F(1)=1$. This sort of a specification is, for instance, frequently adopted in macroeconomic models of income distribution. For any such $F$, we let $\mu_F = \int_0^1 x dF(x)$, which is the total income in the society. (Since incomes are distributed on $[0,1]$, that is, we effectively concentrate on relative incomes, $\mu_F$ also corresponds to the per-capita income in this model.) In what follows we naturally assume that $\mu_F > 0$.

For any such income distribution $F$, the \textit{pseudo-inverse} of $F$ is defined as the function $F^{-1}: (0, 1) \rightarrow \mathbb{R}$ with

\[ F^{-1}(t) = \inf \left\{ x \geq 0 : F(x) \geq t \right\}, \quad 0 < t < 1. \]

Intuitively, we may think of $F^{-1}(t)$ as the income level of the person who belongs to the poorest $100t$ per cent in the income distribution. We next define the map $L_F: [0, 1] \rightarrow \mathbb{R}$ by

\[ L_F(p) = \frac{1}{\mu_F} \int_0^p F^{-1}(t) \, dt, \quad 0 \leq p \leq 1, \]

which corresponds to the cumulative share of income held by the poorest 100 per cent of the population. The graph of the map $p \mapsto L_F(p)$ is called the \textit{Lorenz curve} of the distribution $F$. 

\url{http://www.dictionaryofeconomics.com.proxy.library.csi....du/article?id=pde2008_P000218&goto=B&result_number=1378}
We say that the income distribution $F$ Lorenz dominates another income distribution $G$ whenever $L_F(p) \geq L_G(p)$ holds for all $p \in [0,1]$, with strict inequality for at least one $p$. It is well known that this happens if, and only if, $G$ can be obtained from $F$ by means of finitely many mean-preserving spreads (Rothschild and Stiglitz, 1970). This is one of the reasons why Lorenz dominance is generally accepted as an unambiguous method of making ordinal inequality comparisons. Its welfare basis is identified in the seminal works of Kolm (1969) and Atkinson (1970).

Now take any income distribution $F$. A tax function $T$ applied to this distribution induces the post-tax income distribution $F^T$ where $F^T(x) := F(x - T(x))$ for any $x \in \mathbb{R}$. A celebrated theorem of public economics – often called the Jakobsson–Fellman theorem – maintains that $F^T$ Lorenz dominates $F$, that is, tax is inequality-reducing, if, and only if, $T$ is progressive (see Fellman, 1976; Jakobsson, 1976). That is, progressive taxes, and only progressive taxes, possess the property of reducing the level of income inequality no matter to which pre-tax income distribution they are applied. (For variations on this theme, see Eichhorn, Funke and Richter, 1984, and Thon, 1987.) This shows, in a nutshell, why the progressivity of a taxation scheme may be justified on the basis of desire for inequality reduction.

The Jakobsson–Fellman theorem also leads to a natural method of quantifying the redistributive effect of a tax function $T$ that is applied to an income distribution $F$. To see this, let us consider the function $R_{F,T} : [0,1] \rightarrow \mathbb{R}$ defined by

$$R_{F,T}(p) := L_F(p) - L_{F^T}(p).$$

In words, $R_{F,T}(p)$ measures the income share of the poorest $100p$ per cent in excess of what they would obtain under an equal yield flat tax. Obviously, the Jakobsson–Fellman Theorem says that $R_{F,T} \geq 0$ for any income distribution $F$ if, and only if, $T$ is progressive. (But, of course, we may have $R_{F,T} \geq 0$ for some $F$ even if $T$ is not progressive.) Now the discussion above suggests to declare a tax function $T_1$ to be more redistributive than $T_2$ – due to the Jakobsson–Fellman theorem, one often says $T_1$ is more progressive than $T_2$ – relative to the income distribution $F$ if $R_{F,T_1} \geq R_{F,T_2}$. This is, of course, a partial ordering, and when it does not apply one may wish to resort to a compatible index that sizes up the redistributive effects of $T_1$ and $T_2$. The most widely used index to this effect is the Reynolds–Smolensky progressivity index defined (as a function of a tax function $T$) by

$$I_{RS}^F(T) := 2 \int_0^1 R_{F,T}(p) \, dp,$$

which is the difference between the Gini coefficients of the distributions $F$ and $F^T$. Other indices are proposed in the literature to compare the progressivity of tax functions (which are based, for instance, on
the departure of a tax function from the equal-yield proportional tax). For an extensive discussion of such indices, and further results on the redistributional effects of progressive taxes, we refer the reader to the excellent survey by Lambert (1999).

**Political economy of progressive taxation**

Now that we have examined a number of normative rationales for progressivity of income taxes, let us turn to the strand of literature that has attempted to explain the prevalence of such tax schemes from the viewpoint of behavioural political economy. This literature maintains that, given that her views about income tax policy is one of the most important traits of a political candidate, it is natural to expect this prevalence to reflect (however indirectly) the majority support in the population. In fact, this way of thinking seems to suggest a straightforward explanation of the empirically observed popularity of marginal-rate progressivity, provided that one subscribes to the ‘one-man one-vote’ rule. Since the income distribution of a country is always globally right-skewed (in the sense that the median income is strictly smaller than the mean income for any right truncation of the income distribution), the number of poorer voters always exceeds the number of richer voters, regardless of how one defines the cut-off that separates the poor from the rich. Since poorer voters are typically the supporters of progressive policies, so the argument goes, there would then be a natural tendency for the marginal-rate progressive tax policies to be favoured by the majority. Even though the actual political processes are far more complex than the scenario in which people vote directly over policies, this argument appears to suggest a convincing reason for why progressive tax policies are so widely adopted.

While there are a few direct democracy models in the literature that provide support for this argument (cf. Romer, 1975; Roberts, 1977; Cukierman and Meltzer, 1991; Gouveia and Oliver, 1996; Marhuenda and Ortuno-Ortin, 1998; Roemer, 1999), these models are either confined to rather specific settings (in which a tax function is characterized by means of at most two parameters) or are not couched in a political equilibrium framework. A natural direct democracy model of voting over income taxes would be a two-party voting game in which each party (whose objective is to win the elections) proposes a tax function from an exogenously given set of admissible tax functions (that raise a given amount of revenue), and voters vote selfishly for the tax function that taxes them less. To make transparent the difficulties that pertain to the political economic approach to progressive taxation, we now describe such a voting model in precise terms.

Let $F$ be a strictly increasing income distribution (as modelled above), and assume that the median income is strictly less than the average income according to $F$, that is, $m_F = F^{-1}\left(\frac{1}{2}\right) < \mu_F$. (This assumption is but a straightforward formalization of the heuristic statement that ‘the number of poor people in the society is strictly less than that of rich people’.) To focus on the issue of *redistribution*, it is assumed that tax policies are designed to collect an exogenously given amount of revenue $0 < \alpha < \mu_F$, or put differently, an *admissible tax function* $T$ is defined in the model as one with the property $\int_0^1 T dF = \alpha$. We denote the class of all such tax functions by $T_{F, \alpha}$.

Consider a two-party voting model in which each party advocates an income tax policy in $T_{F, \alpha}$ which is to be put in effect in case this party obtains the support of the majority. Citizens evaluate proposals from a selfish point of view. Put precisely, an individual with income $x$ regards the tax function $T^1$ as more...
progressive and regressive taxation: The New Palgrave Dictionary of Economics
desirable than the tax function $T^2$ if $T^1(x) < T^2(x)$, that is, if this individual's tax liability is lower under $T^1$. It is assumed that indifferent voters abstain from voting. Thus, if party 1 proposes tax policy $t_1$ and party 2 proposes tax policy $t_2$, the share of votes obtained by the first party is determined as

$$\omega(T^1, T^2) = p_F \{ x \in [0, 1] : T^1(x) < T^2(x) \},$$

where $p_F$ is the probability measure induced by $F$ on [0,1]. Of course, in this case the share obtained by party 2 is $\omega(T^2, T^1)$. The formal model takes the form of a two-person strategic game in which the two players are the parties both of whose action spaces equal $T_F, \alpha$. There is a multitude of ways of modelling the objectives of the parties here. We follow Carbonell-Nicolau and Ok (2007), and presume that the goal of party $i$ is the maximization of the net plurality defined as the difference between the vote shares obtained by the candidates. (For instance, the payoff function of party 1 is the map $(T^1, T^2) \mapsto \omega(T^1, T^2) - \omega(T^2, T^1)$ on $T_F, \alpha \times T_F, \alpha$.)

While this model is one of the simplest of its kind, it readily exhibits the familiar difficulty of (infinite-dimensional) voting games: it does not have a Nash equilibrium (for any given $F$ and $\alpha$). Intuitively speaking, this is because, given any admissible tax $T$ in $T_F, \alpha$, one can always find another tax function which is below $T$ over an interval of $p_F$ measure greater than one half. Not all hope is lost here, however, as it can be shown that there is at least one mixed strategy equilibrium of this game. The question then becomes whether or not the support of any such equilibrium consists only of progressive taxes.

Curiously, Carbonell-Nicolau and Ok (2007) show that, if $F$ and $\alpha$ satisfy a certain condition, then, generically, in at least one equilibrium the probability of parties proposing a non-progressive tax function is positive. All in all, after a lot of work, and absent a good economic reason for working with a particular way of restricting the set of admissible tax functions, one is left with the feeling that the prevalence of tax progressivity that we find in all industrial democracies cannot be attributed solely to the right-skewedness of income distributions.

In passing, we should note that, in the context of representative democracies (à la Osborne and Slivinski, 1996; Besley and Coate, 1997), one is sometimes able to escape from the equilibrium existence problem discussed above. Indeed some positive results on the majority support for progressive taxation are obtained in this setting (cf. Carbonell-Nicolau and Klor, 2003). Unfortunately, it is not known whether or not these results would survive the inclusion of disincentive effects of taxation into the model. Furthermore, if we add to the picture dynamic considerations of voters, things would get even more complicated. Indeed, we know from Benabou and Ok (2001) that if the income mobility process has a particular property (called concavity in expectation) that is often met in reality, then individuals who are currently poor may oppose redistribution because they (rationally) expect to move up in the income ladder in the future. Indeed, it is possible that this prospect of upward mobility (POUM) hypothesis may be strong enough to overturn the majority support of progressivity (even at the steady state of the underlying mobility process).
To wit, it seems at present that we do not have a general political theory of income taxation that provides theoretical support for the observed prevalence of progressive taxation schemes. Nevertheless, this is an area of active research, and it is not unreasonable to expect that lasting contributions on this theme will be made in the near future.

**Optimal tax structures**

Any discussion of progressive taxation would be incomplete without putting on record the large amount of work conducted towards the end of 20th century on the optimal design of income (and commodity) tax schemes. Indeed, after the seminal contribution of Mirrlees (1971), there has been an immense amount of work in this area, which has, however, slowed down significantly in more recent times. Roughly speaking, the canonical model of optimal income taxation works with a population with a given distribution of income earning ability and with a utility function having disposable income and effort as arguments, pre-tax income being a function of ability and effort. Individuals then act to maximize their individual utility subject to an income tax schedule which is to be determined to raise a given revenue while resulting in a maximum of utility for the population which is obtained as an aggregation of the individual utilities. Unfortunately, despite the promise of the early work on this topic – see, for instance, Sadka (1976), Stern (1976) and Seade (1977) – this model is found not to produce robust qualitative results. (See Stiglitz, 1982, for a careful discussion of this issue.) One exception to this is the infamous end-point theorem that states that, when the distribution of skills has a known upper limit, the marginal tax rate should vanish at the level of income of the highest-income earners. (Informally speaking, the argument here is that there is no point to deterring the highest-income earner from earning the last dollar of her income, since if she does not earn it there will be no revenue from it.) This has the unsettling implication that an ‘optimal’ income tax is perforce non-progressive.

There is reason not to take this conclusion too seriously, however. First, simulations show that the end-point theorem is very local (cf. Tuomala, 1990; Saez, 2001). Second, the assumption that the constituent individuals are identical in all aspects but ability is a rather stringent requirement (which is key for the validity of the end-point theorem). Third, if there is uncertainty in the model that results in the expected income distribution having unbounded support, then the result fails. (See Haveman, 1994, for a variety of other critical comments on optimal income taxation theory.) All in all, while it has duly brought the incentive problems into the forefront of public finance, and has provided a new means of evaluating the notion of equity–efficiency trade-off, it appears that the theory of optimal income (and consumption) taxation has not realized its promise in shedding light on the nature of progressive taxation, either normatively or positively.

Perhaps it is best to conclude our discussion, as Haveman (1994) does as well, with the words of Joseph Pechman, taken from his (posthumous) 1990 presidential address to the American Economic Association: ‘Most people support tax progressivity on the ground that taxes should be levied in accordance with ability to pay, which is assumed to rise more than proportionately with income. Economists have … had trouble with the “ability to pay” concept … I believe that the person on the street is right and that we should continue to rely on the income tax to raise revenue in an equitable manner.’

Propensity score is an object often discussed in evaluation studies. It is defined as the conditional probability of treatment given covariates. It has attracted attention for its potential to control for the bias in the presence of high dimensional covariates.

Evaluation research typically begins by comparing the treated group with the control group. For example, estimates of the effect of training programmes on earnings compare the earnings of those who receive training with a candidate control sample of untrained people. Because typically trainees are not chosen randomly, a simple comparison of the two groups may not provide a very accurate picture of what would have happened to the trainees had they not been trained. Under some conditions, such problems can be avoided by comparing the treated and the control groups with identical covariate values. For more formal discussion, denote the covariate vector for person \( i \) by \( X_i \), treatment status by \( D_i \) such that \( D_i = 1 \) if the \( i \)th person is treated and \( D_i = 0 \) otherwise, and define the conditional probability of treatment, or propensity score, as \( p(X_i) \equiv \Pr[D_i = 1|X_i] \). Let \( Y_{1i} \) denote the potential, or counterfactual, outcome if the \( i \)th person receives the treatment, and let \( Y_{0i} \) denote potential earnings if he or she does not receive the treatment. Note that \( Y_{1i} \) is observed only when \( D_i = 1 \). Likewise, \( Y_{0i} \) is observed only when \( D_i = 0 \). This implies that \( Y_{1i} - Y_{0i} \) is not observed by the researcher, and therefore the average treatment effects, which are defined to be \( \beta = E[Y_{1i} - Y_{0i}] \), cannot be estimated by the sample analog of \( E[Y_{1i} - Y_{0i}] \). Because \( D_i \) is not usually assigned randomly, a simple comparison of the two groups, that is, the sample analog of \( E[Y_{1i}|D_i = 1] - E[Y_{0i}|D_i = 0] \), does not provide a consistent estimate of \( \beta \), either. On the other hand, if \( Y_{0i}, Y_{1i} \) is independent of \( D_i \) given \( X_i \), that is,
then the sample analog of 

$$E\{E[Y_{1i}X_i, D_i = 1] - E[Y_{0i}X_i, D_i = 0]\}$$

will provide a consistent estimator for $\beta$. In other words, $\beta$ can be consistently estimated by 'matching' the treated and the control groups with identical covariate values.

A problem that often arises in studies of this type is the need to control for continuously distributed and/or high-dimensional covariates. In many evaluation studies, the sample sizes are small, there are many covariates, and some of the covariates are continuous. A number of variations on exact covariate-matching schemes have been developed to deal with such situations. These typically involve approximate matching, or nonparametric smoothing, of some sort.

An alternative strategy to control for covariates begins with Rosenbaum and Rubin's (1983) observation that bias can be eliminated by controlling for a scalar-valued function of the covariates, namely, the propensity score. Rosenbaum and Rubin's propensity-score theorem states that, if (1) is true, then it must also be true that conditioning on $p(X_i)$ eliminates selection bias, that is,

$$Y_{0i} \perp \perp D_i \mid p(X_i).$$

This implies that the $\beta$ can be consistently estimated by the sample analog of

$$E\{E[Y_{1i}p(X_i), D_i = 1] - E[Y_{0i}p(X_i), D_i = 0]\}.$$

It is easier to estimate $E[Y_{1i}p(X_i), D_i = 1]$ than $E[Y_{1i}X_i, D_i = 1]$, because the former requires the nonparametric regression of $Y_{1i}$ on a scalar object $p(X_i)$ whereas the latter requires the nonparametric regression on a multi-dimensional object $X_i$. (Such difficulty is often called the curse of dimensionality in the nonparametrics literature.) The value of propensity score matching is in the 'dimension reduction' generated by regions where $p(X_i)$ is constant while $E[Y_{1i}X_i]$ or $E[Y_{0i}X_i]$ are not constant. The value of the propensity score is not clear, though, when the applied researcher does not have any information.
about the treatment assignment. Without such information, the propensity score needs to be estimated, which requires a nonparametric regression of \( D_i \) on \( X_i \). Because this estimation suffers from the curse of dimensionality, the propensity score theorem seems to have little practical value when the propensity score itself needs to be estimated nonparametrically. On the other hand, it can be quite useful when applied researchers may have more information or are willing to make stronger assumptions about treatment assignment than about the relationship between covariates and outcomes. A number of empirical examples using the propensity score suggest that this approach works reasonably well (see, for example, Rosenbaum and Rubin, 1984; 1985; Dehejia and Wahba, 1999; Imbens, Rubin and Sacerdote, 2001; Heckman, Ichimura and Todd, 1998).

This evidence of practical utility notwithstanding, from an asymptotic theory point of view propensity-score-based estimators present a puzzle. Hahn (1998) shows that the propensity score is ancillary for estimates of average treatment effects, in the sense that knowledge of the propensity score does not lower the semiparametric efficiency bound for this parameter. Moreover, covariate matching is asymptotically efficient, that is, it attains the semiparametric efficiency bound, while propensity score matching does not. These results based on conventional asymptotic arguments seem to offer no justification for anything other than full control for covariates in estimation of average treatment effects.

The propensity score may still be a useful device. First, the propensity score may enhance finite sample efficiency. Angrist and Hahn (2004) use a non-standard asymptotic argument to point out that the traditional first-order asymptotic theory misses some of the subtleties in finite sample property, and observe that an estimator based on propensity score matching may be superior to the one based on covariate matching. They note, though, that the finite sample efficiency gain becomes smaller as the sample size grows, which is in accordance with the prediction from the traditional asymptotic theory.

Second, when the estimated propensity scores are used as a weight in a certain way but not as a basis of matching, the estimator of the average treatment effects based on estimated propensity score is as asymptotically efficient as the covariate matching (Hirano, Imbens and Ridder, 2003).

property law, economics and

Dean Lueck
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This entry shows how the economics of property rights can be used to understand fundamental features of property law and related extra-legal institutions. It examines both the rationale for legal doctrine and the effects of legal doctrine regarding the exercise, enforcement, and transfer of rights. It also examines various property rights regimes including open access, private ownership, common property, and state property. Property law is understood as a system of societal rules designed to create incentives for people to maintain and invest in assets, which in turn leads to specialization and trade.

Keywords

Article

Property law is the body of court enforced rules that governs the establishment, use and transfer of rights to land and those assets attached to it such as air, minerals, water, and wildlife. In economic terms, property rights are defined as the (expected) ability of an economic agent to freely use an asset (Allen, 1999; Barzel, 1997; Lueck and Miceli, 2007; Shavell, 2004) and represent a social institution that
creates incentives to use, to maintain, and to invest in assets. Property rights may or may not be enforced by courts; and because the actions of courts are costly legal rights are but a subset of economic property rights. In addition to law and regulations, property rights may be enforced by custom and norms (see, for example, Ellickson, 1991) and by markets through repeated transactions.

Property rights, transaction costs, and the Coase Theorem

Consider Coase's (1960) famous example of the rancher and farmer. The rancher's cattle stray onto the farmer's land causing crop damage. The rancher's profit, \( \pi(h) \) and the amount of crop damage \( d(h) \) are functions of the rancher's herd size \( h \), so the first-best optimal herd size, \( h^* \) maximizes \( \pi(h) - d(h) \) and \( h^* \) solves \( \pi'(h) = d'(h) \). This is also the choice made by a single farmer-rancher, Coase's 'sole owner' case. If the rancher initially has the economic (and legal) right to impose crop damage without penalty, he would choose the herd size to maximize \( \pi(h) \), adding cattle until \( \pi'(h) = 0 \), which implies \( h^r > h^* \).

The farmer would be willing to pay up to \( d'(h) \), his marginal damage, for each steer that the farmer removes from the herd in order to avoid crop damage, while the rancher would accept any amount greater than his marginal profit, \( \pi'(h) \).

If transaction costs are zero, the parties will instantly contract to reduce the herd to the efficient size. The farmer will purchase the rights to the straying cattle, and if the farmer had the initial rights the situation would be reversed: either way the outcome is first-best. This is the Coase Theorem: When transaction costs are zero the allocation of resources will be efficient regardless of the initial assignment of property rights. But transaction costs are not zero and thus property rights are not perfectly defined (Allen, 1999; Barzel, 1997; Lueck and Miceli, 2007) so property law becomes important in defining rights and determining the allocation of assets. Indeed, Coase's (1960) discussion of nuisance law suggests an economic logic to the law in its assignment of property rights among various parties to these disputes.

Property rights: taxonomy and models

Property law recognizes several fundamental property rights regimes: private property, open access, common property, and state property (Lueck and Miceli, 2007). Property law also recognizes mixed regimes. Consider a fixed asset (such as a plot of land) used with a variable input \( x \) to produce a market output \( y = f(x) \). If the input price is \( w \), then the first-best use \( x^* \) must maximize \( R = f(x) - wx \) and satisfy \( f'(x) = w \). The first-best value of the land is \( V^* = \int_0^\infty R^* (x^*, t) e^{-rt} dt \), where \( r \) is the discount rate.

If there is 'open access' for \( n \) individuals, then output is \( y = f(\sum_{i=1}^n x_i) \) where \( x_i \) is the effort of the \( i^{th} \) individual, \( f'(\cdot) > 0 \) and \( f'(\cdot) < 0 \), and the opportunity cost of effort is \( w_i \). Each person can only capture (and thus own) the output in proportion to his share of effort, so each solves:
property law, economics and The New Palgrave Dictionary of Economics

\[
\max_{x_i} R_i = f^i(x_i) - w_i x_i \quad \text{subject to} \quad f^i = \left[ x_i / \sum_{j=1}^{n} x_j \right] f \left( \frac{\sum_{j=1}^{n} x_j}{n} \right)
\]

(1)

On the assumption that users are homogeneous \((w_i = w_j \quad \text{for all} \ j)\), the Nash open access equilibrium is \(x = x^{\alpha} \left( n, \ w_1, \ldots, \ w_n \right)\), which satisfies,

\[
(n - 1 / n) \left( \frac{\sum_{j=1}^{n} x_j}{\sum_{i=1}^{n} x_i} \right) - \frac{1}{n} f \left( \frac{\sum_{j=1}^{n} x_j}{n} \right) = w_i \quad i = 1, \ldots, n.
\]

(2)

In the limiting case as \(n \to \infty\), (2) becomes \(f \left( \sum_{j=1}^{n} x_j \right) / \sum_{j=1}^{n} x_j = w\) which is the famous ‘average product rule’ (Gordon, 1954; Cheung, 1970; Brooks et al., 1999). The limiting case implies that rents are completely dissipated, or \(\sum_{j=1}^{n} R_i = \sum_{j=1}^{n} \left[ f^i \left( x^{\alpha} \right) - w x^{\alpha} \right] = 0\) and the present value of the asset is also zero, \(\nu^{\alpha} = \int_{0}^{\infty} R(x^{\alpha}, t) e^{-rt} \, dt = 0\). With heterogeneous costs, the infra-marginal users earn rents and have incentives to maintain open access regime (Libecap, 1989).

With private property the owner chooses \(x^* < x^{\alpha}\) and generates \(\nu^* > \nu^{\alpha} = 0\). Private ownership also creates incentives for optimal asset maintenance and investment (Bohn and Deacon, 2000). Let future output be \(\gamma_{t+1} = f(x_t)\), where \(x_t\) is current investment, available at a market wage of \(w\) and the interest rate is \(r\). The first-best use of the input \((x_t^*)\) must maximize \(R = f(x_t) / (1 + r) - w_t x_t\) and satisfy \(f^t(x_t) / (1 + r) = w_t\). If \(\pi \in [0, 1]\) is the probability of expropriation (because of imperfect rights) of the future output, then an owner will maximize \(R = f(x_t) \left[ \left( 1 - \pi / (1 + r) \right) - w_t x_t \right]\). The solution \((x_t^{\pi*} < x_t^*)\) satisfies \(f^t(x_t) \left[ (1 - \pi) / (1 + r) \right] = w_t\) and implies less than first-best investment. Pure open access means that no investor could claim future output \((\pi = 1)\), so \(x_t^{\alpha} = 0\), and the rent from investment also equals zero. This lack of incentive to invest is essentially the problem of the ‘anti-commons’ described by Heller (1998) and formalized by Buchanan and Yoon (2000).

Common property is exclusive ownership by a group and may arise out of explicit private contracting (for example, unitized oil reservoirs) or out of custom (for example, common pastures); it may have legal (for example, riparian water rights) or regulatory (for example, hunting regulations) bases that have implicit contractual origins. Common property is well documented for natural resource stocks in less developed economies (Bailey, 1992; Ostrom, 1990). It is also seen in modern ‘common interest communities’ (such as condominiums, homeowner's associations) where residents use quasi-governments to maintain common areas (such as pools, open space) and provide local public goods.
Contracting to form common property creates a group that can realize economies of enforcing exclusive rights. Equal sharing is a typical internal allocation rule; it avoids costs of measuring and enforcing individual use but still leads to overuse compared with first-best. With equal sharing rules a homogeneous membership maximizes the present value of a common property resource (Lueck, 1994; 1995).

Governments own vast amounts of land, buildings, and capital equipment. State property rights are governed by administrative agencies, and the range of property rights regimes incorporates aspects of the three major types: private property, common property, and open access. State property rights commonly – and often severely – limit the transferability of rights, perhaps to limit the moral hazard incentives of agency bureaucrats. The relevant law for state property has its origins in common law (for example, mining on federal land is a first-possession rule) but is primarily governed by statutes and regulations, all shaped by bureaucrats, interest groups and politicians.

Real property regimes tend to mix the four fundamental types: open access, private property, common property and state property (Barzel, 1982; 1997; Eggertsson, 1990; Ellickson, 1993; Kaplow and Shavell, 1996; Merrill and Smith, 2000; Rose, 1998; Stake, 1999), implicitly recognizing that assets are a collection of valuable attributes. A rancher's land is not typically completely private: the streams running through the property may be open access for fishing or recreation; the grass may be a lease from a federal agency with mineral rights held by yet another private party. Similar scenarios are found in residential and commercial real estate, and Bailey (1992) found a mixture of ownership regimes among aboriginal peoples. Smith's (2000) study of the common field system of medieval Europe is a rare study of the underlying economic logic of a mixed property regime.

Origin of property rights

In law and custom, first possession is the dominant method of establishing rights, be it to the flow of output from a stock or to the stock itself (Lueck, 1995). Let \( R(x(t)) \) be the flow of benefits from an asset, where \( x(t) \) is a variable input supplied at time \( t \), \( r \) is the interest rate, and \( g < r \) is the rate at which \( R(t) \) grows over time. The first-best, full-information outcome is

\[
\psi^{FB} = \int_{t=0}^{\infty} R(x^*(t)) e^{-(r-g)t} dt, \tag{3}
\]

where \( x^*(t) \) is the optimal input level and \( r^* = 0 \) since production begins immediately.

Under first possession the asset's first claimant obtains exclusive rights to the temporal flow of rents, \( \int_{0}^{\infty} R^*(t) dt \). Since establishing a bona fide claim will be costly and because \( g < r \), property rights to the asset will emerge as the value of the asset increases (Demsetz, 1967). Along these lines an entire literature has developed to explain the ‘evolution of property rights’ or, more generally, the determinants
property law, economics and : The New Palgrave Dictionary of Economics

– both temporal and cross section – of property rights regimes (Lueck and Miceli, 2007; Rose, 1998). This literature, mostly empirical, notes that property rights regimes can move in both directions (to and away from private property), that property rights regimes can move among mixed regimes, and that political and other institutions also shape the choice of property regimes. Returning to first possession, a single claimant will choose the claiming time to maximize

\[ V^S = \int_t^\infty [R(x^*(t))e^{-(r-g)t}dt] - C e^{-rt}, \]

where \( C \) is the cost of enforcing the claim and \( t \) is the time at which ownership of the stock (and the temporal flow of output) is established. The optimal time to establish ownership is when the present value of the asset's flow equals the present value of the opportunity cost of establishing rights at \( t^S \), or \( R^* e^{-(r-g)t^S} = rC e^{-rt^S} \). The asset value falls short of first-best, or \( V^S < V^{FB} \), because the costs of establishing ownership delay ownership and production to \( t^S \) from \( t = 0 \).

First possession can dissipate value when there is unconstrained competition among homogenous claimants (Barzel, 1968; Mortensen, 1982). A competitive rush to claim rights causes ownership to be established at exactly the time \( t^R \) when the present value of the rental flow at \( t^R \) equals the present value of the entire costs of establishing ownership at \( t^R \), or \( R^* e^{-(r-g)t^R} = rC e^{-rt^R} \). In this 'race equilibrium' rights are established at \( t^R \), where \( t^R < t^S \) since \( t^R = \frac{ln(r-g) + \ln C - \ln R}{g} \) and \( t^S = \frac{\ln r + \ln C - \ln R}{g} \), and the rental stream is fully dissipated; or

\[ V^R = \int_t^{\infty} [R(x^*(t))e^{-(r-g)t^R}dt] - C e^{-rt^R} = 0. \]

Heterogeneity among claimants can reduce, or eliminate, dissipation (Barzel, 1994; Lueck, 1995). If there are two competitors (\( i \) and \( j \)) with possession costs \( C_i < C_j \), and neither party knows the other's costs, then \( i \) gains ownership just before \( j \) makes a claim, at \( t^i = t^R - \varepsilon \), and earns rent equal to the present discounted value of his cost advantage. The key implication is that, as the differential between the two lowest cost claimants \( C_j - C_i \) increases, the level of dissipation will decrease. With complete information there is no dissipation because only the low-cost claimant has a positive expected payoff in a race (Fudenberg et al., 1983; Harris and Vickers, 1985).

If the costs of enforcing a claim to the asset are prohibitive, ownership may be established only by
capturing or ‘reducing to possession’ a flow from the asset. The legal term ‘rule of capture’ describes this derivative of the rule of first possession. Wildlife and crude oil are the classic examples: ownership is established only when a hunter bags a pheasant or when a barrel of oil is brought to the surface. The stock itself (that is, the pheasant population or oil reservoir) remains unowned. The new ‘race’ is to claim the present flow $R(t)$ and leads to open access dissipation (Epstein, 1986; Lueck, 1995) since no one owns the asset’s entire stream of flows, $\int_0^\infty R(t) \, dt$. The formal analysis is static rather than inter-temporal as in the asset claim race, and is identical to the open access model developed above in equation (1).

Property law implicitly recognizes the two potential paths of dissipation – racing and over-exploitation – and is structured to limit such dissipation (Dharmapala and Pitchford, 2002; Lueck, 1995; 1998). Where first possession rules establish ownership in a resource stock, first possession tends to be defined so that valid claims are made at low cost and before dissipating races begin, thus exploiting claimant heterogeneity. Also, the transfer of rights to the resource is allowed, routinely reflecting security of ownership in the corpus. Where the rule of capture emerges (for example, oil and wildlife) access to the resource tends to be limited through legal, contractual or regulatory methods. As well, the transfer of rights to capturable flows tends to be restricted in order to limit overuse of the asset itself.

Externalities and property law: nuisance, trespass and zoning

Externalities arise because property rights to at least some of the attributes of an asset will be imperfect and thus generate problems of open access or moral hazard. Land externalities are ubiquitous because any parcel (except an island) will have neighbouring owners and because related resources (for example, air, noise, minerals, water) do not tend to coincide with the surface ownership boundaries. Property law addresses externalities through doctrines of trespass, nuisance, servitudes, and through regulatory zoning. Consider, à la Coase (1960), a railroad whose trains emit sparks that occasionally set fire to adjacent farmland. The number of trains is $n_T$ and the number of farms is $n_F$, resulting in crop damage of $n_T n_F D(x, y)$, where $D$ is the damage (reduced crop value per acre) each train causes, $x$ is the cost of precaution per train, and $y$ is the cost of precaution by each farmer. Assume $D_x < 0$, $D_y < 0$, $D_{xx} > 0$, and $D_{yy} > 0$. The marginal benefits are $b_T(n_T)$ and $b_F(n_F)$, where $b_j' < 0$, $j=T,F$. The total value of the two activities is

$$W = \int_0^{n_T} b_T(n_T) \, d\mu + \int_0^{n_F} b_F(n_F) \, d\zeta - [n_T n_F D(x, y) + n_T x + n_F y]$$

(6)

If the numbers of trains and farms are fixed, as in tort models (Shavell, 1980) that hold ‘activity levels’ fixed, the optimal precaution choices $(x^*, y^*)$ that maximize (6) are $n_F D_x(x, y) + 1 = 0$ and $n_T D_y(x, y) + 1 = 0$. If the number of trains and farms $(n_T, n_F)$ is endogenous, the resulting first-order
Conditions are \[ b_T(n_T) - [n_TD(x, y) + x] = 0 \] and \[ b_F(n_F) - [n_TD(x, y) + y] = 0. \]

Remedies for externalities can be viewed as a choice between ‘property rules’ and ‘liability rules’ (Calabresi and Melamed, 1972; Polinsky, 1980). Under property rules, rights holders can refuse any unwanted infringements of their rights, enforceable by injunctions (or criminal sanctions in the case of theft). Property rules thus form the legal basis for voluntary (market) exchange of rights. With liability rules, however, owners can only seek monetary compensation in the form of damages. Liability rules thus form the basis for court-ordered or non-consensual transactions. The choice between the two rules turns on transaction costs, particularly the costs of contracting, the costs of court adjudication, and legal administration. When contracting costs are relatively low, property rules are preferred because they ensure that all transactions are mutually beneficial. When contracting costs are high (for example, in public nuisance cases), property rules may prevent otherwise efficient transactions from occurring. Liability rules have an advantage because courts can force an efficient transfer. This advantage of liability rules must be weighed against the possibility of court error in setting damages, and, because liability rules require courts to establish the initial terms of a transaction by setting damages, the administrative costs of using this rule will likely be higher than under a property rule (Kaplow and Shavell, 1996).

In the railroad–farmer case, if liability is strict the railroad must pay full compensation regardless of its level of precaution. Strict liability induces efficient precaution by the railroad, but farmers are fully compensated and thus have no incentive for precaution. Negligence, which holds the railroad liable for damages only if it takes less than the efficient level of abatement, will induce both parties to take efficient care. Neither rule, however, will achieve first-best railroad and farm activity levels. In general, liability rules cannot create first-best incentives because of the constraint that what one party pays the other must receive. This is an example of the paradox of compensation which is also found in tort law and contract law remedies (Cooter, 1985). It can be avoided by ‘decoupling’ liability and compensation, or by using a contract or compensation mechanism that defines and enforces the optimal choices for both parties.

Trespass (for example, squatting, boundary encroachment) and nuisance (for example, air, water, noise pollution) doctrines are the primary common law responses to externalities. The primary remedy under trespass is an injunction, a property rule. The remedy under nuisance law is more complicated. A landowner can obtain relief only if the invasion is substantial, and even then he may have to be satisfied with money damages (a liability rule). If a landowner wishes the harm to be enjoined, he must meet the further legal standard of showing that the harm outweighs the benefit of the nuisance-creating activity. The trespass–nuisance distinction can be understood as a property–liability rule choice (Merrill, 1998).

Trespass ordinarily involves a small number of parties where the intruder is easily identifiable, so contracting costs tend to be low and property rules are likely optimal. Nuisance often involves large numbers or sources of harm that are difficult to identify, so liability rules are likely optimal.

Zoning is a common legal response to urban land externalities. The economic rationale for zoning is that ‘similar land uses have no (or only small) external effects on each other whereas dissimilar land uses may have large effects’ (White, 1975), creating what the common law calls a ‘public nuisance’.

Ellickson (1973) argues that zoning may have administrative and enforcement costs that often exceed the saved ‘nuisance costs’. A private alternative to zoning is the use of land use servitudes (for example, covenants, easements) that impose limits on what landowners can do with their property. Such
restrictions are frequently observed in condominiums, homeowner associations, and other ‘common interest communities’ (Dwyer and Menell, 1998; Hansmann, 1991). The economic function of these restrictions is twofold: to overcome free rider problems in the provision of certain jointly consumed amenities; and to internalize neighbourhood and rental externalities.

Public trust, public property and public use

The ancient doctrine of ‘public trust’ grants ownership of navigable rivers, shorelines, and the open sea to the public. It is judicially created common property, or sometimes open access. In its traditional application the public trust asset was a public good. When an asset is a public good, unrestricted access will not cause dissipation from overuse of the resource, but it could lead to underinvestment. When the resource has private good characteristics, unrestricted access can trigger the rule of capture and creates a classic open access problem, possibly causing resource degradation through overuse. Some courts have recently extended the doctrine into environmental assets, such as beaches, lakes, stream access and wildlife.

Large-scale projects like dams, railroads and highways often involve the assembly of a large contiguous parcel of land from relatively small and separately owned parcels. Developers face a potential holdout problem because, once assembly becomes public information, parcel owners might hold out for prices in excess of their true valuations, endangering completion of an otherwise efficient project. One solution is to force sales by replacing property rule protection of each owner’s land with liability rule protection. This is the economic justification for the eminent domain power of the state (Posner, 2003), which has common law origins. The ‘takings’ clause of the Fifth Amendment of the US Constitution explicitly grants such eminent domain power for ‘public use’ but requires ‘just compensation’, which courts have interpreted to mean ‘fair market value’. Since subjective value is part of the opportunity cost of a taking, failure to compensate for it potentially results in excessive acquisition of land by the government, though one study (Munch, 1979) found that high-valued properties were overcompensated, while owners of low-valued properties were undercompensated.

A large literature has studied the link between compensation and investment decisions of landowners (Blume, Rubinfeld and Shapiro, 1984; Fischel and Shapiro, 1988). Suppose there are many parcels, each worth \( V(x) \) if the landowner makes an irreversible investment \( x \), where \( V' > 0 \) and \( V'' < 0 \). The land also yields a public benefit of \( B(y) \), where \( y \) is the number of parcels taken and \( B' > 0, B'' < 0 \). Compensation of \( C(x) \) will be paid for each parcel taken, where \( C'(x) \geq 0, C'' \geq 0 \), and total compensation is \( yC(x) \). Landowners choose \( x \) given the anticipated behaviour of the government and the compensation rule; then the government chooses \( y \) and pays \( C(x) \). The first-best choices \( (x^*, V^*) \) maximize \( B'(y) + (1 - y)V(x) - x \), the sum of private and public benefits, and must satisfy \( (1 - y)V'(x) - 1 = 0 \) and \( B'(y) - V(x) = 0 \). If the taking is exogenous, \( y \) is fixed and the landowner will maximize \( (1 - y)V(x) + yC(x) - x \), which must satisfy \( (1 - y)V'(x) + yC'(x) - 1 = 0 \) and also gives \( x^l \) as the solution. This means that compensation must be lump sum \( (C'(x) = 0) \) to ensure that \( x^l = x^* \); a positive relationship between \( x \) and compensation creates over-investment moral hazard (another example of the paradox of compensation). Thus no compensation \( (C(x) \equiv 0 \text{ for all } x) \) is actually
efficient, although any lump sum rule is consistent with efficiency. The efficiency of zero compensation, however, depends on assumptions about government behaviour. Government regulations often restrict land uses without depriving the owner of title (for example, zoning laws, environmental regulations). Historically, courts have granted broad powers to enact such regulations but, when a regulation becomes especially burdensome, the affected landowner may claim that a ‘regulatory taking’ has occurred and seek compensation. As above, the trade-off for regulatory takings concerns the efficiency of the land use decision on the one hand and the regulatory decision on the other. Miceli and Segerson (1994; 1996) propose the following compensation rule, where $y$ is a landowner's lost value from the regulation:

$$
C = \begin{cases} 
0 & \text{if } y \leq y^* \\
V(x) & \text{if } y > y^*. 
\end{cases}
$$

Like a negligence rule in tort law, this rule requires full compensation if the government over-regulates ($y > y^*$) but requires no compensation otherwise ($y \leq y^*$). It also establishes a standard that is economically equivalent to the common law definition of a nuisance (an activity that is efficiently prohibited), and hence is consistent with the threshold for compensation implied by the nuisance exception.

Inalienability of property rights

Posner (2003, p. 75) notes, ‘the law should, in principle, make property rights freely transferable in order to allow resources to move to their most highly valued uses and to foster the optimal configuration of assets.’ Yet there are many legal restrictions that limit the alienability of property: body parts, children, voting, military service, cultural artifacts, endangered animal species, the right to freedom (laws against slavery), certain natural resources and state property.

The dominant economic reason for restrictions on alienability is that externalities can arise from transfers (Barzel, 1997; Epstein, 1985; Rose-Ackerman, 1985; Posner, 2003) if the rights to the assets are not well-defined with respect to the stock (and its stream of flows over time). This generates a rationale for limiting, even prohibiting, certain transfers of the claimed flows in order to protect the asset and its value. For example, the widespread prohibition on trade in wild game is likely to be such a case (Lueck, 1989; 1998), though even here limits on markets can potentially deter the formation of property rights. Restrictions on the sale of children may have a similar rationale: a market for children (or game) would lead to ‘poaching’ of kids (or animals) for which property rights enforcement is extremely costly. Another reason for restricting transfers is asymmetric information, particularly that leading to adverse selection (Rose-Ackerman, 1998). Adverse selection can potentially dry up markets where product quality cannot be observed prior to purchase. Similar restrictions on the types of property servitudes
allowed (such as limits on ‘negative and in gross’ easements) might be explained by reference to asymmetric information (Dnes and Lueck, 2006). Legal scholars have argued that limitations on servitudes prevent ‘clogging title’ (Gray and Gray, 2000). Consider the market for land of two types: fee simple (that is, unencumbered) and land encumbered with a servitude. Assume that only the seller knows whether the land is encumbered. Buyers do not have this information but know only that one-half of the land is encumbered. The value of an unencumbered plot is $V_f$, while the value of the encumbered plots is $V_s < V_f$. Given the information asymmetry, buyers will pay only the expected value of a plot, $EV = (V_s + V_f) / 2 < V_f$. Following Akerlof (1970) and related literature, this means there will be no market equilibrium for the unencumbered plots; that is, only ‘low-quality’ encumbered plots will be present in the market. Institutions that provide information (such as title recording and registration systems) could eliminate asymmetry and even alter the law of property by allowing an expanded set of servitudes.

Summary

Economic analysis reveals a fundamental logic to the main doctrines and features of property law (Lueck and Miceli, 2007). The observed structure of property rights and property law can be best understood as a system designed to create incentives for people to maintain and invest in assets, which in turn leads to specialization and trade. Among the most important remaining issues for study is a systematic analysis of how the law addresses the use and transfer of complex assets.

Private property rights

A property right is a socially enforced right to select uses of an economic good. A Private property right is one assigned to a specific person and is alienable in exchange for similar rights over other goods. Its strength is measured by its probability and costs of enforcement which depend on the government, informal social actions, and prevailing ethical and moral norms. In simpler terms, no one may legally use or affect the physical circumstances of goods to which you have Private property rights without your approval or compensation. Under hypothetically perfect Private property rights none of my actions with my resources may affect the physical attributes of any other person's private property. For example, your Private property rights to your computer restrict my and everyone else's permissible behaviour with respect to your computer, and my Private property rights restrict you and everyone else with respect to whatever I own. It is important to note that it is the physical use and condition of a good that are protected from the action of others, not its exchange value.

Private property rights are assignments of rights to choose among inescapably incompatible uses. They are not contrived or imposed restrictions on the feasible uses, but assignments of exclusive rights to choose among such uses. To restrict me from growing corn on my land would be an imposed, or contrived, restriction denying some rights without transferring them to others. To deny me the right to grow corn on my land would restrict my feasible uses without enlarging anyone else's feasible physical
property rights: The New Palgrave Dictionary of Economics

uses. Contrived or unnecessary restrictions are not the basis of Private property rights. Also, because those restrictions typically are imposed against only some people, those who are not so restrained obtain a ‘legal monopoly’ in the activity from which others are unnecessarily restricted. Under Private property rights any mutually agreed contractual terms are permissible, though not all are necessarily supported by governmental enforcement. To the extent that some contractual agreements are prohibited, Private property rights are denied. For example, it may be considered illegal to agree to work for over ten hours a day, regardless of how high a salary may be offered. Or it may be illegal to sell at a price above some politically selected limit. These restrictions reduce the strength of private property, market exchange and contracts as means of coordinating production and consumption and resolving conflicts of interest.

Economic theory and Private property rights

A successful analytic formulation of Private property rights has resulted in an explanation of the method of directing and coordinating uses of economic resources in a private property system (that is, a capitalistic or a ‘free enterprise’ system). That analysis relies on convex preferences and two constraints: a production possibility and a private property exchange constraint, expressible biblically as ‘Thou Shalt Not Steal’, or mathematically, as the conservation of the exchange values of one's good. For the decentralized coordination of productive specialization to work well, according to the well known principles of comparative advantage, in a society with diffused knowledge, people must have secure, alienable Private property rights in productive resources and products tradable at mutually agreeable prices at low costs of negotiating reliable contractual transactions. That system’s ability to coordinate diffused information results in increased availability of more highly valued goods as well as of those becoming less costly to produce. The amount of rights to goods one is willing to trade, and in which Private property rights are held, is the measure of value; and that is not equivalent to an equal quantity of goods not held as private property (for example, government property). It probably would not be disputed that stronger Private property rights are more valuable than weaker rights, that is, a seller of a good would insist on larger amounts of a good with weaker Private property rights than if Private property rights to the goods were stronger.

Firms, firm-specific resources and the structure of property rights

Though Private property rights are extremely important in enabling greater realization of the gains from specialization in production, the partitionability, separability and alienability of Private property rights enables the organization of cooperative joint productive activity in the modern corporate firm. This less formally recognized, but nevertheless important, process of cooperative production relies heavily on partitioning and specialization in the components of Private property rights. Yet this method is often misinterpreted as unduly restrictive and debilitating to the effectiveness and social acceptability of Private property rights. To see the error, an understanding of the nature of the firm is necessary, especially in its corporate form, which accounts for an enormous portion of economic production. The ‘firm’, usually treated as an output-generating ‘black box’, is a contractually related collection of resources of various cooperating owners. Its distinctive source of enhanced productivity is ‘team’ productivity, wherein the product is not a sum of separable outputs each of which is attributable to
specific cooperating inputs, but instead is a non-decomposable, non-attributable value produced by the group. Thus, for something produced jointly by several separately owned resources, it is not possible to identify or define how much of the final output value each resource could be said to produce separately. Instead, a marginal product value for each input is definable and measurable.

Whereas specialized production under comparative advantage and trade is directed in a decentralized process by market price and spot exchanges, productivity in the team, called the firm, relies on long-term, constraining contracts among owners who have invested in resources specialized to the group of inputs in that firm. In particular, some of the inputs are specialized to the team in that once they enter the firm their alternative (salvage) values become much lower than in the firm. They are called ‘firm-specific’. In the firm, firm-specific inputs tend to be owned in common or else contracts among separate owners of the various inter-specific resources restrict their future options to those beneficial to that group of owners as a whole rather than to any individual. These contractual restrictions are designed to restrain opportunism and ‘moral hazard’ by individual owners, each seeking a portion of each other’s firm-specific, expropriable composite quasi-rent. Taking only extremes for expository brevity, the other ‘general’ resources would lose no value if shifted elsewhere. A firm, then, is a group of firm-specific and some general inputs bound by constraining contracts, producing a non-decomposable end-product value. As a result, the activities and operation of the team will be most intensively controlled and monitored by the firm-specific input owners, who gain or lose the most from the success or failure of the ‘firm’. In fact, they are typically considered the ‘owners’ or ‘employers’ or ‘bosses’ of the firm, though in reality the firm is a cooperating collection of resources owned by different people.

Firm-specific resources can be non-human. Professional firms – in law, architecture, medicine – are comprised of teams of people who would be less valuable elsewhere in other groups. They hire non-human general capital, for complex example building and equipment. The contract, which defines ‘hiring’, depends on the specificity and generality, not on human or non-human attributes nor on who is richer. Incidentally, ‘industrial democracy’ arrangements are rare, because the owners of more general resources have less interest in the firm than those of specific resources.

The corporation and specialization in private property rights

In a corporation the resources owned by the stockholders are those the values of which are specific to the firm. The complexities in specialization in exercise of the components of property rights and the associated contractual restraints have led some people to believe that the corporation tends to insulate (for example, ‘separate’) decisions of use from the bearing of the consequences (that is, control from ownership) and thereby has undermined the capacity of a private property system to allocate resources to higher market value uses. For example, it has been argued that diffused stock ownership has so separated management and control of resources from ‘ownership’ that managers are able to act without sufficient regard to market values and the interests of the diffused stockholders. Adam Smith was among the first to propound that belief. Whatever the empirical validity, the logical analysis underlying those charges rests on misperceptions of the structure of private property rights in the corporation and the nature of the competitive markets for control and ownership which tend to restrain such managers. What individual managers seek, and what those who survive are able successfully to do in the presence of competition for control, are very different things.

An advantage of the corporation is its pooling of sufficient wealth in firm-specific resources for large-
Property rights

The New Palgrave Dictionary of Economics

Scale operations. Pooling is enabled if shares of ownership are alienable private property, thereby permitting individuals to eliminate dependence of their time path of consumption on the temporal pattern of return from firm-specific investments. Alienability is enabled if the shares have limited liability, which frees each stockholder from dependence on the amount of wealth of every other stockholder. The resultant ability to tolerate anonymity, that is, disinterest in exactly who are the other shareholders, enables better market alienability.

When voluntary separability of decision authority over firm-specific resources from their market value consequences is added to alienability, the ability to specialize in managerial decisions and talent (control) without also having to bear the risk of all the value consequences, enables achievement of beneficial specialization in production and coordination of cooperative productivity. Specialization is not necessarily something that is confined to the production of different end products; it applies equally to different productive inputs or talents. Voluntary partitionability and alienability of the component rights enable advantageous specialization (sometimes called ‘separation’) in (a) exercise of rights to make decisions about uses of resources and (b) bearing the consequent market or exchange values. The former is sometimes called ‘control’ and the latter, ‘ownership’. Separability enables the achievement of the gains from specialization in selecting and monitoring uses, evaluating the results, and bearing the risk of consequent future usefulness and value. Because different uses have different prospective probability distributions of outcomes, and because outcomes are differentially sensitive to monitoring the prior decisions, separability and alienability of the component rights permit gains from specialization in holding and exercising the partitionable rights.

Thus, the modern corporation relies on limited liability to enhance alienability and on partitionability of components of private property rights in order to achieve gains from large-scale specialization in directing productive team activity and talents. Rather than destroying or undermining the effectiveness of private property rights, the alleged ‘separation’ enables effective, productive ‘specialization’ in exercising private property rights as methods of control and coordination.

Government property rights

It might be presumed that government property rights in a democracy are similar to corporate property with diffused stockholdings and should yield similar results. The analogy would be apt if each voting citizen had a share of votes equivalent to one’s share of the wealth in the community, and if a person could shift wealth among governments, as one can among different corporations. If, for example, one could buy and sell land (as assets capturing essentially most of the value of whatever the government does in that particular state) in several different governments and could vote in each in proportion to the value of that ‘land’ then government property would be closer to private property in its effects. But it is difficult to take that possibility seriously. The nature of government, public or communal property rights surely depends on the kind of government. Because these are so vaguely and indefinitely defined, attempts to deduce formally the consequences of resource allocation and behaviour under each have been hampered.

Non-existent property rights

Not all resources are satisfactorily controlled by private property rights. Air, water, electromagnetic...
radiation, noises and views are some examples. Water under my land flows to yours. Sounds and light from my land impinge on yours. Other forms of control are then designed, for example, political or social group decisions and actions, though these other forms are sometimes employed for ideological or political purposes, even where Private property rights already exist.

If these other forms permit open, free entry with every user sharing equally and obtaining the average return, use will be excessive. Extra uses will be made with an increased realized total value that is less than the cost added, that is, the social product value is not maximized. This occurs because the marginal yield is less than the average to each user, to which each user responds. So, use occurs to the point where the average yield is brought down to marginal cost, with the consequence that the marginal yield is less than the marginal cost – often exampled as excessive congestion on a public road or public park, or over-fishing of communal, free access fishing areas. The classic ‘communal property’ implication that apples on the public apple tree are never allowed to ripen is an extreme example of the proposition that property rights, other than private, reduce conformity of resource uses to market revealed values.

Alternatively, if communal property rights mean that incumbent users can block more users, the resource will be underutilized as incumbents maximize their individual yield, which is the average, not the marginal. This results in fewer users. Though more users or uses would lower the average value to the incumbents and hence dissuade a higher rate of use, the addition to the total group value (of the extra use) exceeds the extra costs. Examples are public, low tuition colleges that restrict entry to maximize the ‘quality’ of those who are educated – that is, to maximize the average yield of those admitted. Some labour unions (that is, teamsters) are examples of similar situations.

A mistaken inference commonly suggested by the example of fishermen who overfish unowned lakes is that independent sellers with open access to customers will ‘over-congest’ in product variety and advertising to catch customers, with unheeded costs borne by other sellers. If, for example, Pall Mall cigarettes attract some customers from Camel, the loss to Camel is the reduced value of Camel-specific resources, not its lost sales revenue. General resources will be released from making Camels for use elsewhere with no social loss. But Camel-specific resources fall in value by the extent to which Pall Mall's product is better or cheaper. Camel's loss is more than offset by the sum of Pall Mall's increased net income plus the transfer gain to customers from lower prices or better quality. The loss to Camel is not from new entry itself, but from its incorrect forecasts of its earlier investment value. It is presumed here that mistaken forecasts should not be protected by prohibiting the unexpected future improvements.

This differs from the over-fishing case in that consumers, in contrast to fish, have property rights in what they pay and what they buy. If every fish had a separate owner or owned itself, none would allow it to be caught unless paid enough, and over-fishing would not occur. One owner of all the fish is unnecessary; it suffices that each fish (or potential customer) be owned by someone who can refuse to buy. (Of course, unless the lake were owned, the lake surface might be over-congested with too many fishermen, each fishing to a lesser area, even if the fish were owned.)

Ownership of tradable rights by customers is the feature that is missing in the over-fishing, over-congestion case. Because rights to (or ‘of’) the fish or whales need not be bought, over-fishing does not imply over-customering where customers own rights to what the competing sellers are seeking.

Otherwise, customers could be caught like fish, wherein sellers would be competing both to (1) establish property rights over the customers and to (2) possess those rights. Costly redundant competition for initial establishment of rights could be avoided simply by establishing customers’ rights to themselves, as is in fact done. If the preceding seems fanciful, replace ‘fish’ with people and the lake surface with
streets on which taxi-drivers cruise for customers. Excessive costs will be incurred in competition for use of unowned, valuable resources, in this case, the streets.

**Mutual property rights**

‘Mutual’ forms of organization are used apparently in order to sustain the maximum average per member, or to reserve for the incumbent members any greater group value from more members. Mutual private property, a form that has barely been analysed, does not permit anonymous alienability of interests in what are otherwise Private property rights. A ‘mutual’ member can transfer its interest to other people only upon permission of the other mutually owning members or their agents. Fraternal, social and country clubs are examples. These activities have not typically been viably organized and their services sold, as for example, in restaurants and health and exercise gymnasia. The intragroup-specific resources are themselves the members (erstwhile customers) who interact and create their social utility. More members affect each incumbent's realized utility in two ways: by social compatibility and by congestion. An outside, separate owner interested in the maximum value of the organization, but not the maximum average-per-member, could threaten to sell more memberships which, although enabling a larger total social value with more members, would reduce the average value to the existing members.

This is an example of the earlier analysed difference between maximizing the average yield per input rather than the total yield by admitting more members, who while they would be made better off than if not admitted nevertheless reduce the average value to the incumbent members. In addition, the ability of newcomers to compensate incumbents for any loss in the individual (average) value to incumbent members is restrained if the membership fee were to go instead to an outside owner of the club. To the extent that a pecuniary compensation, via an initiation fee, were paid to an outside owner and exceeded the reduction in their average individual and total group utility, newcomers would be admitted, and the outside owner would gain, but incumbent members would lose their composite quasi-rent of their interpersonal sociability. (It is not yet well understood why, aside from tax reasons, the mutual form occurs in savings and loans and insurance firms.)

**Torts, conditional and unassigned property rights**

Private property rights may exist in principle, but, quite sensibly, not be blindly and uncompromisingly enforced against all possible ‘usurpers’. For example, situations arise in which someone’s presumed Private property rights do not exclude an ‘invader’s’ use. Accidental or emergency use of some other person's private property without prior permission constitutes an example, sometimes called a ‘tort’. Another possibility is that the property rights are so ill-defined that whether a right has been usurped or already belonged to the alleged ‘usurper’ is unclear. For example, my newly planted tree may block the view from your land. But did you have a right to look across my land? If the rights to views (or light rays) were clearly defined and assigned, we could negotiate a price for preserving the view or my putting up a tree, depending upon which was more valuable to the both of us and with payment going to whoever proved to have the rights. Or, while sailing on a lake, to escape a sudden storm and save my boat and life, I use your dock without your prior permission. Did I violate any of your rights, or did your rights not include the right to exclude users in my predicament? If such emergency action is deemed appropriate, then rights to use of the dock are not all yours, as you may have thought. Whereas in the
property rights: The New Palgrave Dictionary of Economics

tree and view case, where a prior negotiation might have avoided a ‘tort’ (except that initially we did not agree about who had what rights), in the emergency use of the dock, prior negotiation was unfeasible. If prior negotiation is uneconomic, rights to that emergency use ‘should’ and will exist if that use is the most valuable use of the resource under the postulated circumstances. And compensation may or may not be required to the erstwhile ‘owner’. The principle underlying such a legal principle seems straightforward and consistent with principles of efficient economic behaviour. It suffices for present purposes merely to call attention to this aspect of economic efficiency underlying the law.

Abstract

Property taxation of both residential and non-residential land and structures is the most common form of wealth taxation worldwide, and is often the revenue instrument of choice for local governments. Despite widespread use of the property tax and a voluminous academic literature examining the tax, its incidence and economic effects are still contentious issues, with the debate centring around whether the capital portion of the tax should be viewed as distorting the allocation of capital or as an efficient benefit tax or user charge for local public services.

Article

Property taxation of both residential and non-residential land and structures – or ‘real property’ – is the most common form of wealth taxation worldwide, and is often the revenue instrument of choice for local governments. For example, in the United States property taxes account for over 70 per cent of local own-source tax revenues. Property tax liability is calculated as the product of the statutory rate and the assessed tax base, subject to a variety of adjustments, such as partial exemptions for primary residences and ‘circuit breakers’ designed to reduce tax burdens for certain groups, especially relatively poor elderly homeowners. Although vagaries in the assessment process have long been a source of inequity in the administration of the tax, recent advances in computer-based assessment practices have mitigated
property taxation: The New Palgrave Dictionary of Economics

this problem. More recently, rapid growth in residential home values and the concomitant increase in property tax burdens and the share of total local taxes paid by homeowners have led to increasing dissatisfaction with the tax in some regions, culminating in the passage of numerous property tax limitation measures. In addition, concerns about the equity implications of financing primary and secondary public education with the property tax when the tax base, including non-residential property, is unequally distributed across school jurisdictions have led to reduced reliance on the tax as well as equalization mechanisms that redistribute property tax revenues across school districts (Anderson, 1994).

The incidence debate – the three views of the property tax

The academic literature on the property tax – as reviewed by Mieszkowski and Zodrow (1989), Ladd (1998), Ross and Yinger (2000) and Netzer (2001) – has focused on the incidence and effects on the allocation of resources of the residential property tax. There is general agreement that the land component of the property tax is capitalized into land values, is borne by landowners at the time of the imposition of the tax, and – since land is immobile – does not distort the allocation of resources. Indeed, the efficiency advantages of taxing land values, coupled with a belief that most increases in land values reflect the benefits of public services, have led some observers, most prominently Henry George (1879), to advocate replacing property taxes with taxes on land values.

By comparison, the incidence and economic effects of property taxation of the capital or structures component of real property are among the most contentious issues in state and local public finance. Three views dominate the debate. The ‘traditional’ view dates back to Simon (1943) and Netzer (1966), who focused on the partial equilibrium effects of increasing the tax in a local housing market. From this perspective, one can make the standard ‘open economy’ assumption that the national return to capital is fixed. This in turn implies that local capital bears none of the local property tax, as capital in the long run migrates from the jurisdiction until the local after-tax return to capital equals the national value. The burden of the tax is thus borne by local factors and/or consumers, with the traditional view holding that the entire burden is borne by local housing consumers. The traditional view thus implies that the property tax inefficiently reduces the size of the local housing stock and that its burden is borne in proportion to housing consumption – and is thus somewhat regressive with respect to annual income but, more importantly, roughly proportional with respect to lifetime income.

A second popular theory is the ‘benefit tax’ view, developed by Hamilton (1975; 1976); Fischel (2001a; 2001b) provides a recent discussion. This view is an extension of the renowned Tiebout (1956) model, which argues that consumer mobility (‘voting with the feet’) and inter-jurisdictional competition in the provision of local public services can ensure efficiency of resource allocation in the local public sector. Although Tiebout assumed the existence of benefit/head taxes, Hamilton extended the analysis by deriving conditions under which the property tax can be converted into the head tax assumed by Tiebout. Specifically, following Tiebout, Hamilton assumes that individuals sort into local jurisdictions according to their demands for local public services, and that there are enough local tax-expenditure packages to accommodate all tastes. In addition, Hamilton (1975) assumes that local jurisdictions are homogeneous with respect to house values, and that there are enough jurisdictions to accommodate all desired housing and government service/tax packages. Finally, Hamilton assumes the existence of binding zoning constraints that established a minimum house value for each community. Under these circumstances,
individuals are precluded from purchasing homes with a value below the minimum, and would never elect to pay taxes in excess of benefits received by purchasing a home with a value greater than the minimum; all individuals in a given community thus pay exactly the same property tax, which becomes a benefit tax.

Hamilton (1976) extends this model to the more realistic case in which house values within a community are heterogeneous. In this case, Hamilton assumes all communities are fully developed, effectively precluding any tax-induced changes in the housing stock, and that alternative communities which are homogeneous with respect to both demands for public services and housing are available. Under these circumstances, Hamilton shows that ‘perfect capitalization’ converts the property tax into a benefit tax, as a relatively expensive home sells at a discount equal to its ‘fiscal differential’ or the present value of all future taxes in excess of benefits received, while a relatively inexpensive home sells at a premium reflecting its fiscal differential, the present value of all future benefits in excess of future taxes. The implications of the benefit tax view are striking, as it implies that the property tax is effectively a non-distortionary user charge that has no direct effects on income distribution.

Finally, the ‘capital tax’ view (or ‘new’ view) of the property tax, developed by Mieszkowski (1972), subsequently extended by Zodrow and Mieszkowski (1983; 1986b), and reviewed in Zodrow (2001a; 2001b), argues that the property tax is a distortionary tax on the local use of capital that results in a misallocation of the national capital stock across local jurisdictions. Mieszkowski (1972) stresses that earlier partial equilibrium analyses ignored the fact that the property tax is used by virtually all local jurisdictions and applies to a large fraction of the capital stock, including most non-residential capital. Adapting the Harberger (1962) general equilibrium model of tax incidence, he models the economy as having a fixed national capital stock and two types of local jurisdictions, characterized by ‘high’ tax rates and ‘low’ tax rates. In this context, Mieszkowski shows that property tax rates that exceed the national average drive capital out of high-tax jurisdictions into low-tax jurisdictions, with opposing effects occurring in relatively low-tax jurisdictions. Property tax differentials thus result in an inefficient allocation of capital across jurisdictions. In addition, concern about the extent to which use of the property tax may drive capital out of a jurisdiction creates a tendency for local governments to under-provide public services (Zodrow and Mieszkowski, 1986b; Wilson, 1986). In terms of incidence, the ‘average burden’ of all of the property taxes imposed across the nation – known as the ‘profits tax’ effect of the tax – is borne by capital owners generally, implying that the tax is relatively progressive (with respect to annual income). In addition, Mieszkowski stresses that property tax differentials about the national average result in ‘excise tax effects’ in the form of housing and commodity price increases and wage and land price declines in relatively high-tax jurisdictions, with offsetting effects in relatively low-tax jurisdictions.

Differentiating among the three views

Much of the subsequent literature has focused on reconciling or differentiating among these three views, and the issue of which view most accurately describes the effects of the property tax is still contentious. Matters are simplified somewhat because the traditional view has been shown to be a special case of the capital tax view. Specifically, the traditional view can be interpreted as a partial equilibrium analysis that focuses exclusively on the excise tax effects of the capital tax view, while neglecting its general
equilibrium profits tax effects. Moreover, the traditional view that these excise tax effects are fully reflected in higher housing prices is accurate only under special circumstances; more generally, excise tax effects are borne in some combination by housing consumers and the owners of labour and land in the taxing jurisdiction (Wildasin, 1986). In addition, the profits tax effect still obtains when one takes a general equilibrium perspective of the use of the property tax by a single small jurisdiction facing a perfectly elastic supply of capital. Specifically, although the capital outflow caused by an increase in the property tax by a small local jurisdiction depresses the overall return to capital only very slightly, this reduction affects a large capital stock; under certain circumstances, the overall reduction in national capital income precisely equals the revenue raised by the taxing jurisdiction, yielding the profits tax result (Zodrow and Mieszkowski, 1983; Brown, 1924; Bradford, 1978). At the same time, the burden of a property tax increase in a single jurisdiction is borne entirely by local residents as higher prices or lower factor returns (with offsetting effects in all other jurisdictions). A critical implication is that even under the capital tax view there is a close link between local public services and the burden of the property tax, as the cost of financing local expenditures largely falls on local factor owners and consumers; thus, this interpretation of the capital tax view clearly has a strong benefit view flavour as local residents ‘pay for what they get’ in public services.

Nevertheless, the debate between proponents of the benefit tax view and the capital tax view is still far from resolved. The original Mieszkowski (1972) derivation, based on a model of national tax incidence, has been criticized for ignoring many of the features of local government service provision stressed by Tiebout and Hamilton. However, Zodrow and Mieszkowski (1986a) present an expanded derivation of the capital tax view that includes most of these aspects, including interjurisdictional competition, varying tastes for local public services, individuals sorting into differing communities according to tastes for local public services, and a simple form of land use zoning. They conclude that these factors thus do not distinguish between the two views; instead, the key factor in determining the incidence of the property tax is whether housing consumption can vary in response to the imposition of the tax.

Moreover, although zoning requirements are pervasive, take a wide variety of forms, and can have a significant impact on property values (Fischel, 1992), these facts do not demonstrate that zoning ordinances are sufficiently binding on housing consumption choices to ensure the validity of the benefit view (Rubinfeld, 1987; Ross and Yinger, 2000). In addition, although empirical evidence suggests that intrajurisdictional and interjurisdictional capitalization of differences in property taxes and local expenditures is widespread (Oates, 1969; Yinger et al., 1988; and Fischel, 2001a; 2001b, who concludes that evidence of ‘capitalization is everywhere’), capitalization is consistent with both the assumption of fixed housing stocks that underlies the benefit tax view and the tax-induced reallocations of capital that underlie the capital tax view (Zodrow, 2006); moreover, some observers have argued that in the long run capitalization is inconsistent with the benefit view (Ross and Yinger, 2000). Finally, although some recent empirical tests are consistent with the capital tax view (Carroll and Yinger, 1994; Wassmer, 1993), these results are quite tentative. The primary empirical issue remaining to be resolved is whether the zoning restrictions or other mechanisms stressed by proponents of the benefit tax view are sufficiently binding to preclude the long-run adjustments in housing capital predicted by the capital tax view. This question promises to be a fertile topic for future research, which hopefully will help clarify the answer to the long-standing and critical questions of the incidence and economic effects of the property tax.

proportional hazard model

Jerry A. Hausman and Tiemen M. Woutersen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews proportional hazard models and how the thinking about identification and estimation of these models has evolved since the mid-1970s.

Keywords

baseline hazard; convergence; duration dependence; duration measurements; duration models; gamma distribution; heterogeneity; mixed proportional hazard (MPH) model; partial likelihood estimators; proportional hazard models; semiparametric estimation; time-varying regressors; Weibull model

Article

The estimation of duration models has been the subject of significant research in econometrics since the late 1970s. Cox (1972) proposed the use of proportional hazard models in biostatistics and they were soon adopted for use in economics. Since Lancaster (1979), it has been recognized among economists that it is important to account for unobserved heterogeneity in models for duration data. Failure to account for unobserved heterogeneity causes the estimated hazard rate to decrease more with the duration than the hazard rate of a randomly selected member of the population. Moreover, the estimated proportional effect of explanatory variables on the population hazard rate is smaller in absolute value than that on the hazard rate of the average population member and decreases with the duration. To account for unobserved heterogeneity Lancaster proposed a parametric mixed proportional hazard (MPH) model, a partial generalization of Cox's proportional hazard model, that specifies the hazard rate as the product of a regression function that captures the effect of observed explanatory variables, a baseline hazard that captures variation in the hazard over the spell, and a random variable that accounts for the omitted heterogeneity. In particular, Lancaster (1979) introduced the mixed proportional hazard model in which the hazard is a function of a regressor X unobserved heterogeneity ν, and a function of time λ(t),
The function $\lambda(t)$ is often referred to as the baseline hazard and $v|X$ has a gamma distribution. The popularity of the mixed proportional hazard model is partly due to the fact that it nests two alternative explanations for the hazard $\hat{\theta}(t|X)$ to be decreasing with time. In particular, estimating the mixed proportional hazard model gives the relative importance of the heterogeneity, $v$, and genuine duration dependence, $\lambda(t)$ (see Lancaster, 1990, and Van den Berg, 2001, for overviews). Lancaster (1979) uses functional form assumptions on $\lambda(t)$, which were not required by the Cox model, and distributional assumptions on $v$ to identify the model. Examples by Lancaster and Nickell (1980) and Heckman and Singer (1984), however, show the sensitivity to these functional form and distributional assumptions. Thus, Lancaster's MPH model is fully parametric and from the outset questions were raised about the role of functional form and parametric assumptions in the distinction between unobserved heterogeneity and duration dependence. (Heckman, 1991, gives an overview of attempts to make this distinction in duration and dynamic panel data models.) This question was resolved by Elbers and Ridder (1982), who showed that the MPH model is semi-parametrically identified if there is minimal variation in the regression function. A single indicator variable in the regression function suffices to recover the regression function, the baseline hazard, and the distribution of the unobserved component, provided that this distribution does not depend on the explanatory variables. Semi-parametric identification means that semi-parametric estimation is feasible, and a number of semi-parametric estimators for the MPH model have been proposed that progressively relaxed the parametric restrictions. Nielsen et al. (1992) showed that the partial likelihood estimator of Cox (1972) can be generalized to the MPH model with gamma-distributed unobserved heterogeneity. Their estimator is semi-parametric because it uses parametric specifications of the regression function and the distribution of the unobserved heterogeneity. The estimator requires numerical integration of the order of the sample size, as originally discussed by Han and Hausman (1990), which further limits its usefulness and makes it impractical for most situations in econometrics. Heckman and Singer (1984) considered the non-parametric maximum likelihood estimator of the MPH model with a parametric baseline hazard and regression function. Using results of Kiefer and Wolfowitz (1956), they approximate the unobserved heterogeneity with a discrete mixture. The rate of convergence and the asymptotic distribution of this estimator are not known. As a result, these estimators that use discrete mixture with an increasing number of support points cannot be used to test hypotheses. Another estimator that does not require the specification of the unobserved heterogeneity distribution was suggested by Honoré (1990). This estimator assumes a Weibull baseline hazard and uses only very short durations to estimate the Weibull parameter. Han and Hausman (1990) and Meyer (1990) propose an estimator that assumes that the baseline hazard is piecewise-constant, to permit flexibility, and that the heterogeneity has a gamma distribution. Both papers find that the hazard rate, conditional on heterogeneity, is non-monotonic so that the Weibull

\[
\theta(t|X, v) = ve^{X\beta}0_{\lambda}(t).
\]
proportional hazard model: The New Palgrave Dictionary of Economics

model cannot hold. Hausman and Woutersen (2005) present simulations and a theoretical result that show that using a nonparametric estimator of the baseline hazard with gamma heterogeneity yields inconsistent estimates for all parameters and functions if the true mixing distribution is not a gamma, which limits the usefulness of the Han–Hausman–Meyer approach. Thus, Hausman and Woutersen (2005) find it important to specify a model that does not require a parametric specification of the unobserved heterogeneity.

Horowitz (1999) was the first to propose an estimator that estimates both the baseline hazard and the distribution of the unobserved heterogeneity nonparametrically. His estimator is an adaptation of the semi-parametric estimator for a transformation model that he introduced in Horowitz (1996). In particular, if the regressors are constant over the duration, then the MPH model has a transformation model representation with the logarithm of the integrated baseline hazard as the dependent variable and a random error that is equal to the logarithm of a log standard exponential minus the logarithm of a positive random variable. In the transformation model the regression coefficients are identified only up to scale. As shown by Ridder (1990), the scale parameter is identified in the MPH model if the unobserved heterogeneity has a finite mean. Horowitz (1999) suggests an estimator of the scale parameter that is similar to Honore's (1990) estimator of the Weibull parameter and is consistent if the finite mean assumption holds so that his approach allows estimation of the regression coefficients (not just up to scale). However, the Horowitz approach permits estimation of the regression coefficients only at a slow rate of convergence and it is not \( N^{-1/2} \) consistent, where \( N \) is the sample size. The reason for the slower than \( N^{-1/2} \) convergence is that the information matrix of the MPH model is singular under Horowitz assumptions (see Hahn, 1994; Ishwaran, 1996a). In particular, Horowitz (1999) assumes that the first three moments of the heterogeneity distribution exist, and Ishwaran (1996b) shows that the fastest possible rate of convergence is \( N^{-2/5} \) for that case and Horowitz's (1999) estimator converges arbitrarily close to that rate. In other words, the slow rate of convergence is implied by the assumptions and is not a peculiarity of the estimator.

Subsequent research has focused on strengthening the assumptions of the MPH model so that \( N^{-1/2} \) convergence is possible. Ridder and Woutersen (2003) derive a \( N^{-1/2} \) consistent estimator for the MPH model by assuming that the baseline hazard rate is constant over a small interval, \( \lambda(t) = \lambda \) for \( 0 \leq t \leq \varepsilon \) for any \( \varepsilon > 0 \) while allowing for a nonparametric baseline hazard function for \( t > \varepsilon \). For parametric baseline hazards, Ridder and Woutersen (2003) assume that \( \lim_{t \to 0} \lambda(t) = \lambda \) for \( 0 < \lambda < \infty \) and derive another \( N^{-1/2} \) consistent estimator. Hausman and Woutersen (2005) derive an estimator for the mixed proportional hazard model (with heterogeneity) that allows for a nonparametric baseline hazard and uses time-varying regressors. No parametric specification of the heterogeneity distribution or nonparametric estimation of the heterogeneity distribution is necessary. Intuitively, Hausman and Woutersen (2005) condition out the heterogeneity distribution, which makes it unnecessary to estimate it. Thus, they eliminate the problems that arise with the Lancaster (1979) approach to MPH models. In this model the baseline hazard rate is nonparametric, and the estimator of the integrated baseline hazard rate converges at the regular rate, \( N^{-1/2} \) where \( N \) is the sample size. This convergence rate is the same rate as for a duration model without heterogeneity. The regressor parameters also converge at the regular rate.
rate. A nice feature of the estimator is that it allows the durations to be measured on a finite set of points. Such discrete measurement of durations is important in economics; for example, unemployment is often measured in weeks. In the case of discrete duration measurements, the estimator of the integrated baseline hazard converges only at this set of points, as would be expected.

It may be argued that the bias in the estimates of the regression coefficients is small if the estimates of the MPH model indicate that there is no significant unobserved heterogeneity. The problem with this argument is that estimates of the heterogeneity distribution are usually not very accurate. Given the results in Horowitz (1999), this finding should not come as a surprise. The simulation results in Baker and Melino (2000) show that it is empirically difficult to find evidence of unobserved heterogeneity, in particular if one chooses a flexible parametric representation of the baseline hazard. However, Han and Hausman (1990) and applications of their approach have found significant heterogeneity using a flexible approach to the baseline hazard. Bijwaard and Ridder (2002) find that the bias in the regression parameters is largely independent of the specification of the baseline hazard. Hence, failure to find significant unobserved heterogeneity should not lead to the conclusion that the bias due to correlation of the regressors and the unobservables that affect the hazard is small.

Because it is empirically difficult to recover the distribution of the unobserved heterogeneity, estimators that rely on estimation of this distribution may be unreliable. Therefore, it may be advisable to avoid estimating the unobserved heterogeneity distribution and the remainder of the MPH model simultaneously. Nevertheless, after estimating the baseline hazard and regression function, one can usually identify the mixing distribution. In particular, Horowitz (1999) uses the following equation to estimate the mixing distribution,

$$\ln \{\Lambda (T)\} + X\beta - \ln (Z) = - \ln (\nu)$$

where \(\Lambda (T)\) and \(\beta\) can be estimated and the unobserved \(Z\) has an exponential distribution with mean one. Thus, Horowitz (1999) solves a deconvolution problem and the speed of convergence depends on the assumptions on the distribution of \(\nu\).

A hazard model is a natural framework for time-varying regressors if a flow or a transition probability depends on a regressor that changes with time since a hazard model avoids the curse of dimensionality that would arise from interacting the regressors at each point in time with one another. A non-constructive identification proof for the duration model with time-varying regressors can be produced using techniques similar to Honoré (1993b), and Honoré (1993a) gives such a proof. (A non-constructive identification proof is an identification proof that does not suggest an estimator.) In particular, Honoré (1993a) does not assume that the mean of the heterogeneity distribution is finite (nor does Honoré, 1993a, assume a tail condition as in Heckman and Singer, 1984). Ridder and Woutersen (2003) argue that it is precisely the finite mean assumption that makes the identification of Elbers and Ridder (1982) ‘weak’ in the sense that the model of Elbers and Ridder (1982) cannot be estimated at rate \(N^{-1/2}\). As in Honoré (1993a), Hausman and Woutersen (2005) do not need the finite mean \(N^{-1/2}\).
assumption which gives an intuitive explanation of why Hausman and Woutersen (2005) can estimate the model at rate $N^{-1/2}$.

prospect theory

Graham Loomes
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Prospect theory sought to provide a descriptive model of risky choice which could accommodate a number of seemingly systematic violations of conventional ‘expected utility’ analysis. Although there are phenomena which the model cannot explain (even in its later ‘cumulative’ form), it constitutes a landmark in the development of alternative theories which have modified standard theory and/or have tried to incorporate psychological factors into decision theories.

Keywords

Allais paradox; behavioural economics; choice; common consequence effect; common ratio effect; cumulative prospect theory; decision weights; expected utility hypothesis; isolation effect; Kahneman, D.; probability distribution; prospect theory; rational behaviour; reference point; reflection effect; stochastic dominance; subjective probability; transitivity; Tversky, A.

Article

Prospect theory (PT) was developed by psychologists Daniel Kahneman and Amos Tversky to try to account for a number of patterns of response to risky choices which departed systematically from the conventional wisdom about rational decision making in the form of von Neumann and Morgenstern's (1944) expected utility (EU) hypothesis. Kahneman and Tversky's (1979) paper ‘Prospect Theory: An Analysis of Decision Under Risk’ has proved to be enormously influential. According to Kim, Morse and Zingales (2006), it is the second most frequently cited paper published in economics journals since 1970, with more than 4,000 citations in the 25 years since its publication. It provided a major stimulus to the development of a number of other ‘non-expected-utility’ theories in the 1980s and 1990s – see Starmer (2000) for a survey and review. It has also inspired much work in behavioural economics and in economic and psychological experiments exploring individual decision making under risk and uncertainty. The following subsections consider what PT set out to do and how it did it. There then follows a discussion of the importance of the theory as well as its possible limitations.

Background

In the 1950s and 1960s, evidence had begun to accumulate which suggested that EU failed as a general descriptive model of risky choice. Two of the most influential ‘paradoxes’ had been identified by Maurice Allais in the early 1950s (see Allais, 1953). These were renamed by Kahneman and Tversky (henceforth K&T) and are now widely known as the ‘common ratio effect’ and the ‘common consequence effect’. Briefly, they are as follows, starting with the common ratio effect.

Consider the choice between two ‘prospects’ A and B where A offers a sum of money $x$ with probability $p$ (and 0 with probability $1-p$) while B offers a smaller sum $y$ with a larger probability $q$ (and 0 with probability $1-q$). An extreme form of this might involve setting $q=1$, so that B offers the certainty of $y$: in an example used by K&T, B offered the certainty of 3,000 Israeli pounds while A offered a 0.8 chance of 4,000 (and a 0.2 chance of 0). EU does not predict which of A and B an individual will choose – that depends on the individual's personal tastes concerning risk – but what the independence axiom of EU does entail is that, if $p$ and $q$ are scaled down by the same factor so that the ratio of 'winning'
probabilities is maintained, the preference between the scaled-down prospects will be consistent with the preference between A and B.

So to continue the example used by K&T – suppose that both p and q are scaled down to a quarter of their original values, generating prospects C and D, where C offers a 0.2 chance of 4,000 and a 0.8 chance of 0, while D offers a 0.25 chance of 3,000 and a 0.75 chance of 0. Then EU entails that anyone who prefers A over B should also prefer C over D, and vice versa. However, the common ratio effect form of the Allais paradox is manifested when a substantial proportion of those who choose the safer option B in the first case switch to the riskier prospect C in the second case, while the combination of choosing A in the first case and D in the second case is relatively rare.

In the above case, the scaling down operated on the magnitudes of the winning probabilities, while maintaining the ratio between them. Another way of manipulating the prospects could work in terms of replacing some probability of a particular sum common to both prospects by the same probability of a different sum. Consider another example used by K&T. This time, E offers 2,500 with probability 0.33, 2,400 with probability 0.66 and with probability 0.01, while F offers 2,400 with certainty. Now, for both prospects, replace the 0.66 probability of 2,400 by a 0.66 probability of 0: this transforms E into a prospect G which offers a 0.33 chance of 2,500, and a 0.67 chance of 0, and transforms F into a prospect H which offers a 0.34 chance of 2,400 and a 0.66 chance of 0. Once again, EU entails that individuals should either choose E in the first case and G in the second, or else they should choose F and H. However, the common consequence effect form of Allais paradox involves many more individuals switching from safer to riskier (that is, choosing F and G) than switch from riskier to safer (that is, choose E and H).

In addition to the common ratio and common consequence effects, two other ‘effects’ were influential in the formulation of PT. One of these is the ‘isolation effect’. Consider again the ‘scaled-down’ pair of prospects from the common ratio example. In the way they were presented there, C offered a 0.2 chance of 4,000 together with a 0.8 chance of 0, while D offered a 0.25 chance of 3,000 alongside a 0.75 chance of 0. In this case, the implication is that the uncertainty is resolved in a single stage: perhaps a 20-sided die is rolled, and if a number from 1 to 4 comes up C pays 4,000 (and 0 otherwise), whereas D pays 3,000 if the number is anything in the range 1 to 5.

However, there is another way of presenting this choice which EU would regard as amounting to exactly the same thing, but which PT suggests people are likely to treat differently. Suppose that the uncertainty is resolved in two stages, as follows. In the first stage, there is a 0.75 chance of being ‘knocked out’ and getting 0, and there is a 0.25 chance of getting through to the second stage – at which point the choice is between, on the one hand, a 0.8 chance of 4,000 and, on the other hand, the certainty of 3,000. The logic of EU entails that the two stages can be ‘reduced’ to a single stage by multiplying through the probabilities: a 0.25 chance of getting through and facing a 0.8 chance of 4,000 can thus be reduced to a 0.2 chance of 4,000, as offered by prospect C; and a 0.25 chance of getting through to receive the certainty of 3,000 is regarded as just the same as a direct 0.25 chance of 3,000, as offered by prospect D.

Put another way, a 0.25 chance of what was prospect A in the common ratio example is equivalent to C, and a 0.25 chance of prospect B is regarded as the same as D. Yet the evidence of what K&T called the ‘isolation effect’ shows that people do not process the two-stage game in the way presumed by EU. When faced with such a two-stage problem and told that they have to make a commitment ahead of the first stage, most individuals appear to disregard (or isolate) the common first stage, focus on the alternatives that are contingent on getting through to the second stage, and then make much the same choices as they do when presented with the simple one-stage choice between A and B. In other words, when asked to commit ahead of this two-stage resolution of uncertainty, there is a much stronger tendency to pick the safer option than when presented with the one-stage choice between C and D where the calculus of probability ‘reduction’ has already been applied.

The fourth regularity that played a significant role in the formulation of PT was the ‘reflection effect’. Essentially, this refers to the observations that changing payoffs from gains to losses (relative to the status quo) tended to reverse individuals’ choices. Thus if A and B above were transformed into A’ and B’ such that A’ offered a 0.8 probability of losing 4,000 (and a 0.2 probability of losing nothing) while B’ entailed the certainty of a 3,000 loss, the modal preference for B over A would often be ‘reflected’ into a modal preference for A’ over B’. Thus, what appears as a predominant pattern of risk aversion in the choice between prospects such as A and B which involve gains seems to transform into a predominant pattern of risk seeking when the non-zero payoffs are losses.

Combining the reflection effect with the isolation effect can produce striking ‘framing’ effects. For example, consider first a scenario where an individual is given a lump sum of 1,000 and then asked to choose between a further 500 for sure or else a risky prospect offering a 50–50 chance of either 0 or an extra 1,000. If the individual isolates the initial 1,000 and displays risk aversion towards the 50–50 gamble involving gains, she will end up with a sure 1,500 rather than a portfolio consisting of a 0.5 chance of a net 1,000 and a 0.5 chance of a net 2,000. But now consider a scenario framed somewhat differently. The individual is given a lump sum of 2,000 and then asked to choose between the certainty of losing 500 or else a 50–50 chance of either losing 1,000 or losing 0. If the individual again isolates the lump-sum but now displays risk seeking towards the 50–50 gamble involving losses, she will end up with exactly the opposite portfolio preference: that is, she will choose the portfolio consisting of a 0.5 chance of a net 1,000 and a 0.5 chance of a net 2,000 rather than 1,500 for sure. K&T presented evidence which showed that this was indeed a strong tendency among those who answered their hypothetical questions framed in these various ways.

The aims and structure of prospect theory

PT can be seen as offering a descriptive (rather than a prescriptive/normative) model of a particular area of decision making. K&T were careful to specify the domain to which their model applied: it was a theory of choice over pairs of prospects each involving no more than two non-zero payoffs where the objective probabilities were given to decision makers. As formulated in the 1979 paper, the theory did not apply to valuation tasks (for example, tasks that asked people how much they would pay or accept in exchange for some risky
prospect), nor to prospects involving larger numbers of possible payoffs, nor to cases where there was ambiguity about the likelihood of different events occurring (although in their concluding remarks K&T expressed some optimism that the model could be extended to accommodate the latter two features, while relevant valuations might be inferred via some iterative procedure involving a series of choices between a prospect and different sure sums). Most importantly, because it set out to provide an account of actual behaviour rather than a prescription for how decision makers ought `rationally’ to behave, PT allowed the possibility of patterns of behaviour that decision makers might wish to modify if they ever became aware of the ‘inconsistencies’ involved (although, in the absence of opportunities for such realization, the ‘anomalies’ implied by PT could be expected to occur and persist).

To some extent, the elimination of some potentially undesirable possible implications of PT was handled by dividing the modelling of people’s decision processes into two phases: first, the editing phase, which involved simplifying prospects and screening out transparent transgressions of reasonable behaviour; and then the evaluation phase, in which the preferred alternative was identified.

The editing phase prepared the ground for the evaluation phase in various intuitively appealing ways. It involved the detection of transparent dominance and the discarding/rejection of dominated alternatives in such cases (while allowing the possibility that dominance might be violated if more complicated ways of presenting the prospects obscured the dominance relationship). There was also scope for some simplification of prospects (for example, rounding of payoffs and/or probabilities). In cases where there were transparently common and/or riskless components, these were liable to be segregated and/or cancelled. It was also supposed that, when a prospect offered the same payoff contingent on different events with separately expressed probabilities, those probabilities would be added together. For example, suppose a prospect offered a payoff of 100 if a card drawn at random from a standard pack of playing cards turned out to be a spade, and offered the same payoff if the card turned out to be a heart: then the probabilities of these two events – each 0.25 – would be combined to give an overall 0.5 chance of receiving 100. Finally, all payoffs were coded into gains or losses relative to some reference point – this latter normally being the status quo, although in some circumstances it might be otherwise (as discussed in the penultimate subsection of the 1979 paper).

The evaluation phase involved the interaction of two components: the value function, and the decision weight function.

A careful reading of the 1979 exposition makes it clear that the subjective value associated with a particular payoff should, strictly speaking, be expected to be a function of two factors: the asset position that constitutes the individual’s reference point, and the positive or negative change from that point represented by the payoff in question. However, K&T argued that, over quite broad ranges of initial asset positions and for many practical purposes, it is sufficient to focus just on one argument, namely, the size of the gain or loss entailed by any particular payoff.

Drawing on existing evidence, including a substantial body of work from the realm of psychophysics, K&T argued that such a value function is characterized by two key characteristics.

First, the marginal value of both gains and losses is presumed to diminish as the magnitudes increase. Thus the difference between a gain (or loss) of 100 and a gain (or loss) of 150 registers more strongly than the difference between a gain (loss) of 1,100 and a gain (loss) of 1,150. Such diminishing sensitivity means that the gradient of the value function becomes progressively less steep as payoffs are located further from the reference point. Denoting the value of any monetary payoff \( x \) by \( v(x) \), diminishing sensitivity in the domain of gains can be more formally represented as

\[
v(x + a) - v(x) > v(x + a + k) - v(x + k) \text{ for all } x, a, k > 0;
\]

in the domain of losses, it entails

\[
v(-x) - v(-x - a) > v(-x - k) - v(-x - a - k).
\]

Second, the marginal value of losses is modelled as being greater than the marginal value of gains of the same magnitude: that is, for all \( x \), the gradient of the function is steeper at \(-x\) than at \( x \). More formally, \( v’(-x) > v’(x) \) wherever the derivative of \( x \) exists. In conjunction with the first characteristic, this implies a value function as shown in Figure 1: that is, concave in the domain of gains, convex and steeper in the domain of losses, and kinked at the \((0)\) reference point.

Figure 1
Prospect theory’s value function
Thus one part of the evaluation of any prospect involves converting money payoffs to their values via the \( v(\cdot) \) function as specified above. The other part of the evaluation requires decision weights to be attached to the various values. These decision weights are not the objective probabilities, nor even degrees of belief of the kind that are conventionally supposed to constitute subjective probabilities. In the context of the 1979 exposition, they represent a psychological transformation, or modification, of the objectively given probabilities, with the weighting function being denoted by \( \pi (\cdot) \).

The key assumptions about \( \pi (\cdot) \) are as follows. First, the weight attached to a zero probability event is 0, and the weight attached to a certainty is 1: that is, \( \pi (0) = 0 \) and \( \pi (1) = 1 \). Second, for low probability events, \( \pi (p) > p \); but for higher probability events, \( \pi (p) < p \); the ‘crossover point’, where \( \pi (p) = p \), may vary from one individual to another, but is often depicted as being somewhere in the region of \( p = 0.15 \). Third, it is generally supposed that \( \pi (p) + \pi (1-p) < 1 \): this property, labelled subcertainty, conveys the idea that complementary intermediate probabilities are jointly disadvantaged relative to certainty.

Taken together, the above assumptions are consistent with a decision weighting function of the kind depicted in Figure 2. Over most of its range, the fact that \( \pi (\cdot) \) is flatter than the 45° line suggests that the evaluation of a prospect is less sensitive to changes in the probability of its non-zero payoff(s) than would be the case under EU where the utilities of payoffs are weighted in exact proportion to their respective probabilities of occurring. It also has the implication that for any given ratio of probabilities, the ratio tends to get closer to 1 as the magnitudes of the probabilities fall: more formally, \( \frac{\pi (pq)}{\pi (p)} \leq \frac{\pi (pr)}{\pi (q)} \) for all \( p, q, r < 1 \).

Figure 2
Prospect theory's decision weighting function
However, such a formulation also has the property that it entails abrupt changes/jumps in the vicinities of $p=0$ and $p=1$. It might be said that the function is not ‘well-behaved’ – or indeed, not defined – in those regions, where there are ‘quantal effects’. And this allows at least one pattern of behaviour that many decision theorists would find normatively undesirable/unacceptable, as follows. Consider a case where prospect C offers the certainty of some gain $x$, while A offers $x$ with probability $p$ and $x+a$ with probability $1-p$, where $a$
is some (small) positive amount. Evaluating each prospect separately,

\[ v(C) = v(x) \text{ and } v(A) = \pi(p) v(x) + \pi(1-p) v(x + a). \]

However, because \( \pi(p) + \pi(1-p) \) is liable to sum to less than 1, \( v(A) \) may be less than \( v(C) \), even though A dominates C. In a direct choice between the two, PT supposes that this dominance (if transparent) will be detected as part of the editing process, so that A will be chosen. But it should be possible to construct some other prospect B which neither dominates nor is dominated by either A or C but whose value lies between the two, so that \( v(C) > v(B) > v(A) \). Hence in separate pairwise choices, C will be preferred to B and B will be preferred to A, while A will be chosen over C on the basis of transparent dominance, thereby giving a violation of transitivity.

More recent developments in theory and evidence

Because PT does allow such violations of principles that many decision theorists regard as normatively compelling, various modifications have been proposed to 'fix' this supposed defect: in particular, a method of deriving decision weights which ensured that they summed to 1 and disallowed any violations of stochastic dominance or transitivity was proposed by Quiggin (1982) and was subsequently incorporated into a revised and extended form of PT known as cumulative prospect theory (CPT) (see Tversky and Kahneman, 1992).

The essence of Quiggin's proposal involved ranking the possible outcomes \( x_1 \ldots x_n \) offered by a prospect according to their values and then assigning weights to each of the cumulative probabilities that the prospect pays at least \( x_i \), for all \( i = 1 \ldots n \). (Hence this kind of model came to be labelled as 'rank-dependent'.) The function used to transform cumulative probabilities – call it \( w(\cdot) \) to distinguish it from the \( \pi(\cdot) \) discussed above – is fully defined in \([0, 1]\) space, with \( w(0) = 0 \) and \( w(1) = 1 \). Like \( \pi(\cdot) \), it is usually supposed to have an increasing inverse-S shape (although by contrast with \( \pi(\cdot) \), the 'crossover point' in CPT is more often regarded as lying in the 0.3–0.4 region – see Figure 3.

Figure 3
CPT’s cumulative probability transformation function
As a consequence of being steeper in the vicinities of 0 and 1, and less steep across the intermediate range, this form of \( w(\cdot) \) gives greater weight to extreme than to intermediate outcomes. Although it may be psychologically implausible that most individuals transform probabilities strictly according to the rather cumbersome procedure specified by CPT and other rank-dependent models, the approach captures the general intuition that extreme outcomes may attract more attention and receive relatively more weight in decisions. And it appeals to those theorists who are inclined towards models that respect what are perceived to be 'fundamental' requirements of rationality such as transitivity, while also having the advantage of being applicable to prospects involving probability distributions over any number and range of outcomes.

However, the spirit of PT was to provide a descriptive model of risky choice, so that violations of transitivity of the kind outlined earlier were an implication of the model; and, to the extent that they occur in practice, PT can claim to be descriptively successful. And indeed there is evidence of such violations (see Starmer, 1999).

On the other hand, as K&T acknowledge, there are limitations to the scope of PT. As discussed above, the domain of the theory was very specific and excluded a number of tasks that are of economic significance (such as the formulation of certainty equivalence values). Moreover, certain assumptions made in the model are open to question. For example, the
phenomenon of ‘event-splitting’ (see Humphrey, 1995) suggests that people may only imperfectly add the probabilities of the same payoff under different ‘states of the world’, contrary to the supposed process of combination in the editing phase. There may also be questions about just how transparent dominance needs to be before it is detected in the editing phase. And some researchers – see, for example, Birnbaum (2006) – have amassed evidence of patterns of choice which appear to run counter to the claims of prospect theories to provide a satisfactory description even of the behaviour which should lie within their domain.

All that having been said, there can be no doubt whatsoever of the success of PT in focusing the attention of decision theorists on patterns of behaviour that do not conform with the conventional (and still predominant) wisdom of EU, and in stimulating a very substantial body of experimental, empirical and theoretical work exploring behaviour outside of the strictures of standard economic ‘rationality’.

protoindustrialization

Sheilagh Ogilvie
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Proto-industrialization’ is the name given to the massive expansion of export-oriented handicrafts which took place in many parts of Europe between the 16th and the 19th centuries. An influential theory holds that these proto-industries generated the capital, labour, entrepreneurship, agricultural commercialization, and consumer demand needed for factory industrialization. Protoindustrialization, it is argued, also transformed traditional economic mentalities and institutions. However, deeper empirical study has cast doubt on most of these claims. Theories of protoindustrialization have stimulated much excellent research, but do not explain the significant economic growth, demographic change, and institutional transformation that occurred in Europe before the Industrial Revolution.

Keywords

agriculture; fertility; industrial revolution; industrialization; nuptiality; population growth; protoindustrialization; putting-out system; surplus labour; urbanization; workshop system

Article

‘Protoindustrialization’ is the name given to the massive expansion of export-oriented handicrafts which took place in many parts of Europe between the 16th and the 19th centuries. Often, although not always, such proto-industries arose in the countryside where they were practised alongside agriculture; usually, they expanded without adopting new techniques or centralizing production into factories. This growth of pre-factory industry in early modern Europe has long been a subject of specialized study. But in the 1970s it began to attract much wider interest, when several influential works christened it ‘protoindustrialization’ and argued that it was a major cause of industrialization and capitalism.
The term ‘protoindustrialization’ was invented by Franklin Mendels, who first used it in his 1969 dissertation on the Flemish linen industry (published in 1981) and popularized it in a now famous article based on that research (Mendels, 1972). Mendels claimed that protoindustrialization was the first phase of industrialization. In the 18th century, seasonally underemployed European country-dwellers moved massively into cottage crafts, exporting their wares beyond the immediate region. This, Mendels argued, broke down traditional urban institutions such as guilds that had previously limited industrial growth. Mendels contended that it also weakened rural institutions such as inheritance systems, communes, and manorial systems that had traditionally calibrated population growth to economic resources. Mendels claimed that this made nuptiality (and thus fertility) ratchet upwards: proto-industrial upswings saw more marriages, but downswings did not see fewer. High protoindustrial fertility fuelled rapid population growth, Mendels argued, in turn causing further industrial expansion. This self-sustaining proto-industrial spiral, according to Mendels, generated the capital, labour, entrepreneurship, agricultural commercialization, and consumer demand needed for factory industrialization.

Protoindustrialization and proletarianization

Mendels’s arguments were initially widely adopted, giving rise to several schools of protoindustrial theory. One emanated from David Levine, whose study of two villages in 19th-century Leicestershire appeared to confirm that proto-industry led to population growth (Levine, 1977). For Levine, proto-industry was important mainly because he believed it broke down rural social structure and land ownership, creating a large group of landless people who had to work for wages. This broader process of ‘proletarianization’ was, Levine argued, crucial for capitalism and industrialization.

Protoindustrialization and surplus labour

A third view of protoindustrialization was put forward by Joel Mokyr (1976), who rejected almost all the arguments advanced by Mendels and Levine but argued that proto-industries provided the cheap ‘surplus’ labour to fuel a ‘dualistic’ growth of the European economy as modelled for modern less developed countries (LDCs) by Lewis (1954) and Fei and Ranis (1964). The key empirical problem for the Lewis–Fei–Ranis model was whether ‘surplus’ labour existed and where it came from. Mokyr argued that in pre-industrial Europe surplus labour came from protoindustry, creating a flat labour supply curve and hence very low wages for early factory industry. This ‘dualistic labour surplus’ view of protoindustrialization has hardly been pursued empirically, but is important because of its links with development economics and with Jan De Vries's influential theory of European urbanization (De Vries, 1984).

Protoindustrialization and the transition to capitalism

The protoindustrialization debate was intensified by the publication of a massive book by Peter Kriedte, Hans Medick and Jürgen Schlumbohm (German original 1977, English translation 1981). Combining Mendels's and Levine's findings with the voluminous earlier literature on cottage industries, these
scholars turned the theory of protoindustrialization into a general model of European economic transformation between the medieval and modern periods. For them, protoindustrialization was the ‘second phase’ of this transformation process. The first phase, they claimed, was a loosening of feudalism caused by commutation of feudal burdens from labour or grain dues into money rents, polarizing the rural population into two classes: well-off peasants with enough land to live solely from farming, and land-poor or landless strata who had to seek work outside agriculture. The second phase, in their view, was the 16th-century growth in supra-regional and international trade, creating a growing demand for manufactures which the new rural proletariat could satisfy more cheaply than guild-regulated urban craftsmen. So protoindustries arose in the countryside. These scholars proposed a stage theory according to which rural protoindustries then gradually transformed industrial organization. The first stage, they claimed, was the Kaufsystem (artisanal or workshop system), in which rural producers retained autonomy over production and selling. The second stage, the argument continues, was the Verlagssystem (putting-out system), in which merchants bought raw materials, ‘put them out’ to the rural producers who processed them in return for a wage, and then collected the output for transfer either to the finishing stages of production or to the final consumer market. This ultimately led to a third stage, it was claimed: the concentration and mechanization of production in centralized, mechanized factories.

Extensions to the theories of protoindustrialization

By 1977 at the latest, therefore, protoindustrialization had generated a family of different theories, based on differing definitions of protoindustry and differing explanations of economic development. Almost all they had in common was to emphasize the significance of European economic and demographic growth before factory industrialization, and to ascribe such growth to changes in a certain economic sector – export-oriented cottage industry. Over the following decades, these various branches of protoindustrialization theory stimulated a huge outpouring of research into pre-industrial manufacturing, not just in Europe but also in the non-European world, including modern LDCs.

By 1982 protoindustrialization had become such an influential concept that Franklin Mendels and Pierre Deyon were invited to convene one of the three main sessions of the Eighth International Economic History Congress in Budapest, with protoindustrialization as their theme. They pre-circulated a set of hypotheses, 48 researchers contributed papers (Deyon and Mendels, 1982), and Mendels summarized the session with a report, a revised definition, and a set of hypotheses for subsequent debate (Mendels, 1982).

This new 1982 definition of protoindustrialization stressed five key characteristics. First, protoindustrialization occurred not nationally or internationally, but regionally: ‘within a small radius around a regional capital’. Second, protoindustries must be distinguished from traditional crafts: they produced not for local or regional consumption, but for sale to export markets outside the region. Third, protoindustry was mainly rural and part-time – only in its final or extreme phase did it involve full-time industrial employment. Fourth, protoindustrialization arose symbiotically with agricultural commercialization. Finally, protoindustrialization was ‘dynamic’: it was defined as a growth over time in the industrial employment of rural workers.

Deyon and Mendels also proposed four central hypotheses about the effects of protoindustrialization.
First, protoindustry led to population growth and land fragmentation because it broke down traditional demographic regulation by communes, landlords and inheritance systems. Second, protoindustrial profits created the capital for factory industrialization. Third, protoindustry trained merchants and workers in the skills needed for factory industrialization. Finally, protoindustrialization caused agriculture to commercialize, thereby feeding urbanization and industrialization. Through these four mechanisms, proto-industry led to factory industry – although the authors admitted that sometimes it led to de-industrialization instead (Mendels, 1982).

**Criticisms of the theories of protoindustrialization**

Somewhat more slowly than they attracted support, the theories of protoindustrialization also began to draw criticism.

For one thing, the precise size and structure of the unit that qualified as a protoindustrial *region* was unclear. Protoindustries could and often did extend beyond the radius around a single market town, or alternatively were sometimes found in only one or two communities in such a radius. One pragmatic solution was to define the region as simply the area within which a certain proto-industry was practised. But this seemed to leach the concept of the region of much of its analytical content. Second, there was no agreement about how large a proportion of the regional labour force must have been employed in protoindustry, or how fast or sustained the growth of this labour force must have been, in order to qualify as ‘protoindustrialization’ (Ogilvie and Cerman, 1996).

There was also confusion about the precise importance of *export markets* for protoindustrialization. First, why were export markets uniquely important? Second, what proportion of production had to be exported in order for any given industry to qualify as a proto-industry instead of a craft? Third, how distant did final markets have to be to qualify as ‘supra-regional’ rather than ‘local’? The demarcation between local crafts and export-oriented proto-industries was thus very unclear and its analytical importance remained obscure.

The *neglect of other forms of industry* was another weak point. The theories of protoindustrialization concentrated solely on one sort of pre-industrial manufacturing: cottage industry. But what justified this emphasis? Did manufacturing really develop just because of this single sort of industry, which was often technologically very primitive? What about highly skilled and technologically innovative crafts, export-oriented urban industries, or centralized manufactories? Mainstream historians of pre-industrial manufacturing argued that all these branches of the secondary sector should be included in any analysis of industrialization before the Industrial Revolution (Schremmer, 1981; Coleman, 1983; Mager, 1993). Others argued that large *urban* export industries, and those involving centralized production units, should also be included under the rubric of protoindustrialization (Cerman, 1993).

The *neglect of industrial technology and physical geography* was also criticized. Mendels referred in passing to industrial production functions and transportation costs, but neither he nor other proponents of the theory explored these factors further. Critics argued that any coherent view of protoindustry must consider the technical requirements of different branches of industry and the geographical and physical characteristics of the region (Mager, 1993). Others urged that protoindustry, like any economic activity, be analysed in terms of ‘opportunity costs’, and pointed out that this would imply taking into account a whole array of technological, geographical, and institutional variables (Ogilvie, 1993; 1997).
The theories adopted strong assumptions about the ‘traditional societies’ transformed by proto-industry, and these assumptions began to be questioned (Coleman, 1983; Houston and Snell, 1984; Schremmer, 1981; Ogilvie and Cerman, 1996; Ogilvie, 1997). Protoindustrialization theorists had uncritically accepted the theories of Alexander Chayanov, who regarded peasants as unable and unwilling to calculate costs, seek profits, use money, or transact in markets (Chayanov, 1966). But was this really true of the early modern European rural population? The subsistence-orientation assumed for rural domestic workers was not confirmed by empirical studies, and was inconsistent with the fact that proto-industrial producers often became traders, middlemen, putters-out and even manufactory-operators. The demographic decisions and productive choices of protoindustrial workers, rather than being governed by ‘traditional mentalities’, began to look highly rational (Ogilvie, 1997).

The *demographic* predictions of the theories were widely falsified as empirical studies proliferated. It emerged that pre-industrial demographic behaviour was influenced by such a wide array of variables that proto-industry could have highly divergent effects on nuptiality, fertility, mortality and migration in different European societies. Case studies showed that not all protoindustrial regions had greater population density, faster demographic growth, lower ages of marriage, higher fertility rates, larger households, or a breakdown in the family and gender division of labour – all of which had been postulated in the original theories. Furthermore, many – even all – of these demographic changes could also be observed in some primarily agricultural regions (Schremmer, 1981; Coleman, 1983; Houston and Snell, 1984; Ogilvie and Cerman, 1996; Ogilvie, 1997).

The relationship between *commercial agriculture* and protoindustry was also disputed. Protoindustries arose alongside many different kinds of agriculture, including subsistence cultivation, market farming, and even large feudal domains worked by serf labour. Protoindustries derived food and raw materials not just from commercial agriculture but from local cultivation by proto-industrial workers themselves. Simultaneous employment in proto-industry and agriculture was common but not universal in protoindustrial regions. While traditional agrarian institutions and rural social structure broke down in some protoindustrial regions, in others they survived unaltered for centuries (Houston and Snell, 1984; Ogilvie and Cerman, 1996; Ogilvie, 1997).

The role of *social and political institutions* in theories of protoindustrialization has also been critically revised (Ogilvie, 1993; Ogilvie and Cerman 1996; Ogilvie, 1997; Ogilvie, 2004). The original theorists assumed that protoindustrialization both required and furthered the replacement of ‘traditional’ social institutions with markets. But deeper research has shown that urban privileges, craft guilds, monopolistic merchant companies, village communities and manorial institutions remained important in many European protoindustries, and crucially influenced economic, demographic and social change in proto-industrial regions.

A final major criticism questioned the role of proto-industry in causing *factory industrialization*. Each of the mechanisms by which protoindustrialization is supposed to have led to industrialization has been subject to sceptical re-evaluation. Research shows that the demographic effects of protoindustrialization were extremely various, as was its impact on the fragmentation of landholdings. Protoindustry appears to have been only one of many sources of capital invested in the early factories, and in many cases proto-industrial profits flowed into agriculture, landholding or socio-political investments. Proto-industry was also only one of many sources of entrepreneurial skills for industrialization, and sometimes did not encourage entrepreneurship at all. There is little evidence that it was proto-industry that led to...
commercial agriculture rather than that agricultural surpluses made possible both proto-industrial regions and urbanization. It is now widely acknowledged by both the theorists and their critics that proto-industry often led not to factories but to de-industrialization and a return to agriculture. The critics argue that this finding denudes the theory of most of its empirical content (Coleman, 1983; Houston and Snell 1984; Clarkson, 1985; Ogilvie and Cerman, 1996). Although, therefore, the theory of protoindustrialization has stimulated much excellent research, it does not explain the significant economic growth, demographic change, and socio-institutional transformation that indisputably occurred in Europe well before the industrial revolution.

psychological games

Martin Dufwenberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Traditional game-theoretic models assume that utilities depend only on actions. This is not sufficient for describing the motivations and choices of decision makers who care about reciprocity, emotions, or social rewards. Psychological games allow utilities to depend directly on beliefs (about beliefs) in addition to which actions are chosen, and they can capture a wider range of motivations. This article contains several examples and it is indicated where research on psychological games is headed.

Keywords

Allais paradox; belief-dependent motivation; commitment; decision theory; emotions; extensive game forms; game theory; guilt aversion; psychological forward induction; psychological games; reciprocity; signalling; trust; von Neumann and Morgenstern

Article

Traditional game-theoretic models presume that utilities depend on actions. While this framework is quite general (it can, for example, accommodate profit-maximization, altruism, inequity aversion and Rawlsian maximin preferences) it is not rich enough to adequately describe several psychological or social aspects of motivation which depend directly on beliefs (about beliefs) in addition to which actions are chosen. The following example illustrates.

Karen feels guilty if she lets others down. When paying her landscaper (Jim), this influences her tipping. The more she believes Jim believes he will receive as a tip, the more she gives. More precisely, she gives just as much as she believes Jim believes he will get, in order to avoid the feelings of guilt that will plague her if she gives less.

Beyond depicting something arguably realistic, the example illustrates in the simplest possible way how one may have to transcend traditional game theory to model a belief-dependent motivation. Consider a standard game form where Karen chooses a tip \( t \) such that \( 0 \leq t \leq w \), where \( w \) is the number of dollars in
her wallet, and where the landscaper has no choice (his strategy set is modelled as a singleton \{x\}).
Karen's choice of tip thus pins down a strategy profile \((t,x)\). In traditional game theory, payoffs are defined on strategy profiles (or on endnodes induced by strategy profiles), so Karen's best choice (or choices) would be independent of her belief about Jim's belief about her choice of tip. This runs counter to the example.

Gilboa and Schmeidler (1988) and Geanakoplos, Pearce and Stacchetti (1989) present several examples that illustrate the inadequacy of traditional methods of representing preferences that reflect various forms of belief-dependent motivation. Geanakoplos, Pearce and Stacchetti develop a new analytical framework, in which the centrepiece is the notion of a psychological game, which may be seen as a generalization of a traditional game and which can model some of the desired effects. A psychological game differs from a traditional game in that utilities are defined on beliefs (about actions and beliefs), as well as on which actions are chosen. (The term ‘game with belief-dependent motivation’ would be more descriptive than the term ‘psychological game’, but I stick with the latter, which has become established.)

**Reciprocity**

The best-known example of a psychological games-based application is Rabin's (1993) highly influential model of reciprocity, according to which players wish to act kindly (unkindly) in response to kind (unkind) actions. The key notion of kindness depends on beliefs in such a way that reciprocal motivation can be described only by using psychological games. To see why, suppose that I jump out in front of your car, blocking your way, so that you can't cross a bridge and therefore arrive late to an important meeting. Am I kind? Clearly one cannot say without knowing what my beliefs are. If I believe the bridge is as sturdy as bridges usually are and I am just goofing around, then I am unkind. However, if I believe the bridge is about to collapse, then I am kind. Arguably, I would be kind even if I mistook a sturdy bridge for a dangerous one. So should you be kind or unkind in return? The answer depends on your beliefs about my kindness, and hence on your beliefs about my beliefs. It takes a psychological game to model that. (The example given here is similar in spirit to another example given in Rabin, 1998, p. 23. Rabin's model is normal-form based. See Dufwenberg and Kirchsteiger, 2004, for an extension to extensive game forms. See Fehr and Gächter, 2000, and Sobel, 2005, for general discussions of why reciprocity has important economic consequences.)

**Emotions**

Reciprocity is but one form of motivation that can be modelled by means of psychological games. Many emotions are good candidates. In his article ‘Emotions and Economic Theory’, Elster (1998) argues that a variety of emotions have important economic consequences, and he laments how little attention economists have paid to this. He argues that a key characteristic of emotions is that ‘they are triggered by beliefs’ (1998, p. 49). He discusses anger, hatred, guilt, shame, pride, admiration, regret, rejoicing, disappointment, elation, fear, hope, joy, grief, envy, malice, indignation, jealousy, surprise, boredom, sexual desire, enjoyment, worry, and frustration. He asks (1998, p. 48): ‘[H]ow can emotions help us explain behavior for which good explanations seem to be lacking?’ Psychological games may be useful for providing answers.
But little work has been done. One exception is Caplin and Leahy’s (2004) health care model in which a physician is concerned with a patient’s belief-dependent anxiety (compare also Caplin and Leahy, 2001). Another exception is the emotion of guilt for which a string of results, both theoretical and experimental, have been established for the specific context of trust games (see Huang and Wu (1994), Dufwenberg (1995; 2002), Dufwenberg and Gneezy (2000), Bacharach, Guerra and Zizzo (2007), and Charness and Dufwenberg (2006). I shall elaborate in some detail on these latter findings (borrowing eclectically from the cited works), since they may be suggestive of the importance of psychological games more generally in a variety of ways.

Consider the game in Figure 1, where payoffs reflect money income (first for player $A$, then for player $B$) but not the players’ preferences which may depend also on guilt as will be indicated.
Assume that the more strongly player B believes that player A believes that B will make choice $r'$, the more guilt B would feel making choice $l'$ and the more likely B is to make choice $r'$. Specifically, the players’ utilities at the various end nodes in the game form of Figure 1 coincide with the monetary payoffs, except following the choice sequence $(r, l')$ where B's utility is $3 \cdot (1 - \beta)$ rather than 3, and where $\beta$ is a measure of B's belief (with range from 0 to 1) about A's belief that B will choose $r'$. (More specifically, B has a probability measure describing her beliefs about which probability A assigns to the choice $r'$ conditional on A choosing $r$; $\beta$ is the mean of that measure.) Say that B is guilt averse. This is all modelled in the psychological game in Figure 2:
I wish to make several points. First, the guilt aversion modelled in Figure 2 is similar to that involved in the above example featuring Karen and Jim. In fact, the idea that people feel guilty in proportion to the degree to which they do not live up to another's expectations can be extended to any game. (See Battigalli and Dufwenberg, 2007, for a recent attempt at doing this.)

Second, one can test for guilt aversion experimentally, but this requires one to measure $B$'s belief $\beta$. This can be done by inviting subjects to make guesses about one another's choices and guesses, rewarding accuracy in the guesswork. Such experimental tests have indicated that the prediction of guilt aversion is empirically supported in trust games. (The involved form of belief elicitation could conceivably be usefully complemented by two other forms of measurement: emotional self-reports and neurological methods such as functional magnetic resonance imaging.)

Third, guilt aversion may provide the seeds of a theory why communication can help foster trust and cooperation. To illustrate with reference to Figure 2, suppose that, before play, $A$ and $B$ meet and talk. Player $B$ looks player $A$ in the eye and promises to choose $r'$. If $A$ believes this, and if $B$ believes that $A$ believes this, then guilt aversion would make $B$ live up to her promise. A promise by $B$ can thus feed a self-fulfilling circle of beliefs about beliefs that $r'$ will be chosen. In combination with guilt aversion, words may be tools that create commitment power, which may in turn foster trust and cooperation.

Fourth, even without communication between $A$ and $B$, one may argue that if $B$ is guilt averse (as described above) then trust and cooperation will ensue. If $A$ is rational and maximizes his expected monetary income (recall that we have assumed that $A$ is selfish in this way) then by choosing $r$ he signals a certain strength of belief in $B$ choosing $r'$; if $A$ did not assign a probability of at least 1/2 to $B$ choosing $r'$ then he would rather chose $l$. If $B$ figures this out, it puts a lower bound of 1/2 on $\beta$. So $B$ is forced to hold a belief such that she would feel so guilty if she choose $l'$ that she prefers $r'$; in numbers, with $\beta \geq 1/2$ we get $3(1-\beta)<2$. If $A$ figures this out, he should of course choose $r$. The illustrated phenomenon has been labelled *psychological forward induction*.

To sum up: the idea of guilt aversion is intuitively plausible, experimentally testable, empirically supported, relevant for explaining why communication matters to economic behaviour, and suggestive of intriguing signalling issues that may shape emotions and behaviour. These insights concern a very special emotion and a very special psychological game, but seem profound given that limited scope. One may reasonably suspect that exciting conclusions are in store also for other emotions and other strategic settings, and that these conclusions may in part concern communication or belief signalling.

**Social rewards**

The discussion so far may have been misleading with its rather heavy emphasis on reciprocity and
emotions. Psychological game theory may be relevant also for describing certain social rewards (norms, respect and status), where decision makers somehow care about the opinions or views of others. Bernheim (1994) and Dufwenberg and Lundholm (2001) present models that bear this out. These authors do not make explicit mention of psychological games, but if one takes a close look at the mathematical details one can discover connections.

Developing the theory

One might hope that Geanakoplos, Pearce and Stacchetti’s framework is appropriate for tackling all the interesting problems to which psychological games may be relevant. However, this is not the case. A careful scrutiny reveals that their approach is too restrictive to handle many plausible forms of belief-dependent motivation (as they acknowledge themselves; see 1989, pp. 70, 78). There are several reasons, including the following:

1. (1) Geanakoplos, Pearce and Stacchetti only allow initial beliefs to enter the domain of a player’s utility, while many forms of belief-dependent motivation require updated beliefs to play a role.
2. (2) Geanakoplos, Pearce and Stacchetti only allow a player’s own beliefs to enter the domain of his utility, while there are conceptual and technical reasons to let others’ beliefs matter.
3. (3) Geanakoplos, Pearce and Stacchetti follow the traditional extensive-games approach of letting strategies influence utilities only in so far as they influence which end node is reached, but many forms of belief-dependent motivation become compelling in conjunction with preferences that depend on strategies in ways not captured by end nodes.
4. (4) Geanakoplos, Pearce and Stacchetti restrict attention to equilibrium analysis, but in many strategic situations there is little compelling reason to expect players to coordinate on an equilibrium, and one may wish to explore alternative assumptions.

(1) is manifest, for example, in the above psychological forward induction argument which hinges crucially on B’s motivation depending on an updated belief. (2) is relevant, for example, for modelling social rewards (compare the above comments on Bernheim’s and Dufwenberg and Lundholm’s models). As regards (3), one can show that the issue comes up if one wants to model, for example, regret, disappointment or guilt. (4) echoes considerations relevant also for traditional games; equilibrium play is not a self-evident proposition in many contexts, for example if one assumes (only) that there is common belief in rationality or in learning scenarios.

The list (1)–(4) is adapted from Battigalli and Dufwenberg (2005), who elaborate in more detail on each issue and take first steps towards developing psychological game theory in the indicated directions. Their approach draws crucially on Battigalli and Siniscalchi’s (1999) work on how to represent hierarchies of conditional beliefs.

Decision-theoretic foundations

The decision-theoretic foundations of psychological game theory are not well understood. Classical decision theory (say, von Neumann and Morgenstern) does not apply straightforwardly. Too see this,
take the emotion of disappointment as an example. It is plausible that disappointment is a belief-dependent emotion. To exemplify, I have I just failed to win a million dollars and I am not at all disappointed, which, however, I clearly would be if I were playing poker and knew I would win a million dollars unless my opponent got extremely lucky drawing to an inside straight, and then he hit his card. Another example could be based on the lotteries used in the so-called Allais paradox. In both cases the level of disappointment, which if anticipated might affect choice behaviour, may plausibly depend on the strength of the prior belief that a decision maker will win a lot of money. It follows that, unless consequences are described so as to include a specification of disappointment, the so-called ‘independence axiom’ will not make much sense for decision makers who are prone to disappointment. Decision theorists have given related matters some attention, but not a lot. Machina (1981, pp. 172–3; 1989, p. 1662) presents examples in spirit related to the one million dollar example above. Bell (1985), Loomes and Sugden (1986), Karni (1992), and Karni and Schlee (1995) go on to develop models in which utility may depend directly on beliefs; the latter two references take axiomatic approaches. Robin Pope has written extensively, over many years, about how conventional decision theory excludes various forms of belief-dependent motivation; Pope (2004) expounds her programme and gives further references. Caplin and Leahy (2001) develop a model of ‘psychological expected utility’ that admits belief-dependent motivation. However, these contributions mainly develop perspectives for settings with single decision-makers, and more will be needed to address games more generally.

Conclusion

Research on psychological games is still in its infancy. This is true for all facets of investigation: the development of basic classes of games and solution concepts, the investigation of decision-theoretic underpinning, tests of empirical (most likely experimental) validity, and finally applied theoretical work which uses psychological game theory to analyse various economic models. In each of these domains some work has been done which is indicative of the viability of the line of research, and there is good reason to be thrilled about the prospects for future research.

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We review the psychological processes underpinning network formation and network-based processes, focusing first on the nature of relationships and their formation, and then on the consequences of networks for individual outcomes and behavior. We argue that it is important to develop methodological approaches that allow us to regard these processes as hypotheses to be tested rather than as unquestioned assumptions. We suggest that different types of networks and processes are likely to lead to different conclusions about these hypotheses, and that the development of models for networks and network processes should therefore be grounded in careful empirical analysis.

Article

The significance of social networks for an understanding of the structure and dynamics of our contemporary social world is now widely acknowledged. Different types of networks serve as channels through which, for example, knowledge is diffused, opportunities are recognized, cooperation is garnered and actions are coordinated. Networks have been invoked in many disciplines in order to explain the nature and consequences of these channelling effects, spawning interest in the capacity to model network structure. This capacity is important because of the potentially powerful interplay between network structures and the dynamics of the social transactions that they support.

Two broad strategies for network model building have been identified (Jackson, 2005): a statistical approach, in which networks are seen as the outcome of locally interactive and self-organizing tie-formation processes; and a deterministic, game-theoretic approach, in which networks are seen as the outcome of self-interested behaviour of utility-maximizing actors. In association with the statistical
approach, there has been a dramatic increase in our capacity to build theoretically defensible statistical models for social networks whose parameters can be estimated from empirical observations and that have the capacity to reproduce many important global characteristics of observed social networks (for example, Snijders et al., 2006). The game-theoretic approach, on the other hand, is responsible for an impressive accumulation of theoretical results linking strategic activities of pairs of actors to the emergence of ‘efficient’ network structures.

These two modelling approaches differ in two important respects. The first is in the use of deterministic or stochastic models (but see Snijders, 2001). The second distinction is a deeper one, contrasting a conceptualization of actors as self-interested rational decision makers, on the one hand, with more socialized and enculturated actors, on the other. The latter may sometimes be driven by personal utility, but may also engage in non- or extra-rational behaviours that are enabled and constrained by local social network configurations. Indeed, whereas the game-theoretic approach largely assumes that the actor's decision to form or discontinue a relationship is mediated by the actor's conscious computation of utility, the statistical approach treats this as a hypothesis, and empirically examines whether an actor's local network configuration appears to constrain or enable tie formation or maintenance. Thus, this second distinction encapsulates a fundamental empirical question: can network structures and processes be explained in terms of the rational activity of self-interested individuals, or are extra-rational affective, social and/or cultural processes systematically at work in the formation and impact of networks?

With this question in mind, we outline what is known about the social and psychological processes that underpin the formation of networks and the dynamics of network-based processes. We first discuss the nature of relationships and their development, and then examine their consequences for individual outcomes and behaviour. We finish by drawing some implications for model-building.

What is a network tie and why do relationships form?

A network relationship, or tie, is assumed to have some continuity in time, with a relevant past and a somewhat predictable future. This temporal continuity is facilitated by cognitive representation and the use of culturally laden relational descriptors, such as friend and friendship, or partner and partnership, features that also facilitate communication about the nature of ties. Relationships, in other words, entail complex socio-cultural schema that not only frame interpretations of past interactions but also shape expectations concerning future ones by the actors concerned as well as by third-party onlookers.

Although tie formation has sometimes been explained in terms of the utility that ties bring for tie partners (for example, Cook and Whitmeyer, 1992), recent psychological research suggests that significant extra-rational psychological processes may also underlie tie formation. Andersen and Chen (2002) have invoked the concept of relational self to explain the pervasive impact of relationships with significant others on the way in which individuals interpret and respond to interpersonal encounters, and therefore form future interpersonal ties. This concept is founded on a demonstrable ‘transference’ effect, in which past experiences with significant others can be shown to influence new relationships, often outside of conscious awareness. Holmes (2000) has argued that the concept of relationship is best seen as grounded in the interaction between interdependent actors, and hence as an emergent property of dynamic interaction and influence processes. Generic cognitive representations about relationships called relational schemas are postulated to represent actors’ developing knowledge of self, partner and
expected sequences of interaction (for example, Baldwin, 1992). More generally, Fiske (2004) has proposed that four elementary and universal cognitive schemas frame all interpersonal relationships. These four schemas are proposed to structure potential interactions between two actors in terms of: collective belonging or solidarity, as in family membership (the communal sharing schema); asymmetrical difference, as in hierarchies based on skill, knowledge or social class (authority ranking); an egalitarian relationship, based on turn-taking and exchange, as in many friendship ties (equality matching); and a rational analysis of costs and benefits, as in a payment-for-service regime (market pricing). Fiske claims that any actual social relationship is constituted by some mixture of these forms, and that socially transmitted interpretive guidelines link these universal forms to specific relationship characteristics in a particular culture.

While relational schemas have advanced our understanding of the nature and variety of dyadic relationships, there is a recognized need to understand the specific ways in which they depend on social situations and give rise to interdependencies among relationships across a network. As Haslam (2004, p. 297) has observed, Fiske's relational models theory posits ‘a universal grammar of social relations … out of whose rules and representations the myriad local forms of social life can be generated’. Haslam argues that the categorical nature of the relational models may underpin the complexity of human social organization by facilitating the required coordination of interpersonal obligations, rights and responsibilities. Social roles are important intermediate-level constructs in this account, and are seen as ‘distinctively implemented admixtures’ of relational models, a view that is supported by evidence that relational models mediate the effects of social roles on social cognition. More generally, social roles have been invoked by many theorists to explain interdependencies among multiple relationships across multiple actors (White, Boorman and Breiger, 1976).

It follows from these claims that tie formation processes should depend on the type of tie under consideration. While some ties may be consciously negotiated at a dyadic level, independently of other ties, others may be subject to subtle influences arising from the embedding of the potential tie in a local social setting that comprises ties to and among third-party actors with their own mix of potentially competing and potentially cooperative goals. As a result, Fiske's communal sharing relations, for example, should exhibit much stronger interdependencies across pairs of relation partners than relations of the market pricing kind. Such effects have been empirically demonstrated. For example, Granovetter's influential hypothesis concerning the ‘strength’ of weak ties was based on the distinction between the highly clustered structure of ‘strong’ tie networks and the less structured, more open, spreading character of ‘weak’ tie networks, an hypothesis that has received empirical support (Granovetter, 1982). There is also evidence that different types of network tie can be mutually interdependent and subject to generalized forms of exchange and interlock through ties to third parties (for example, Lomi and Pattison, 2006). Indeed, changes in patterns of cross-network interdependence have been invoked in explanations of social and economic innovation (for example, Padgett and McLean, 2006).

In addition to the interdependencies just described, there is also compelling evidence for the impact of individual actors’ characteristics on the formation of network ties. Tie partners are more likely to share socio-demographic characteristics such as gender, age, ethnicity and religion (for example, McPherson, Smith-Lovin and Cook, 2001). The formation of relationships is also clearly a function of social settings that affect the probability of any two actors having an opportunity to interact (Feld, 1981). The psychological literature on relationship formation emphasizes the importance of more psychological...
similarities among potential tie partners, a premise that has been extended by Robins and Boldero (2003) to include a comparison of potential tie partners’ aspirations and obligations. Taken together, these structuring influences on tie formation can be seen as operating at multiple levels, with broad socio-demographic factors at work on a larger scale, and more micro-social and psychological factors at work at more local scales. Whereas the broader factors can often be regarded as exogenous influences on tie formation, the more micro-level factors are usually best seen as endogenous, with the tie formation processes for one pair of actors having consequences for tie formation among their network partners, and their partners, and so on. While some of these interdependencies may operate outside the awareness of individual actors, there are also circumstances in which actors seek out institutional settings and particular relationships precisely for the strategic ‘networking’ opportunities that they provide. Moreover, expected interdependencies can themselves be countered: Padgett and Ansell (1993) coined the term ‘robust action’ to describe behaviour that is open to multiple interpretations, and therefore has the capacity to elide third-party influences on tie formation.

How do relationships affect individual outcomes?

An actor's location in a social network is an important aspect of social context and hence potentially plays an important role in determining many types of future behaviour apart from the development of social ties. There are a number of related mechanisms by which such effects might occur (for example, Pattison, 1994). First, network ties serve as a conduit for information, and hence specific network locations can have a dramatic impact on the information or other resources that any one actor possesses (for example, Burt, 2004). This information can itself be subject to subtle filtering effects, such as the suppression of information perceived to be inconsistent with shared understanding at a community level (Lyons and Kashima, 2003). Second, network ties can influence actors’ understanding of relationships among others as well as expectations about the future behaviour of others. For example, they are likely to be more certain (and more accurate) in judging the relationships involving their network partners and, to a lesser extent, their network partners’ partners (Kumbasar, Romney and Batchelder, 1994). Finally, social influence effects may be brought to bear as actors weigh up – consciously or unconsciously – the views of others in forming or modifying their own beliefs (for example, Friedkin, 1998; Robins, Pattison and Elliott, 2001).

Implications for model-building

Models for network structure and network evolution almost certainly need to accommodate many of the exogenous and endogenous influences on tie formation just described. An appropriate model class is the exponential family of random graph models that was first introduced by Frank and Strauss (1986), building on the general formulation of statistical models for interacting systems of variables by Besag (1974). The use of principled approaches to specifying potential tie interdependencies (Pattison and Robins, 2002) has led to models that yield impressive fits to even large observed network structures (for example, Goodreau, 2006). Interestingly, these models combine a Markov dependence assumption (that potential network ties with an actor in common are dependent, conditional on the state of all other
potential ties in a network) with a ‘longer range’ form of assumed dependence (Snijders et al., 2006) in which, in some circumstances, ties involving discrete pairs of actors are also conditionally dependent. The necessity of these assumptions in many empirical contexts (Robins et al., 2006) suggests that interdependencies among ties within local social contexts are indeed an important influence on observed network forms.

Models for individual states and choices (including beliefs and actions) may likewise need to accommodate subtle network-based interdependencies among the states and choices of their tie partners. Robins, Pattison and Elliott (2001) have developed a general social influence modelling framework for this purpose, akin to the network modelling framework just mentioned.

It is important in the context of the question posed earlier – whether network structures and processes can be explained in terms of the rational activity of self-interested individuals, or whether there are extra-rational processes at work in the formation and impact of networks – to develop observational designs and analytic methods that allow us to regard tie formation and network processes as hypotheses to be tested rather than unquestioned assumptions. We might speculate that different types of networks and different types of social processes are likely to lead to different conclusions about these guiding hypotheses, and that, as a consequence, models should continue to be developed from multiple perspectives and to be grounded in careful empirical analysis. Finally, it is worth noting that the development of methods for estimating models from longitudinal observations may prove particularly helpful in sifting among alternative approaches to model building, not just for models of network evolution and social influence dynamics but also for new approaches to modelling the co-evolution of networks and behaviour (Snijders, Steglich and Schweinberger, 2006).

Public capital (or often ‘infrastructure’) encompasses the publicly provided capital facilities which form the basis for private sector economic activity.

Empirically, public capital typically is defined as a net (of depreciation) stock of non-military structures and equipment and is often decomposed into core public capital (consisting of transportation facilities – such as streets and highways, mass transit, rail, and airports, water and sewer systems, and electrical and gas facilities), and other public capital (comprising educational structures, public hospitals, courthouses and the like).

The productivity of public capital

Beginning at the end of the 1980s, a significant research effort has focused on estimating the contribution of public capital to macroeconomic performance. The research initiative seems to have been the result of the recognition of certain facts about public capital expenditures in the United States. First, infrastructure capital accumulation, when expressed as a fraction of output, began to decline...
toward the end of the 1960s and, as a result, was seen as a potential factor in explaining the productivity growth slowdown of the 1970s and 1980s. Second, during the same period, the United States devoted a smaller share of output to infrastructure than did other industrialized economies (such as those in the Group of Seven), which was taken as possible force in explaining the relatively low rate of productivity growth in the United States vis-à-vis other countries such as Japan and Germany.

The first stage of the research effort centred on estimating the contribution of infrastructure to private sector productivity, where infrastructure is taken as another factor of production, along with private capital and labour, in an aggregate production function of the form

\[ Y = A \cdot F(l, K, K^G) \]

where \( Y \) denotes the aggregate level of economic output, \( A \) an index of total factor productivity, \( L \), the labour force or employment, \( K \) private capital (usually restricted to business fixed capital), and \( K^G \) the stock of public capital. The basic goal of the research was to ascertain the value of the output elasticity of public capital

\[ \varepsilon = \frac{K^G}{Y} \cdot \frac{\partial Y}{\partial K^G} \]

in order to determine the ‘productivity of public capital’.

The early empirical results, typically employing level data in estimating a Cobb–Douglas production function, indicated (strikingly) high elasticity estimates, in the range of 0.25 to 0.50 for the United States and even higher for countries such as Canada and Sweden. These elasticity estimates, in turn, implied very high rates of return to public capital investments which some took as implausible. For example, Gramlich (1994) used Aschauer's (1989) elasticity estimate of 0.39 to generate an estimate of the marginal productivity of public capital in the range of 0.70 to 1.00, which, in his view, was implausible since it implied that investments in government capital generate enough extra output to pay for themselves in a year.

Later, a number of researchers estimated the production function using first-differenced data, arguing that the initial results were ‘spurious’ because (a) variables such as output and public capital were first-order integrated series and (b) the production function did not serve as a cointegrating relation between output and the various factors of production (including public capital). These studies (for example, Tatom, 1991) often generated much lower, and less reliable, estimates of the output elasticity of public capital.

Recently, Kamps (2004) has developed new estimates of public capital stocks for 22 OECD countries over the period 1960–2001, and has estimated the output elasticity of public capital. The point estimates are positive in 20 of 22 cases and statistically significant in 12 of 22 cases. A panel regression...
employing first-differenced data leads to a reasonable elasticity estimate equal to 0.22 which leads the
author to conclude that public capital is productive on average in the countries comprising the OECD.

Public capital and economic growth

The finding that public capital is productive is not, in and of itself, evidence that increasing public
capital investment will raise long-term economic growth. There are at least three considerations which
must be addressed. First, there is the question of whether a permanent increase in public investment will
induce a permanent or transitory increase in growth. The traditional neoclassical growth model predicts
that an increase in national savings and investment rates will have only a transitory effect on growth;
more recent endogenous growth models, on the other hand, would predict permanent effects. Second,
given the level of national savings, the effect of public investment on economic growth depends not just
on a positive output elasticity of public capital, but on the relative marginal productivities of private and
public capital; an increase in public investment at the expense of public investment will raise or lower
the economic growth rate depending on whether the marginal product of public capital exceeds, or is
exceeded by, the marginal product of private capital. Third, the effect of public capital on economic
growth will depend on the method of public finance – whether by current taxes, debt, or (potentially)
money creation.

One approach which allows tentative answers to all three questions is that of Aschauer (2000), who
extends the Barro (1990) model of productive government spending to explicitly include public
investment. This model, which assumes (a) that public investment is debt-financed and (b) a production
function which displays constant returns to scale across private and public capital stocks (per worker)
generates endogenous growth in per worker output at the rate

$$\gamma_y = \frac{1}{\sigma} \cdot [(1 - \tau) \cdot (1 - \varepsilon) \cdot \left(\frac{K G}{K}\right)^\varepsilon - \rho]$$

where \(y\) is the level of output per worker, \((1/\sigma)\) the intertemporal elasticity of substitution, \(\tau\) the tax
rate necessary to service the public debt associated with public capital, and \(\rho\) a rate of time preference.
Evidently, increases in the tax rate lower economic growth, while increases in the ratio of public capital
to private capital raise economic growth. It turns out that increases in public capital will raise or lower
economic growth depending on whether the tax rate is lower or higher than the output elasticity of
public capital – that is, there is a nonlinear relationship between public capital and growth and an
‘optimal’ level of public capital. Using US state level data, Aschauer finds robust evidence that the
relationship between public capital and growth is, indeed, nonlinear and that public capital is
underprovided – that is, the ‘optimal’ ratio of public capital to private capital is in the range of 0.60
while the actual average ratio equals 0.44. As a consequence, a ten per cent increase in the public capital
ratio is estimated to raise economic growth by approximately one percentage point per year.

public choice

Gordon Tullock
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

By assuming that voters, politicians and bureaucrats are mainly self-interested, public choice uses economic tools to deal with the traditional problems of political science. Its findings revolve around the effects of voter ignorance, agenda control and the incentives facing bureaucrats in sacrificing the public interest to special interests. The design of improved governmental methods based on the positive information about how governments actually function has been an important part of public choice. Constitutional reforms advocated variously by public choice thinkers include direct voting, proportional representation, bicameral legislatures, reinforced majorities, competition between government departments, and contracting out government activities.

Article

In the 18th and 19th centuries a number of mathematicians (Condorcet, Borda, Laplace and Lewis Carroll) became interested in the mathematics of the voting process; their work was forgotten until Duncan Black rediscovered it (see, e.g., Black, 1958). Black can be called the father of modern Public Choice, which is in essence the use of economic tools to deal with the traditional problems of political science. Historically, economics (political economy) dealt to a very large extent with the choice of government policies with respect to economic matters. Whether protective tariffs were or were not good things would be a characteristic topic of traditional economics and in examining the question, it was assumed, of course, that the government was attempting essentially to maximize some kind of welfare
function for society.

We do not expect businessmen to devote a great deal of time and attention to maximizing the public interest. We assume that, although they will of course make some sacrifices to help the poor and advance the public welfare, basically they are concerned with benefiting themselves. Traditionally economists did not take the same attitude towards government officials, but public choice theory does. To simplify the matter, the voter is thought of as a customer and the politician as a businessman/entrepreneur. The bureaucracy of General Motors is thought to be attempting to design and sell reasonably good cars because that is how promotions and pay rises are secured. Similarly, we assume that the government bureaucracy will be attempting mainly to produce policies which in the views of their superiors are good because that is how their promotions and pay rises are secured.

In all these cases, of course, the individual probably has at least some willingness to sacrifice for the public good. Businessmen contribute both time and money to worthy causes and politicians on occasion vote for things that they think are right rather than things which will help them get re-elected. In both cases, however, this is a relatively minor activity compared to maximizing one's own well-being. The only surprising thing about the above propositions is that they have not traditionally been orthodox either in economics or political science. Writers who did hold them, like Machiavelli in parts of The Prince, were regarded as morally suspect and tended to be held up as bad examples rather than as profound analysts.

Public Choice changes this, but even more important, by using a model in which voters, politicians and bureaucrats are assumed to be mainly self-interested, it became possible to employ tools of analysis that are derived from economic methodology.

As a result, fairly rigorous models have been developed which can be tested with the same kind of statistical procedures that are used in economics, although their data are drawn from the political sphere. The result is a new theory of politics which is more rigorous, more realistic, and better tested than the older orthodoxy.

While the basic thrust of the Public Choice work has been positive (directed towards understanding politics), from the very beginning it has also had a strong normative component. Students of Public Choice might modify Marx to read that 'the problem is to understand the world so that we can improve it'. Thus the design of improved governmental methods based on the positive information about how governments actually function has been an important part of Public Choice work, and is usually referred to as the theory of constitutions.

Before discussing this, it is necessary to outline briefly related discoveries in four general areas, viz: voters, politicians, the voting process which relates voters to politicians, and the theory of bureaucracy. We begin with voters. One of the earliest discoveries of the new Public Choice (see Downs, 1957, pp. 207–78) was that a rational voter would not bother to be very well informed about the votes that he cast. The reason is simply that the effect of his vote on his well-being is trivially small (see Tullock, 1967a, pp. 100–14). Apparently voters have always known this, since empirical studies of voter knowledge show them extremely ignorant, but it was something of a revelation to traditional professors of Political Science. Further, this general ignorance of the voter is not symmetrical. The voter is likely to know a good deal about any special interest which he has. Further, organized special interest groups will put effort into propagandizing the voter in such areas. Thus the voter is not only badly informed, but what information he has tends to be biased very heavily in the direction of his own occupation or avocation. The farmer is much more likely to know the views of the candidates on farm programmes than their
views on nuclear war. It could be said that even on the farm programme he is probably not very well informed, just better informed.

One should not exaggerate of course. The voter, simply by living and following current events in newspapers and on television, does acquire a certain amount of general information about politics. Not much of it seems to stick, however, and in any event it is very heavily affected by temporary fads. It should also be emphasized that some kinds of special interests of the voter are not in any real sense selfish. For example, in the USA many people are influenced in their vote by such institutions as Common Cause and Liberty Lobby and make voluntary cash contributions to them. Clearly, this is an expression by those people of their interest in good government, even though the two groups define this in a radically different way. There is no doubt, however, that a well organized special interest is apt to have more impact on any specific issue than either the general media or so-called public interest groups like Common Cause or Liberty Lobby, even though in the very long run, considering what one might call the ‘general mystique’ of government, the media are very important.

Consider next the politician. A politician is a person who makes a living by being elected by voters of the kind described above. Further, many politicians are themselves voters as, let us say, members of the House of Representatives. While in the latter capacity, although it is not true that politicians’ information is as bad as that of the voter, a similar effect is still at work. An individual member of the House of Representatives or the House of Commons who switches one hour a week from general study of the issues on which he must vote to constituency service will normally reduce only trivially the quality of the legislation as it affects his constituency. On the other hand, by so re-allocating his time, he may materially improve his relations with his electors. Thus we would expect that politicians will be less well-informed on general matters than we would like.

This is simply one example of a large number of cases in which politicians’ behaviour is not necessarily that which maximizes the public welfare: they vote in Congress and seek public positions in terms of what they think the voters will reward, not in terms of what they think the voters should reward. Since a politician knows that his constituents are badly informed, these two positions can be radically different. Nevertheless, if we are believers in democracy, which literally means popular rule, then the government should do what the people want and not what some wiser person feels that they should want. In any event, ‘in order to be a great Senator, one must first of all be a Senator’.

Obviously the cost to the public of this kind of behaviour is quite considerable. It is particularly so when we think of the investment of resources and influence in the government which are, to a considerable extent, wasted. However, if we contrast functioning democracies with the other types of government which we observe, we are not likely to feel that democracies are markedly less efficient.

We now turn to the voting process, which connects the public to the politicians and the latter to the actual policy outcomes. Uninformed people think that this is basically a trivial problem, you simply count the votes. Unfortunately, this does not follow, even though the author of this essay is one of the few Public Choice theorists who regards the problems to be discussed next as being possibly illusory. Condorcet, Borda, Laplace and Lewis Carroll and, in the 20th century, mathematical economists like Black and Kenneth Arrow discovered a set of mathematical problems sufficiently difficult to be taken as proof that democracy is either an illusion or a fraud. Basically, if we assume that all individuals can order various policy proposals, producing a personal ranking from top to bottom (indifference between alternatives being permitted) and that these orderings differ from person to person (and do not fall into a set of narrowly specified and rather unlikely patterns), then one of the following three phenomena can
occur under any conceivable system of voting:

1. Endless cycling with A beating B and B beating C then C beating A.
2. An outcome which is dependent on the order in which the various proposals are voted on. (It should be pointed out in this connection that if this is so, and the people are well informed, voting on the order of voting reproduces the same problem.)
3. A situation in which the choice between alternative A and alternative B depends on whether alternative C (which in itself has no chance of winning) is or is not entered into the voting process. Most legislatures follow procedures which fall under the second of these possibilities.

If there is a possibility of arranging all of the alternatives in a single dimension with individuals having an optimal point and their preferences falling away monotonically as one moves away from that optimal point in either direction (single peakedness), then the problem is avoided. Unfortunately, most choices involve policies that differ from each other in more than one dimension and so cannot be arrayed in such a one-dimensional continuum. Furthermore, voting on them one aspect at a time reintroduces the second of the problems above. Nevertheless, the assumption of single peaks (whose validity is probably due to voter ignorance) has been successfully used in much empirical work.

While there is no doubt about the mathematical accuracy of the proofs of the above propositions, the real problem is whether they are of great practical significance in voting. Unfortunately, this turns out to be an extremely difficult question whose solution is unlikely to be found in the near future. In essence there are two possibilities when we observe such voting bodies as the House of Representatives and look at the outcome. The first is that the outcome is essentially random, that is, matters are taken up in some order, that order determines the voting outcome and the members of the House do not realize that they could then change that outcome by changing the order in which the propositions are voted on. This possibility would imply that luck plays an immense role in democracy.

The alternative is to say that the outcome is manipulated by somebody who understands the situation and who has control over the agenda. The House majority leader, or the chairman of the Rules committee, is sometimes suggested as that person. This implies that we really have a dictatorship, one that is well concealed.

In my opinion, the indeterminacy thrown into the outcome by these propositions of social choice theory is actually quite small in practical terms. Thus the Chairman of the House Rules Committee may be able to change an appropriation bill by, say, one hundred thousand dollars, but not by an amount which (given the size of these appropriations) is particularly relevant (see Tullock, 1967b). Among Public Choice theorists mine is a minority point of view. The majority, although it is deeply concerned about these problems, tends to ignore the implications of its point of view on the desirability of democracy as a form of government.

Empirical evidence has clearly demonstrated that agenda control can to some extent affect the outcome. This of course is going to surprise nobody. One does not need the complex mathematics of voting in order to realize that those members of any assembly who are in a position to control the order upon which things are voted have power. Similarly the control of what propositions are actually put before the voters can have considerable impact on the outcome. The demonstration of the empirical impact from agenda control, however, does not really support the theorems given above. Of course, we cannot say that the failure to find clearcut proofs that the outcome in a democracy is essentially either random or
fraudulent (as would be implied by the mathematical work on voting) proves that it is not. The problem is difficult and subtle and in the present state of our knowledge must be left for further research. Meanwhile, we all go on with faith that the voting process produces an acceptable outcome even though mathematical investigation raises grave doubts.

Turning now to the theory of bureaucracy, once again Public Choice thought has worked a revolution. The traditional view was either that bureaucrats followed the orders of their political superiors or alternatively that they simply did what was right. Public Choice theorists, following the work of Tullock (1965), Downs (1967) and Niskanen (1971), believe that these are not proper statements about the bureaucrats’ motives, although to some extent the bureaucrats do attempt to do what is right – including obedience to the views of their superiors. However, in modern societies where civil service legislation makes it all but impossible for the superiors either to dismiss them or even to reduce their salaries, the degree to which the bureaucrats are so compelled is moderate. Furthermore, in most civil service situations the power of a political appointee to reward his inferiors by promotion is very much restricted. Promotion decisions are to a considerable extent controlled by both legal and public-relations considerations which may compel a superior to promote someone whom he actually thinks has been sabotaging his policy.

While this is a characteristic of most modern civil service structures, there is no law of nature which says that government should be organized in this way. Traditionally, higher officials have been free to promote, demote or dismiss this subordinates. Even here, however, the fact that the higher official cannot possibly know everything that is going on at the lower ranks means that his control gradually diminishes as one moves away from his position down the pyramid of ranks. For example, in the USA it was recently discovered that it is not possible for the Secretary of Defense to know the specifications which a civil servant, located at a vast distance down the pyramid, produced for a new coffee pot for military aircraft. In this case, the civil servant who specified a coffee pot capable of withstanding a crash that would kill the entire crew of the plane was neither dismissed nor even reprimanded. Indeed the newspapers that reported the story did not even mention his name, but instead concentrated on the Secretary of Defense. In 1870 a military procurement agent who make a mistake like this (and which got into the newspapers) would have found it necessary to hunt for a new job within an hour or so.

Basically the average employee in a bureaucracy is interested in retaining his job and gaining promotion and for this purpose wants to please his superiors. Under the old-fashioned system where he had little job security, and where promotion was determined strictly by his superiors, there was considerable pressure on him. In present circumstances, where to all intents and purposes he cannot be dismissed and where even his promotion is to some extent protected from political intervention by his superiors, this pressure is less important. However, even in a different case, in which he did indeed want to please his superiors, this would not necessarily lead to activity which is in the public interest. That would depend on the political situation of the party or individual who at that time was in control of his branch of the government.

This attenuation of control, in which much of what is done by lower-ranking officials is simply unknown to those of higher rank, is characteristic of all bureaucracies. There are however various ways by which the higher ranks can become, to some extent, aware of what is being done by the lower ranks. Undoubtedly the most efficient of these is simply an accounting system. In the case of a private company, whose motive is making money, the accounts do a reasonably good job (no more) of
signalling what the various lower ranking officials are contributing to that goal. When we turn to
government, however, we have the combination of a set of objectives that are either vague or not clearly
specified, and a situation where there is no accurate way of measuring the contribution of each person to
those objectives. Under such circumstances, control is much more severely attenuated.
When we have a civil service structure which separates the individual from much of the control power of
his superiors, the problem is even more severe. Whether an individual bureaucrat works hard or not,
prepares himself or herself well or not, is largely a matter of individual choice. As a rough rule of
thumb, those people who do work hard and prepare themselves well are those people who have their
own idea of what government should do in their particular division and work hard at that. In a way they
are hobbyists. It should be said however, that their hobby is normally motivated by a desire on their part
to maximize what they think is the public good. In other words, they are usually well-intentioned
individuals who can be criticized only in that their idea of the public good may or may not coincide with
that of their superiors. If it does not coincide, this does not prove that they are wrong and the superiors
right, but it does mean that the government is not apt to follow a coordinated policy. In times past, it
used to be normal to refer to the US Department of State as ‘a loose confederation of tribal chieftains’.
The phrase is not used any more, but as far as I can see this is only because the confederation itself has
broken down.
Bureaucrats normally have several private motives. One is, of course, simply not to work too hard – a
motive which does not seriously affect the hobbyist described above. Another is to expand the size of
one's own department and in the process of so doing, being willing to go along with the expansion of all
the rest. A third is to improve the ‘perks’ that accompany the particular position (see Migue and
Balageur, 1974).
Note that this is not intended as criticism of the bureaucrat. We would expect anyone who is given the
kind of opportunities that are given to bureaucrats to do more or less what they do. However, the
consequence is that large bureaucracies tend to grow larger, tend as they grow larger to follow less in the
way of integrated policies and more in the way of policies that develop in the lower reaches of the
pyramid, and tend in fact not to work terribly hard (see Bennett and Orzechowski, 1983).
The problem is multiplied when bureaucracies become very large, because the members of the
bureaucracy can vote. Furthermore, empirical evidence (see Bennett and Orzechowski, 1983) shows
they vote more frequently than non-bureaucrats. Thus their percentage in the voting population is
somewhat larger than their percentage in the actual population (see Frey and Pommernhe, 1982). Thus,
the political superior must consider the people working for him as in part his employers rather than his
employees. He may not be able to fire them, but in the mass they can fire him. Altogether, the system is
not well designed and does not work very well.
So far we have been talking about Public Choice and what has been learned, but not of the lessons of a
normative nature that have been drawn i.e. the theory of constitutions. It is to this that I now turn.
Not all students of Public Choice favour the same reforms in each area. Further, some have not
specifically said what reforms they would prefer because they believe that not enough is yet known
about the process to be able to suggest improvements. Nevertheless, there are several rather general
propositions which most students would agree upon as ways of improving the functioning of
government. In a discussion as brief as this, it is not possible to include all the differences of opinion and
all the modifying clauses which would be appended to each suggestion for reform. Thus the reader
should not assume that everyone studying Public Choice agrees with all the propositions which follow.
To begin with the voter, no student of the subject has any idea of how to improve the voters' information. With respect to voting itself there have been some proposals for improved voting methods, but no widespread support exists for any particular improvement. In spite of this, I think it can be said fairly that most students would like to see voters vote more than they do now, favouring more direct voting on issues, and legislatures with larger membership (so that the connection of an individual voter and his representative is closer).

The basic desire to give voters more control of the mechanism is not based on any false idea of how well the voters are informed. It is simply that the voters are the only people in the whole process who do not have an element of systematic bias in their decision process. They may be badly informed, but what they want is their own well-being. The well-being of its citizens should be the objective of the state. When we turn to other parts of the government invariably we find at least some conflict between the interests of the officials and the interests of the average man. Thus increasing the average man's control is not particularly likely to improve the efficiency of the government using some abstract definition of efficiency. But it is likely to make the government more in accord with the preferences of the common man; i.e. it brings us a little closer to the objective of popular rule which is supposed to be what democracy is about. Those who do not favour popular rule would not regard this as desirable, but there are few elitists among the students of Public Choice.

The actual decision-making procedures used in the legislatures have been widely discussed and some proposed improvements command wide acceptance. First, many would like to have at least one house of the legislature elected by proportional representation. Secondly, Buchanan and Tullock's arguments in *The Calculus of Consent* (1962) for bicameral legislatures have generally been accepted. The further suggestion there that more than a simple majority is desirable for most legislation is seldom directly criticized, but is not so widely approved. The argument that this higher-than-majority requirement would change the structure of the log-rolling process in a favourable way has seldom been directly criticized, but the asymmetrical effect of such a rule (i.e., the status quo is retained unless a reinforced majority can be obtained to change it) offends some people.

Turning to the bureaucracy, there is much more agreement on reform. First, that a bureaucracy should be brought more firmly under the control of the political leaders is, I think, uniformly accepted. The dangers of this are recognized – but there are various ways in which the higher officials could be given the right to discipline civil servants while still reducing their power to fill the government with their cousins.

Apart from such straightforward proposals for changes in the personnel structure there are other ways of putting pressure on the government. The first is to work some competition into the system. Currently, not only do most government departments have a monopoly over whatever function they perform, but almost every proposal to increase the efficiency of government takes the form of eliminating what little competition has popped up. Competition between government departments should be encouraged rather than discouraged.

Finally, it may be possible to ‘contract out’ government activities or literally transfer them wholly to the market. The mere threat of this will frequently lower the cost of government activity. Having several private companies bidding for a government service, however, is better.

It can be seen that at the concrete level, those who study Public Choice have been able to provide more in the way of suggestions for reform within the bureaucratic structure than in the higher level parts of democracy where the voters control the legislature, and the legislature and executive then control the
bureaucracy. This is unfortunate but not surprising. Nevertheless, there are suggestions for improving the whole structure of government and with time, it is hoped, there will be both more ways of making improvements and better scientific evidence that the ‘improvements’ are indeed improvements.

Public Choice is a new and radical approach to government, but its firm foundations in economic methodology mean that we have more confidence in its accuracy than with most new ideas. Further, it has by now been empirically tested very thoroughly. Government is the solution to some problems and the source of others. Public Choice shows strong promise of being able to reduce significantly the difficulties we now have with democratic government.

public debt

James M. Buchanan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Classical principles of public debt limited debt financing to non-recurrent, extraordinary or temporary demands. Keynesian macroeconomics, viewing budget deficits as the only means of financing demand-increasing deficits during depressions, overlooked the exchange between government and lenders in debt-financed public expenditure. In the post-Keynesian 1970s and 1980s, governments explicitly used debt to finance ordinary public consumption, including transfers, which was equivalent to a destruction in national capital value and raised the prospect of default. Fiscal responsibility demands that the classical principles of public debt must eventually return to general acceptance.

Article

Public debt (government debt) is a legal obligation on the part of a government to make interest and/or amortization payments to holders of designated claims in accordance with a defined temporal schedule. Public debt is created through government borrowing from individuals, corporations, institutions, and other governments. Borrowing is part of a bilateral exchange process in which lenders transfer funds to government and government, in turn, transfers to lenders designated instruments that represent claims on government revenues over a series of periods subsequent to that in which the borrowing occurs. In simple balance-sheet terms, public debt is a liability item on the government's account, and an asset on the combined accounts of the holders of the debt instruments. In its essential respects, public debt is not different from the debt of individuals or non-governmental institutions. The positive analysis is equivalent over the several settings, and the normative principles for
the use of debt are the same. These two propositions are not universally accepted by economists, whose understanding and analysis of established classical principles were eroded in the emergence of the macroeconomic mind-set of the postKeynesian era. Because of the continuing confusion and ambiguity in the basic economic theory of public debt, extended discussion is required on what should otherwise seem quite elementary analytics.

I Taxes, money and public debt

In order to finance spending programmes (including transfers) government must first secure revenues. Three means are available to governments with independent monetary systems: taxation, money issue, and public debt. Only two means are available to subordinate governments without money creation powers or to national governments that tie domestic currencies to external forces in the international economy: taxation and public debt.

It is useful to make two critical distinctions between taxation on the one hand, and public debt on the other. With taxation there is only one possible ‘exchange’ embodied in the combined fiscal process, that effectuated via government between individuals as taxpayers and individuals as beneficiaries of government spending programmes. This two-sided fiscal operation is ‘exchange’ only in the aggregative sense that persons in the community secure benefits from the taxes paid by persons, whether or not the taxpayer and beneficiary groups are overlapping. However, even if the fiscal process satisfies the aggregative and the individualistic efficiency standards such that all persons pay tax-prices, at the relevant margins, equivalent to public-goods benefits, coercion is required to implement the solution. The basic fiscal ‘exchange’ is not, and cannot be, voluntary.

With public debt issue, by comparison, two ‘exchanges’ are involved in the combined fiscal operation, one, the political ‘exchange’ analogous to that in taxation, and the other the whole set of privately negotiated and wholly voluntary exchanges between government and those who lend funds to government. Failure to recognize the double set of exchanges that public borrowing combined with spending of the proceeds embodies is the source of major confusion in determining the location of the burden of debt, to be discussed below.

A second critical distinction between taxation and debt issue lies in the temporal difference in the politically determined imputation of the liabilities that are made necessary by the fact of government spending. With taxation, these liabilities are imputed to those persons and institutions that make the funds available directly to government in the period of the spending operation. With public debt, by contrast, there is no current or initial-period imputation of fiscal liability. Revenues are secured from those who lend voluntarily, who do so in exchange for promises of future period interest and amortization payments, and not in ‘political exchange’ for the benefits of spending programmes, even indirectly. With government borrowing (debt issue) the ultimate fiscal liability made necessary by the spending programme in the initial period is postponed. This liability is placed, in the aggregate, on taxpayers in periods subsequent to that in which the debt is issued. The aggregate liability is not, however, imputed or assigned to individuals or to groups of individuals. The postponement of liability implies, therefore, postponement of payments for public programmes.

II The Ricardian theorem on the equivalence between taxation and government borrowing
David Ricardo (1817, 1820) advanced a theorem to the effect that taxation and government borrowing are logically equivalent. This Ricardian theorem was rediscovered by macroeconomists in the 1970s, notably by Robert Barro, and it became an important element in the ‘new classical macroeconomics’ of that period.

On its face, the theorem seems to reject the critical distinctions between taxation and debt discussed above. In what respects are taxation and government borrowing alike rather than different? Both extract revenues from private citizens and transfer these to government for spending on public programmes. The basic Ricardian logic does not reject the difference in status between the taxpayer, who faces governmentally imposed coercive levies, and the bond purchaser, who voluntarily transfers funds to government in private exchange for future-period interest and amortization payments. The theorem does, however, reject the second distinction noted above, that which involves any postponement of the costs of public spending. In the Ricardian model, individuals recognize that any issue of debt by government embodies a commitment to meet payments in future periods. These payments can be converted into individualized shares in the aggregate liability, discounted, and capitalized into a present-value measure, which can then be reckoned as a liability item on individual initial-period balance sheets. If persons think that they will live forever, or if they have intergenerational bequest motives that cause them to act as if their lives are infinite, the liability items, summed over all persons, will just offset the value of the debt in the balance sheets of those who hold debt instruments.

If the equivalence theorem is valid, there are important macroeconomic consequences. If persons treat government debt equivalently with taxation in all respects other than the actual timing of the payments, they will make portfolio adjustments as required by this differential timing. When debt is issued, persons will, knowing that payments must be made in future periods rather than currently, put aside some funds to facilitate such payments. There will be no difference between tax and debt financing in their effect on consumption and investment spending. Individuals, as taxpayers-citizens, will when debt is issued, increase savings to allow a share of the future-period debt obligations to be met. However, this increase in saving will equal the full value of the debt only if the governmental outlays take the form of ideally efficient transfers. This neutrality theorem, which we may associate with Barro, is more restrictive than the Ricardo theorem. If the governmental outlays are made for the provision of real goods and services, the neutrality theorem may not hold although debt financing and tax financing of these outlays may still exert equivalent effects (the Ricardo theorem).

The Ricardo equivalence theorem (along with the stronger neutrality theorem) is best evaluated as an extreme model of rational individual behaviour under idealized sets of circumstances. Ricardo himself recognized that persons did not, in fact, treat taxation and debt in the same way. All persons do not act as if they live for ever; persons differ in age as well as interest in future-period tax obligations. Further, taxes are not lump sum, interpersonally or intertemporally. More importantly, there is no assignment of present-value liability among persons such as would allow portfolio adjustments to be made in the manner postulated in the equivalence theorem setting. Even if individuals do recognize that public debt does embody future-period tax liabilities, they cannot reduce this aggregate to individualized shares in any plausible reckoning.

The central flaw in the equivalence theorem stems from the logic of debt itself, which may be illustrated by analogy with private behaviour. Why does a person borrow? He does so in order to rearrange spending temporally. If borrowing and current payment (the private analogue to taxation) are equivalent, there is no point in the exercise. As an institution, borrowing has as its purpose the adjustment of
spending flows through time. Governments, as agents are citizens, borrow for analogous reasons. There is no *raison d’être* for public debt if this instrument is behaviourally equivalent to taxation. The empirical evidence gained from straightforward observation of modern politics points clearly toward rejection of the equivalence theorem. Taxation and debt are not treated as identical by voting constituents, as is suggested by the fact that politicians responsive to constituents are not indifferent as to the mix between these instruments. Within broad threshold limits, debt financed outlay arouses less political opposition than tax-financed outlay of comparable magnitude. The observed US Federal deficits of the 1980s could not have been eliminated by tax increases without generating significant political struggle.

### III Classical principles of public debt

Both the positive analysis of and the normative precepts for public debt were broadly understood by the classical economists, and these principles were carefully articulated in the dominant theory of public debt developed in the 19th century. There is no essential difference between the government account and the account of an individual or private firm in the classical model. Borrowing is a means of raising revenues that allows the borrower to put off or to postpone payments. It is a means of adjusting spending needs to revenue flows over time; in effect, borrowing allows intertemporal trades to be made.

For the government, as for the individual or firm, there would be no basis for borrowing unless the burden of payment could be delayed in time. By the very meaning of debt, therefore, there must be a shifting forward of burden intertemporally. The ultimate payments for the enhanced spending programme during the initial period when debt is issued must be borne exclusively in later periods. From this straightforward and indeed simple analysis, normative principles for public debt creation emerge. Resort to debt financing is indicated only with nonrecurrent or extraordinary demands, or requirements for public spending that are expected to be temporary. Traditionally, such demands were associated with war emergencies, and the principles of fiscal prudence dictated that debts accumulated during was periods would be retired when the emergency spending demands were past. In addition to these extraordinary spending justifications for resort to borrowing, government is also within bounds under classical norms when debt is issued to finance genuinely productive capital projects, analogously with private firms making capital investments.

When capital spending is debt financed by government, the principles suggested that a scheme for debt retirement be put in place to insure that the pay-off period corresponds to the income-yielding period from the investment asset.

### IV Public debt in Keynesian macroeconomics

The classical principles of public debt were not understood by the pre-classical mercantilists and these principles were also questioned by a few fiscal and monetary expansionists in the pre-Keynesian period. Only with the ‘Keynesian revolution’ in economic thinking in the middle of the 20th century, however, did a rejection of these classical principles become a ‘new orthodoxy’. An analysis of public debt, along with relevant normative implications, came to be dominant during the 1940s and 1950s that sought to contradict basic elements of the classical model.

As noted earlier, the classical principles are starkly simple, and are based on the essential similarity
between the government and the individual account. The Keynesian logic rejected this analogy. Specifically, the argument denied that public debt embodies any shift of burden onto taxpayers in periods of time subsequent to debt issue, a temporal shift that was acknowledged to occur in both private debt and external public debt. The conclusion that public debt could involve no intertemporal shift of burden emerged from an undue concentration on the macroeconomic aggregates and an overlooking of individual adjustments to macroeconomic instruments. Again, the logic is seemingly quite straightforward. Resources are used up only in periods when spending programmes take place; if government borrows to finance spending on guns, the resources that go into producing these guns must be given up by some persons during the period and not later. With internal public debt, therefore, the burden of war spending could not, by definition, be transferred forward.

The basic flaw in the argument is clear from the discussion in section I. The two-part exchange that debt-financed public spending embodies is overlooked. The argument fails to recognize that those who actually give up claims over resources during the period of the spending do so because they voluntarily exchange funds for promises of interest in future periods. These purchasers of bonds do not, in any sense, ‘pay for’ the benefits of the public spending programme. The fact that these persons may also be members of the community of citizens-taxpayers is irrelevant for the temporal location of burden. Taxpayers in later periods are faced with claims against their incomes that must be met, and which exist only because of the initial-period debt issue. If, indeed, the Keynesian orthodoxy of public debt were valid, economists and finance ministers would have discovered the fiscal equivalent of the perpetual motion machine. No non-voluntary transfers of revenues are required to finance spending in the initial period, and, if there is no burden on future-period taxpayers, the spending that is carried out would have required no burden on anyone.

The Keynesian argument was driven by a stance on policy that viewed public debt as the only means of financing demand-increasing deficits during periods of depression. The primary policy instrument of Keynesian economic policy was the budget deficit, and there was an elementary failure on the part of pro-Keynesian economists to recognize that demand-enhancing deficits could be financed with non-interest bearing money creation. If this macroeconomic objective is the only justification for the creation of budgetary deficits, it becomes totally unnecessary to impose the future-period taxes that debt interest reflects. Money creation in such settings carries with it no future-period burden.

V Public debt and deficits in postKeynesian politics

The Keynesian replacement of classical principles of public debt was never total, and in the late 1950s and early 1960s there was a reemergence of economists’ support for the earlier analysis, along with its normative implications. There was not, however, a ‘paradigm shift’ at all comparable to the earlier overthrow of the classical analysis. Somewhat begrudgingly perhaps, economists of the 1960s came to recognize the deficiency in the simplistic Keynesian logic, but there was no general reaffirmation of classical principle. The discussion of public debt that characterized the 1960s, 1970s and 1980s remained confused by an admixture of the two contradictory models of analysis. Economists seemed to concentrate attention on the secondary and tertiary macroeconomic consequences of debt-financed deficits; their considerable formal skills were directed toward attempts to extend the ancient Ricardian theorem.
While confusion and ambiguity described economists’ discussion of public debt, the politicians had learned the Keynesian policy lessons with roughly a two-decade lag. By the early 1960s, the ‘old-time fiscal religion’, based on adherence to the normative precepts of the classical analysis, had lost its constraining influence. The political leaders of the 1960s and beyond had learned that demand-enhancing deficits may be justified in some economic settings. Their natural proclivities to spend without the levy of taxes on constituents caused them to look on economic settings in a biased or one-sided fashion. The idealized Keynesian policy set – deficits in depression, surpluses in booms – proved to be unworkable in democratic politics.

The regime of apparently permanent debt-financed deficit spending was born. During the 1970s and 1980s, for the first time in modern fiscal history, governments explicitly used debt to finance ordinary public consumption outlay, including transfers. This fiscal operation, considered in isolation, is equivalent to a destruction in national capital value. When persons, privately or publicly, abstain from consuming current income, capital value is created. When persons, privately or publicly, consume more than current-period income, capital value (defined as the discounted present value of anticipated future incomes) is destroyed. For both individuals and governments, resort to borrowing allows a ‘using up’ of future-period income as a means of increasing current consumption, just as resort to saving allows a ‘using up’ of current income (in an opportunity cost sense) to increase future-period consumption. Only if borrowing is used to finance genuine capital investment, private or public, will the net effects be intertemporally neutral; only in this case will the capital value of anticipated income be unchanged. With debt-financed public consumption, the present value of anticipated future incomes of persons in the polity is reduced relative to that which might have been maintained in the absence of the combined fiscal operation. The fact that some or all of the debt is held by foreigners rather than citizens does not modify this conclusion.

Consider the case where debt instruments are purchased exclusively by domestic citizens, who may also be future period taxpayers. Securities are purchased voluntarily; hence, there is no change on the asset side of purchasers’ balance sheets at the time of debt issue. Purchasers could, alternatively, hold or buy privately issued securities with equivalent yields. On the other hand, the fiscal operation does place debt-interest claims against the anticipated private income flows of citizens as taxpayers. There is a net increase in the present value of liabilities on properly calculated individual balance sheets. This increase in the value of liabilities is, of course, equivalent to the value of the debt instruments. But these two items are not offsetting since there are two fully offsetting items on the asset side of the accounts, leaving no net change from this side. The combined fiscal operation necessarily reduces net worth, or capital value, in the economy, so long as the government outlay does not generate anticipated income flows from public assets, a result that is ruled out with pure public consumption.

VI Return to classical principles?

Public debt is a topic in political economy in which the level of understanding experienced serious retrogression over the course of the middle decades of the 20th century. Policy-motivated macroeconomic confusion generated political spillovers that remained in the 1980s. Economists seemed unable to contribute to clarification in analysis, in part because they were reluctant to drop either suprarational models of individual behaviour or erratic manipulation of data. The classical analysis, out of which emerged precepts that offered simple guidelines for governmental fiscal authorities, no longer
commanded widespread support, either among political economists or among politicians and, indirectly, their constituencies. Governments in the 1980s were observed to be financing sizeable shares of their public consumption outlays by interest-bearing debt. Interest outlays made up ever-increasing proportions of total government budgets.

The simple logic of compound interest guaranteed that the budgetary regimes observed in the 1980s were not sustainable. Default on government's debt obligations becomes increasingly attractive to politicians as interest charges mount and as borrowing rates for new issues of debt simultaneously increase. Default on public debt has occurred often in history, both through explicit destruction of real value obligations and by means of inflation.

The ultimate prospects for default may be generally recognized, but the political difficulties in restoring some adherence to classical norms cannot be overlooked. Once debt-financed deficit spending for public consumption came to be an element in the quasi-permanent status quo, attempts to restore budgetary balance faced enormous political opposition, as indeed the events of the 1980s demonstrated. To reduce the deficits, and hence merely to reduce the rate of increase in public debt issue, governments must resort to tax increases or to spending cuts, both of which arouse political opposition. Those taxpayers who must bear the burden of continuing debt are, at best, only partially and indirectly represented in the decision structure of democratic politics.

Restoration of the classical principles of public debt seemed unlikely from the temporal perspective of the 1980s. The old-time or pre-Keynesian ‘fiscal religion’ did exert an influence on the behaviour of politicians, and through them, on governments. Public debt, as a revenue-raising instrument, has an appropriate and well-defined use as a means of allowing governments to alter the time stream of payments for extraordinary outlays. There was nothing comparable to a ‘fiscal religion’ in post-Keynesian politics. Public debt, as it was actually used in the years after the 1960s, became a mere balancing element between proclivities of politicians to tax on the one hand and spend on the other. The absence of immediate fiscal breakdown was explained by some residual carry over of classical norms, some introduction of a Ricardian-like consciousness of future tax liabilities, and some fear of default risk on the part of prospective lenders. But the situation observed over the decades of the 1970s and 1980s could not have represented temporal stability.

The classical principles of public debt, whether they be labelled as such, must eventually return to general acceptance if the fiscal responsibility of governments is to be maintained. Whether or not this acceptance comes before or after a sequence of default-engendered fiscal crises could not be predicted from the temporal perspective of the middle 1980s.

Bibliography

**How to cite this article**

Public finance may well be the oldest branch of economics. It concerns not only the effects of fiscal operations on the market but also principles of public sector economics, which address a distinct set of issues and are linked closely to the perspectives of political and social science. This article covers (a) expenditure on public goods and transfers, including its macroeconomic effects as analysed by the classical and the Keynesian schools, and (b) taxation, including issues of tax equity and tax efficiency, definitions of income, consumption and expenditure, and tax shifting and incidence.

Concern with public finances may well be the oldest branch of economics. Statesmen have needed advice, and writing on fiscal affairs dates back to antiquity. It concerned the scholastics of the 16th century and occupied the mercantilists of the 17th. Systematic study of the public household by the Cameralists followed, and the ‘L’impôt unique’ was a central part of Physiocrat doctrine. In England, the writings of Petty, Locke, and Hume preceded Book V of Adam Smith's *Wealth of Nations*, the first ‘modern’ statement of the field. Thereafter, fiscal analysis followed (and in some cases led) the advances of economic science. Ricardo, Mill, the marginalists, Marshall, Pareto, and Pigou all left their stamp on the economics of public finance, not to mention the impact of Keynes and the emergence of stabilization as a goal of budget policy. But fiscal economics also added to the general body of economic analysis. Its concern is not limited to the effects of fiscal operations on the market, and market responses thereto. There remains the more basic question of why a public sector is needed and what rules should be applied to its conduct. Principles of public sector economics are required to provide the answer. These principles, to be sure, are coordinated with those of the market by the broader frame of economic welfare, but they address a distinct set of issues and, by their very nature, are linked more closely to the perspectives of political and social science.

**Public expenditures**

We begin with the expenditure side of the picture, and public goods in particular. Thereafter, transfers are examined.

**Public goods**

Here the basic issue is why certain goods and services have to be provided for through the budget, i.e., paid for by taxes and made available free of direct charge. Such goods and services may be produced under public or private management, e.g., government may install traffic lights itself or engage a private firm. Which is done does not matter here. The crucial point is that traffic signals are provided free of direct charge to the individual consumer when passing the intersection. Given a general presumption that consumer preferences should be met by the *quid pro quo* of the market, why should budgetary provision be chosen in the case of public goods? A modern answer was anticipated by Hume's early insight. Two neighbours, so he argued, might agree to drain a meadow, but no such agreement can be reached by a thousand persons, as each will try to place the burden on others (Hume, 1739, p. 539). Adam Smith also examined why certain services must be provided by the Prince (Smith, 1776, Book V). These included the upkeep of the court, defence, police, and minimal education for the poor. More generally, the Prince was to provide for ‘those
institutions and public works which, though they may be highly advantageous to a great society, are, however, of such a nature that the profit could never repay the expense to any individual’ (Smith, 1776, vol. 2, p. 539). The issue was joined but Hume’s earlier insight had been lost. The reason why private provision will not work remained unanswered. John Stuart Mill subsequently came a bit closer. He noted that individual preferences, under certain conditions, cannot be met without common concert and legal sanction. The lighthouse illustration appeared (Mill, 1848, p. 976), and the difficulty of collecting tolls for the use of its services was stressed. Market failure due to inapplicability of exclusion was thus noted, but not as yet the more basic proposition that exclusion would be inefficient (absent crowding) even if it could be applied.

The discussion took a new turn in the 1880s, when utility analysis grounded value theory on the demand side. Public no less than private services are provided to meet the preferences of individual consumers, so it was argued, and this provision through the budget may be viewed in analogy to the exchange mechanism of the market. Taxes may be viewed as price payments, offered by the consumer. Thus a voluntary exchange model of the tax-expenditure process emerged (Sax, 1887; Mazzola, 1890). This vision of the fiscal process was rejected at once by Wicksell (1896). While public provision should be in line with individual preferences, it could not be implemented by voluntary exchange. As Hume had recognized a century and a half before, exchange will not work in the large number case. The level of public services available to A will not be affected significantly by his own contribution. Hence A will not reveal his preference for public services. Unlike the case of private goods, where the individual must bid to obtain his share in the auctioning process of the market, the consumer will now act as a free rider. A political process of budget determination by voting, combined with a legal sanction of its enforcement, is needed so that preferences are revealed. Thus the basis was laid for the modern discussion of public choice and the voting rules by which an efficient solution may be approximated. Though the simplistic hypothesis of voluntary exchange was rejected, the exchange formulation as developed by Lindahl (1919) nevertheless had an important role to play. With any given supply of the public service available to both A and B, A's demand curve may be viewed by B as a supply curve. Equilibrium is then reached where the vertically aggregated demand curves of A and B intersect the supply schedule for the product, i.e., where the tax prices paid by the two consumers add up to the social cost of the service. Lindahl's formulation, with its vertical addition of demands, thus anticipated a significant feature of Samuelson's later formulation.

The next phase of the development of public goods theory emerged with Pigou's analysis of externalities (1920). External costs and benefits remain unaccounted for by the market and thus call for correction by public policy. Pigou did not develop this theme in his treatise on public finance (1928), where the proper sphere of public services is defined only in general terms, calling for extension to the point where marginal social costs and benefits will be equal. However, the concept of external benefits might be extended readily to that of public goods, where externalities appear not as a by-product of internal gains but all benefits are external. Introduction of the Scandinavian model into the English-language literature followed (Musgrave, 1939), but the crucial implication of public goods for efficient resource use was not drawn clearly until Samuelson's statement (1954). Whereas efficient use of resources in the provision of private goods calls for an equating of the marginal rates of substitution in production and consumption (with the latter equal for all consumers), that of public goods calls for equality of the marginal rate of substitution in production with the sum of the marginal rates of substitution (differing among
consumers) in consumption. Lindahl’s earlier exchange solution, arrived at by the vertical addition of demand curves, was compatible with this outcome; but, as shown in Samuelson’s model, an efficient solution did not require the Lindahl-type determination of tax shares.

The basic difference in the two formulations should be noted. Lindahl, following Wicksell, began with a distribution of money income and then proceeded to assign efficient tax prices. This is accomplished by charging each consumer in line with his marginal evaluation and setting total supply so as to equate the sum of these charges with cost. Moreover, by postulating a just state of distribution to prevail to begin with, a requirement also advanced by Wicksell, the resulting burden distribution of tax shares would also be just. Samuelson, like Wicksell, rejected Lindahl’s ‘pseudo demand curves’ as unrealistic. But where Wicksell proceeded to examine the process of preference revelation, Samuelson provided a more general definition of the efficient solution. Preference revelation is disregarded as the model visualizes an omniscient referee to whom preferences are known. He then establishes a utility frontier, showing various mixes of public and private goods, as well as private good distributions among individual consumers. The optimum optimorum (bliss point) on the utility frontier is then chosen on the basis of a social welfare function. The Lindahl solution becomes a special case only; but given the assumption of known preferences, there is no particular reason why it should be selected.

This more general formulation resolves the allocation and distribution aspects of the problem simultaneously, and deals with distribution in its basic welfare rather than income terms. The Lindahl model by comparison separates allocation and distribution issues. Since welfare is a function of real, not money income, it is open to the objection that the just distribution of money income cannot be determined without also setting tax prices, thus suggesting circular reasoning. However, this critique may be met by adding the determination of the voting rule (designed so as to best secure preference revelation) as a further equation to the model. Moreover, the Lindahl formulation provides a closer linkage to the real world. While tax prices cannot be seen as voluntary offers, there exists no omniscient referee to whom preferences are known. Preferences, as Wicksell noted, must be revealed through a voting process and this presumes a distribution of money income to begin with. The Lindahl price thus remains as a benchmark against which the quality of the voting process can be measured. Separation of the allocation and distribution phase of budget policy was extended subsequently to include the stabilization function as a third branch (Musgrave, 1959).

Subsequent developments in the theory of public goods recognized the fact that particular goods and services may not meet the polar conditions of purely private or public goods, but fall in between. A’s consumption of X may provide benefits internal to A and hence be undertaken by him. But it may also generate external benefits or costs for B, C, and D. Thus, partial provision through the budget, that is, a subsidy solution, may be called for. Or, the number of consumers may be sufficiently small to permit a bargaining solution without voting; yet there is no assurance that an efficient outcome will emerge. Moreover, it may be possible to satisfy certain needs via the provision of public or of private goods, thus permitting a choice between the two modes.

A special problem arises also from the fact that the benefits of public services may be subject to spatial limitation. The resulting distinction between ‘local’ and ‘national’ public goods provided the basis for a theory of fiscal location (see local public finance) according to which the provision of public services should be arranged so that each jurisdiction will provide and pay for the public services the benefits of which accrue within its borders. Moreover, the spatial limitation of benefits led to the proposal (Tiebout, 1956) that preference revelation may occur through ‘voting by feet’. Individuals with similar public
goods preferences would find it advantageous to congregate. At the same time, individuals with lower incomes will find it advantageous to congregate with higher income individuals, so as to generate an unstable distribution across jurisdictions.

The general theory of public goods has thus been extended and qualified to deal with particular situations. It should be noted, however, that all these variants assume public goods to be provided in line with the preferences of individual consumers. The theory of public goods is thus similar in its psychological underpinnings to that of private goods. The concept of communal needs or goods which the community considers meritorious offers an alternative perspective not included in the mainstream view of expenditure theory (see merit goods).

Cost–benefit analysis

Moving from general theory to practical application, the development of cost–benefit analysis has attempted to design an operational framework by which the appropriateness of particular expenditure projects may be evaluated and ranked. In the process, the present value of the expected benefit stream is balanced against that of its opportunity cost. For this purpose, a social discount rate has to be determined, a rate which may or may not be taken to equal that of the market. Moreover, opportunity cost is found to depend upon whether the resource withdrawal is from consumption or from capital formation. Since the income tax enters as a wedge between gross and net return, capital formation in the private sector falls short of the optimal level so that resource withdrawal from private investment carries a higher social cost than does resource withdrawal from consumption. Shadow prices are applied to measure the social cost of labour and other inputs, thus correcting for further distortions in market prices. Finally, distributional weights, based on a social welfare function, may be applied to the resulting costs and benefits. Thus, a framework is provided by which the value of alternative expenditure projects may be assessed and ranked. However, the analysis assumes that the value of the benefit stream can be determined. This involves no difficulty where the output of the public project is sold at the market, but approximations have to be used where the services are in the nature of public goods. Thus, the value of a park may be measured by the opportunity cost reflected in the visitor's travel time or by similar proxies.

Transfers

While economic analysis has focused on the provision of public goods and services, transfers have come to claim an increasing share of total spending. Aimed at correcting the distribution of income, they may be viewed as negative taxes. While resource use for the provision of public goods may be fitted into the Paretian mould of allocation efficiency, transfers pose a more difficult problem. To be sure, a theory of giving, or Pareto optimal redistribution, may be developed in the context of interpersonal utility interdependence. If the donor's satisfaction is derived from the pleasure of individual giving, giving remains a private good. But if it is derived from the welfare of others, giving assumes a social-good quality and calls for budgetary provision. Yet the outcome reflects the initial distribution of income and thus does not resolve the more basic problem of primary distribution. This transcends considerations of Pareto efficiency, and broader grounding in a theory of justice is required, be it a Lockean rule of entitlement, a utilitarian concept of maximum welfare, or a Rawlsian sense of justice as fairness. But notwithstanding this inherent link to a theory of justice, economic analysis retains a decisive role. The
size of the pie is linked to its distribution, and redistribution involves an efficiency cost. The one, therefore, cannot be determined without the other.

Turning to the form in which transfers should be given, economists have traditionally argued in favour of a general income subsidy, rather than selective subsidies designed to support particular uses of income. The general subsidy will be more valuable to the recipient as it does not interfere with his choice among income uses. But various exceptions may be noted. Transferors, consenting to a transfer, may do so on condition that the income is put to specified uses. Giving may take a paternalistic form. Moreover, distributive justice may be viewed in categorical terms, applying different standards of equality to basic items than to other income uses (see merit goods). Beyond this, the logic of optimal commodity taxation, calling for differential rates of tax on various goods and services, may also be shown to call for differential subsidy rates to be applied to various commodities.

**Macroeconomic aspects**

The preceding discussion has dealt with the role of public expenditures in providing for public goods and for adjustments in distribution. In the process, the fiscal system may add to capital formation via public investment and detract therefrom via reduced capital formation in the private sector. Public finances thus have an important bearing on the rate of economic growth, a fact which has been dealt with throughout the literature, and which was central to Ricardo's critique of the public sector. Moreover, the choice between tax and loan finance becomes an instrument of inter-temporal burden distribution. Since loan finance falls more heavily on capital formation, it leaves future generations with a smaller capital stock. Considerations of intergenerational equity thus permit public investment, the benefits from which accrue to future generations, to be loan financed, while calling for current services to be tax financed. This establishes the rationale for a dual budget system, with balance in the current and loan finance in the capital budget. This reasoning, in turn, calls for the inclusion of depreciation in the current budget, with corresponding debt retirement over the useful life of the asset. It should be added that inclusion of outlays in the capital budget does not require public acquisition of real assets (with its fictitious analogy to a balance sheet) but simply the creation of future benefits, including those of investment in human capital through outlays on health and education.

A quite different macro-perspective on public expenditures emerged with the Keynesian model. While the classical framework had left the budget aggregate-demand neutral, deficit and surplus finance now became a source of demand expansion and restriction. With initial emphasis on fiscal expansion (restriction) directed at increase (decrease) in public spending, tax reduction (increase) subsequently entered as an alternative way of achieving similar results. The early Keynesian model, which left money impotent and viewed fiscal policy as all-powerful, was modified in the neoclassical synthesis of the 1950s and 1960s, and attention moved to the correct mix of fiscal and monetary constraint. Moreover, the supremacy of aggregate demand controls become questionable as attention shifted from full employment to inflation. Nevertheless, aggregate demand effects of fiscal operations have remained of major concern, joining the earlier issues of allocation and distribution as a third dimension of fiscal economics.

**Fiscal politics**
The preceding discussion, in line with the tradition of fiscal economics, has dealt with normative issues of expenditure policy, that is, why such expenditures are needed and how they should be designed to obtain efficient results. More recently, a new perspective has been added. Not resting on the assumption that prescription of correct policy will be followed once laid down by economic analysis, attention has turned to how public policy does in fact behave and how its behaviour is determined. In the process, emphasis has shifted from concern with market failure to focus on failure in public policy (Buchanan and Tullock, 1962). Early efforts to develop a theory of public-sector behaviour had been made in a Marxist framework, viewing the state as an instrument of exploitation by the ruling class. Recent analysis proceeds in analogy to microeconomics, involving the self-interested behaviour of voters, bureaucrats and politicians. An important focus in this analysis has been the growth of the public sector, the extent to which it reflects the inherent needs of modern society as expounded in Wagner's Law (1883), or a malfunctioning of the fiscal system based on an inherent bias towards over-expansion (see public choice).

**Taxation**

We now turn to the tax side of the fiscal picture, beginning with the normative requirements for a good tax system.

**Criteria for equity**

From Adam Smith on, students of taxation have been concerned with the qualities of a good tax system. One such requirement, traditionally ranked first, is that the tax burden should be distributed in an equitable fashion. This requirement has taken two forms, one calling for taxation in line with benefits received, and the other for taxation in line with ability to pay. Both approaches were reflected in Smith's maxim that ‘the subject of every state ought to contribute towards the support of the government, as nearly as possible in proportion to their respective abilities, that is, in proportion to the revenue which they respectively enjoy under the protection of the state’ (Smith, 1776, vol. II, p. 310). The benefit principle has the advantage that it links the tax and expenditure side of the budget and thus relates to the theory of public goods. The Lindahl price, after all, was the benefit tax par excellence. But benefits are not readily assigned, thus leaving the benefit rule inoperative in most cases. Moreover, as noted before, fee finance, related to the level of individual consumption of public goods, interferes with their efficient provision; nor does the benefit principle admit redistributional uses of the fiscal process.

The ability to pay approach in turn has the disadvantage that it views the distribution of the tax burden (or the resulting change in the distribution of the tax income) as independent of the expenditure side of the budget. Nevertheless, this approach has received primary attention. Beginning with J.S. Mill (1848, p. 804), taxation was viewed as imposing a sacrifice and the problem was how to distribute this sacrifice in an equitable fashion. Justice requires that people in equal positions be taxed equally so as to undergo an equal sacrifice, people in unequal positions, however, are to pay unequal amounts of tax, differentiated so as to involve an equal sacrifice. Underlying this formulation was the assumption of declining, similar, and comparable marginal utility of income schedules. Subsequent refinement by
Edgeworth (1897) and Pigou (1928) differentiated between equal absolute, equal proportional, and equal marginal (least total) sacrifice. Equal marginal sacrifice calls for maximum progression provided only that the utility schedule is declining. Equal absolute sacrifice calls for progressive proportional or regressive taxation, depending upon whether the elasticity of the marginal utility of income schedule falls short of, equals, or exceeds unity. No simple rule, finally, can be given for the case of proportional sacrifice. Authors such as Edgeworth and Pigou, as had Bentham (1802), opted for the equal marginal sacrifice rule, given the utilitarian premise that least total sacrifice (or a maximum level of remaining welfare) should be the goal of rational conduct. Given the further assumption of equal utility schedules, the formulation calls for a move towards equal distribution. But having drawn this basic conclusion, it is then qualified to allow for incentive effects and the resulting shrinkage in the overall level of income which is available for distribution.

The sacrifice theory of tax equity nicely fitted the framework of the ‘old welfare economics’, which was willing to assume inter-personal utility comparison. As this assumption was discarded in the 1930s, equal sacrifice rules became inoperative but subsequently were replaced by the hypothesis of a social welfare function, assigning marginal social utilities to various levels of income. People with equal income should still pay the same tax (the principle of horizontal equity), while differential taxation at different levels of income would be determined in line with society's view of declining social utility as income rises. Notwithstanding Arrow's demonstration that a social welfare function cannot be derived in an unambiguous fashion, such a concept is now widely used in policy evaluation, including cost–benefit analysis and the setting of optimal tax rates.

Definition of income

Dating back to Adam Smith, the analysis of tax equity has focused on income as the index of ability to pay. While expenditures or consumption have entered as alternatives, income has received the major attention. But the definition of income for purposes of taxation is not obvious, especially not in the context of a highly complex financial and industrial economy where income may be received and used in a variety of forms. A large part of tax analysis has thus been concerned with the definition of income and its application in this complex setting. The analysis has proceeded from the basic concept of net income (Schanz, 1896; Simons, 1938) as accretion to wealth or, which is the same, increase in net worth plus consumption. On this basis, a host of specific issues are dealt with, including the treatment of unrealized gains, depreciation, interest paid, income in kind, imputed income, as well as many other items. While economists have argued for a broad and comprehensive income base which would permit the needed revenue to be obtained at lower rates, they have had only limited success. The tax base has been diluted by an expanding net of tax preferences and it remains to be seen whether a political consensus for base-broadening can be reached. The problem is complicated by the fact that not all omissions from the tax base reflect gross efforts at tax avoidance. Others may be viewed as providing incentives to secure policy objectives which may be valid on their own terms. Economists have opposed such use of ‘tax expenditures’, noting that the underlying policies, if valid, may be pursued more efficiently through the expenditure side of the budget, including subsidies to solicit private sector responses. More recently, the problem of tax base definition has been complicated further by the impact of inflation. With ability to pay relating to real rather than nominal income, inflation adjustments are appropriate, both with regard to the indexing of rate brackets and the
measurement of capital gains and interest income.

A further central issue relates to the tax treatment of the corporation. The purist position has been that equity in taxation refers to the tax treatment of individuals, and that all income ultimately belongs to them, be it directly or via their ownership of legal persons such as corporations. From this it is concluded that corporate source income should be taxed to its owners, and not be subjected to an additional or absolute tax at the corporate level. Dividend and interest disbursement by the corporation should be taxed to the shareholder, as should undistributed earnings. For purposes of administration, shareholders’ taxes on corporate source income may be withheld at the corporate level, but they would then be credited under the individual income tax. This approach, however, is rarely followed. Instead, a separate corporate tax is imposed and corporate source income if retained is allowed for but imperfectly at the individual shareholder level.

Finally, and of increasing importance, the structural problems of the income tax are complicated by international capital flows and multiple jurisdictions. Techniques have been devised to protect capital income against multiple taxation, and the question of which jurisdiction (e.g. origin or destination) is entitled to a particular tax base has been debated.

**Consumption base**

While primary focus has been on the nature of income as the tax base, consumption has been considered as an alternative thereto. Hobbes (1651) argued at an early point that a person should be taxed on what he takes out of the pot (i.e. consumes) and not on what he adds (i.e. saves). Also, economists from Mill to Marshall, Pigou and Fisher, have held that the income tax involves a ‘double taxation’ of saving. By taxing income when saved and then taxing interest thereon, the tax differentiates unfairly against savers and in favour of consumers, and an excess burden or efficiency cost results from such tax discrimination against saving. The case for a consumption base was impeded, however, by the assumption that it would have to be applied in the form of ‘in rem’ taxation, i.e., through excises or general growth income taxes such as the retail sales or value added tax (see Kay, 1987). Because of their impersonal nature, such taxes would not be acceptable on equity grounds. This objection no longer applies, as the case for the consumption base has been reformulated in the context of a personal expenditure tax (Kaldor, 1955), with personal exemptions and progressive rates applicable as under the income tax.

Much recent attention has been given to the way in which a comprehensive expenditure base would be computed. Determined as cash income plus net borrowing minus net investment, consumption would be arrived at as a residual, rather than by attempting the aggregation of outlays. Determination of the expenditure base would bypass certain central difficulties of income determination (especially the treatment of postponed income, unrealized gains, and depreciation), but new problems would arise as well, and pressures for base preferences would not disappear. Difficulties would have to be met, especially in relation to the transition from income to expenditure taxation.

There is also the question whether consumption is indeed the correct base. The expenditure tax avoids disincentive to saving and gives equal treatment to individuals who consume early and late in their lives. But preference is given to those who make gifts and leave bequests. Thus critics hold that the index of equality should be defined as equal present value of potential (not only actual) consumption. It then follows that bequests and gifts should be included in the testator’s expenditure base. Also, it may be
argued that the gain from saving not only consists in increased future consumption but that the holding of wealth itself carries utility, allowance for which may call for a supplementary wealth tax. Viewed as the equivalent of a wage income tax, the expenditure tax stands in uneasy contrast to the traditional view that if anything income from capital should be taxed more heavily than income from wages. The preceding discussion of the tax base has focused on income and expenditures as the primary options. In a fuller treatment, other forms of taxation, in particular the property tax and payroll tax, would have to be considered as well. Indeed, the growth of tax structures has reflected the changing patterns of economic institutions and availability of ‘tax handles’. What are good taxes for a highly developed financial economy such as the US of today were not feasible when selective property taxes provided the main revenue source under colonial conditions. Nor can the same tax rules be applied to developing countries of today. Moreover, the choice of appropriate taxes differs at the central and local levels of government, all of which renders the problem of tax structure design richer and more complex than can be accounted for here.

Efficiency rules

An equitable distribution of the tax burden is one important attribute of a good tax structure. But it is not the only one. We now turn to the further and related issue of efficiency in taxation. As Adam Smith noted (1776, p. 310), taxes ought to be designed so ‘as to take out of the pockets of the people as little as possible over and above what it brings into the public treasury of the state’. Compliance and collection costs should be minimized, but this is not all. At a more subtle level, as later discussion has shown, a given revenue should be drawn from any one taxpayer so as to impose the least welfare loss. Taxes other than lump sum taxes impose an efficiency cost, i.e., leave the taxpayer with a loss which exceeds the value of revenue which government obtains. In the extreme case, a taxpayer may be burdened while there is no revenue gain: for example, a person may cease to consume a taxed product, leaving the treasury without gain and forcing the taxpayer into a less satisfactory consumption mix. Or, imposition of an income tax may induce the taxpayer to substitute leisure for income, thereby reducing the tax base while burdening him with a less satisfactory work–leisure choice.

The measurement of deadweight loss or loss of consumer surplus as a triangle under the demand curve was anticipated by Dupuit (1844) and Jenkin (1871), and was subsequently developed by Marshall (1890, Book III, Chapter 6). Modern discussion of deadweight loss begins with Pigou's treatment of announcement effects (1928). Assuming leisure to be fixed, the optimal solution (which minimizes deadweight loss) calls for all products to be taxed at a uniform ad valorem rate, but the problem is more difficult if leisure is allowed to vary. Since leisure as such cannot be taxed, the taxation of products complementary to leisure must take its place. As first shown by Ramsey (1927), deadweight loss is minimized by imposing a set of differential ad valorem rates, such as to reduce the production of all commodities in equal proportion. After an interval of nearly fifty years, this rule then laid the basis for the theory of optimal taxation (Diamond and Mirrlees, 1971). Discussed elsewhere (see optimal taxation), it will not be expanded on here.

Further problems arise in moving from the optimal treatment of a particular taxpayer to that of the group. If the utility function of all taxpayers is assumed to be the same, no difficulty arises. But if it is allowed to differ, the ideal pattern of optimal taxation would call for the tailoring of differential rates of
tax to the particular preferences of each taxpayer. Since this is impossible, a general tax formula has to be used, based on representative behaviour. This bypasses issues of horizontal equity, issues which arise precisely because behaviour patterns differ.

**Shifting and incidence**

Economists have for long been aware that there exists a difference between the point at which a tax is imposed (its statutory incidence) and that at which its final incidence comes to rest. The in-between process or shifting has filled the largest chapter in the history of public finance, and by its nature as market economics has developed in close linkage to the general body of economic theory. In the context of the Physiocratic model, only a tax on land could be productive as only land was a true source of income. The classics continued to focus on the division of output among factor shares, but the addition of capital to land and labour provided a three-factor model. This expanded model not only fitted the analytical scheme but also reflected the social structure of the times. Ricardo in particular devoted a large part of his treatise to this aspect of taxation. He agreed with the Physiocrats that a tax on rent cannot be shifted, but replaced the view of land as the basic source of income by recognition of rent as an intra-marginal return which does not affect price. A tax on wages must in the short run be borne by profits, so he held, since wages are at subsistence and cannot be reduced. But accumulation declines in the longer run, forcing a reduction in population. The same holds for a tax on necessities. Taxes on luxury products are absorbed by the payee as are taxes on profits. But the latter once more reduce accumulation, and hence the demand for labour. In the end only luxury consumption remains as a solid tax base.

This simple solution crumbled with the subsistence hypothesis. Replaced by a generalized theory of factor pricing, based on marginal products, no factor share remained immune to taxation, and tax incidence had to be viewed in the context of a general equilibrium system of competitive factor and product pricing (Walras, 1874). With factor and product pricing interacting in a general equilibrium setting, a product tax might come to affect the position of households from the sources as well as from the uses side of their account, just as a tax on factor income might come to be felt from the uses as well as from the source side. Advancing in many directions, the theory of incidence came to distinguish between partial and general taxes, short and long run results, as well as outcomes in competitive and imperfect markets. Moreover, while the classics had been concerned primarily with the distribution of the burden among factor shares, subsequent concern turned to the more complex issue of burden allocation among income groups.

Analysis of partial product taxes in terms of supply and demand curves and their elasticities were first undertaken by Jenkin (1871), developed by Marshall (1890), and extended in detail by Edgeworth (1897). As concluded later (U. Hicks, 1947), a tax would be divided between buyers and sellers in inverse relation to the elasticity of substitution in supply and demand. As first suggested by Barone (1899) and later developed by J.R. Hicks (1939), a distinction was drawn between the income and substitution effects of a tax. As the two effects contradict each other, the net effect of an income tax on factor supply was no longer evident. Moreover, it no longer followed that a progressive tax schedule must depress work effort more than would a proportional one. The former, to be sure, involves higher marginal rates at high levels of income, and hence imposes a more severe substitution effect on such
taxpayers; but the latter requires higher rates further down, so that the net effect is not evident. While most incidence analysis has been conducted in competitive markets, attention has also been given to non-competitive conditions. Cournot (1838) early on showed that a tax on monopoly profits cannot be shifted, but later analysis dealing with other forms of market imperfection showed that profits taxes may indeed be passed on. Returning to the competitive case, analysis has focused on the incidence of profits taxes imposed on selected industries only. As Marshall (1890) had pointed out, such profits in the short run are quasi-rents so that the tax stays put; but given sufficient factor mobility, such is not the case in the longer run. A reduction in the return to capital in any particular industry eventually comes to be shared by capital at large. As capital moves from the taxed to tax-free industries, net returns are equalized. In the process, consumers and other factors may come to share part of the burden (Harberger, 1974).

The emergence of neoclassical growth models (Solow, 1956) soon invited a reformulation of long run incidence in the classical tradition (Krzyzaniak, 1967; Feldstein, 1974). Incidence under steady growth is shown to depend on savings propensities as well as the elasticities of factor supplies. Thus substitution of a tax on capital income for an equal tax on labour income will leave part of the burden on labour, even if factor supplies are inelastic, provided that the propensity to save out of capital income is higher; and capital income will bear the entire burden, even if labour supply is elastic, provided that the propensities to save are the same.

As is not infrequently the case, theory advanced more rapidly than its empirical verification. Econometric testing of incidence outcomes has been undertaken but rarely (Musgrave and Krzyzaniak, 1963) and has led to controversial results. Instead, two more hypothetical approaches have been undertaken towards quantitative estimation of tax-burden distribution. One approach has relied on what seem reasonable assumptions regarding the shifting of particular taxes, which assumptions are then implemented on the basis of available income and expenditure data (Colm and Tarasov, 1940; Pechman and Okner, 1974). The other involves simulation of a general equilibrium model, reflecting the observed structure of the economy. This model is then made to respond to the introduction of particular taxes (Shoven and Whalley, 1984), and the resulting changes in household positions are observed. The former approach has the advantage that the implications of various shifting hypotheses can be tested, but it fails to allow for second round effects. The latter has the advantage of accounting for a full sequence of adjustments and includes deadweight losses in the burden estimation, but it has the disadvantage that the result are drawn from the premise of perfectly competitive markets. In comparing the two, much depends on the weight of first round effects.

public goods experiments

Rachel T.A. Croson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economic theory often cites the existence of goods with externalities as justification for government intervention, either as taxation to fund goods with positive externalities which would otherwise be underprovided, or as regulation on goods with negative externalities which would otherwise be overprovided. A series of experiments tests these predictions of under- or over-provision. This article describes the landscape of public goods experiments, identifying similarities and differences between them and summarizing the broad findings.

Article

Since the vivid description of the Prisoner's Dilemma game and the accompanying tension between self-interest and efficiency, economists, political scientists, psychologists, sociologists and others have wondered about how individuals resolve these conflicting motivations. Many have investigated this question by experimentally examining behaviour when individual interest and group interest conflict. This research goes under different names – for example, social dilemmas in psychology, commons dilemmas in political science and public goods problems in economics.

This article does not provide a comprehensive review of this research; other excellent reviews aimed at economists (Ledyard, 1995), psychologists (Dawes, 1980) or sociologists (Kollock, 1998) exist. Instead, I highlight the different categories of public goods problems and introduce their commonalities.

The rest of this article is organized as follows. First, I offer some definitions of characteristics that public goods problems share. Next I discuss some dimensions on which they differ, and how these dimensions translate into different equilibrium and efficient outcomes. Then I describe three specific public goods problem types that have been extensively studied in the economics literature: the voluntary contribution mechanism, the provision point mechanism and the common pool resource. I conclude with a description of other games that have been studied, but where more work could be done.

Similarities

The common feature in public goods settings is the existence of externalities. In public goods problems, individuals can use private resources to provide goods that have positive externalities for others. Since some social benefits are not captured by the individual making the decision, this results in under-provision relative to the socially optimum level. Self-interested economic theory, then, argues that these goods will be under-provided, justifying taxation as a role for government.

Parallel to the public goods situation is the case of public bads. Here, individuals receive private resources by producing goods that have a negative externality for others. Since some social costs are not captured by the individual making the decision, this results in overprovision of public bads relative to the socially optimum level. Self-interested economic theory,

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_P000056&goto=8&result_number=03680
then, argues that these goods will be over-provided, again justifying a role for government, here in regulation. (A number of models have extended the existing theory to internalize the externalities. In models of altruism – for example, Becker, 1974; Andreoni, 1989 – the utility function of one party includes the consumption of others. Thus, when an action creates positive externalities, the value from it is increased over the self-interested model. Charness and Rabin, 2002, posit that individuals care not only about their own consumption but also about social welfare directly. These other-regarding preferences can internalize some of the externalities in public goods problems, but typically the over- or under-provision problems are not eliminated.)

The defining characteristic of the public goods problems described here, however, is the existence of positive externalities. My actions affect others, and I do not take this effect (sufficiently) into account in my own maximization problem. Often these problems are symmetric; each individual faces the identical conflict, but this is not necessary for there to be a public goods problem. For a problem to exist, it must only be that the individual's welfare and the group's (social) welfare conflict.

Differences

The largest, most important and least-recognized difference in public goods situations is the production function. How does an individual's action create positive or negative externalities for others? Different production functions have different implications for equilibrium predictions as well as socially optimal outcomes.

A second important dimension on which these situations differ is the decision space. Public goods problems can involve acting to provide goods with positive externalities at a private cost, refraining from acting so as to avoid imposing negative externalities on others at a personal cost, or acting to capture what would otherwise be public benefits for private consumption. Unlike the first dimension, these differences in the decision space have only a superficial impact on the equilibria; that is, one can easily describe 'not polluting' as 'producing a public good'. However, they may affect how individuals think about (and act in) these problems.

To clarify these differences, let's examine the three classic games discussed below in terms of the production function and decision space. In the voluntary contribution mechanism (VCM), the decision space involves giving. Individuals are given an endowment, which they can use for their private consumption or to produce the public good. Their allocations toward the public good provide value for others in the experiment (positive externalities). The production function of the VCM game most extensively studied is linear (thus it is sometimes also called a linear public goods game). The more that is allocated toward the public good, the greater are the social benefits in a linear fashion. This linearity means that (with appropriate parameters as discussed below) this game has a unique Nash equilibrium in which no participant allocates any resources towards producing the public good. Deviations from the equilibrium are both welfare-enhancing and represent deviations from pure self-interest maximization. They are thus referred to as 'cooperation', and concepts like altruism, warm glow and reciprocity are offered as their explanation.

In contrast, consider the provision point mechanism (PPM). Again, this game typically has a giving decision space. Individuals are given an endowment which can be allocated to private consumption or towards providing the public good. But, in contrast with the VCM, in the PPM the production function involves a threshold. If enough resources are collected, then the public good is provided and all receive its benefits. If too few resources are collected, then the public good is not provided and no positive externalities are enjoyed. The threshold nature of this production function has critical implications for the equilibria of this game. With appropriate parameters (discussed below), the full free-riding equilibrium still exists. But there also exist a set of efficient equilibria, in which the public good is exactly provided with each individual contributing a share of its cost. In each of these equilibria, the share contributed by each individual varies. (For example, there may be one equilibrium in which I contribute 80 per cent and you contribute 20 per cent of the cost of providing the public good, and another where I contribute 20 per cent and you contribute 80 per cent.) The problem then becomes one not of cooperation but primarily one of coordination: how do we select among these efficient equilibria? Formally, this game can be thought of as a large battle-of-the-sexes game (a game of impure coordination), with multiple equilibria each of which is somebody's favourite.

Finally, consider the common pool resource (CPR) game. Here the decision space involves taking; for example, individuals can harvest grass from the commons for personal gain. Surprisingly, these experiments are often described as giving games, with negative externalities rather than positive, as in the VCM or PPM. So the decision is made on 'how many hours to spend grazing' with the resulting negative externalities as cattle eat more grass. The production function used in CPR games is typically nonlinear. A small amount of harvesting creates more benefit for the individual than harm to the society (and is thus socially efficient). However, as the individual harvests more, the personal benefits decrease and the social costs increase until societal costs outweigh private benefits (the socially optimal point). With appropriate parameters (described below), however, private benefit is still above private costs, leading individuals to continue harvesting past the socially efficient point. Eventually, private benefits equal private costs, leading individuals to stop harvesting. These equilibria are thus internal (individuals typically harvest more than zero but less than the full amount) but still suboptimal (total harvesting is larger than the socially optimum level).

There are many additional dimensions on which these games can vary. For example, experimenters have varied the number of players from two (the classic Prisoner's Dilemma game) to as many as 100 (Isaac, Walker and Williams, 1994). The particular parameters can vary, subject to constraints that preserve the public goods nature of the problem. The institutional rules can vary, participants can decide simultaneously or sequentially, they can discuss the game in advance or not, and so on. The games can be (finitely) repeated or one-shot. I discuss some of these variations in the sections below, but their impacts on the equilibria of the games are straightforward.

In summary, when a look at a game, however, it is critical to understand the production function that is being used to translate decisions
into outcomes (positive/negative, linear/threshold/nonlinear), and the decision space that participants face (giving/taking/refraining from action). These dimensions have important impacts on the equilibrium predictions, the observed behaviour and the attributions that one can make about the causes of differences between the two.

The voluntary contribution mechanism (VCM)

The work of Marwell and Ames (1979; 1980; 1981) is often cited as the earliest VCM experiments. Unfortunately these early experiments did not involve a linear production function. Instead the return from the public account was discrete (chunky) although some of the experiments involved a linear approximation (for example, 1981, study I). Furthermore, the experiments were relatively uncontrolled; subjects had instructions mailed to them at home, were individually called and had the instructions explained to them, and then called back one week later and made their (one-shot) decision by phone.

The first paper using a linear VCM in a controlled lab setting was Isaac, Walker and Thomas (1984). This paper set a number of precedents for how such experiments are run. In this experiment, participants were brought into the lab and arranged into fixed groups of four. In each period, each group member was given tokens, which he could allocate between a private account and a group account. Tokens allocated to the private account earned 1¢ per token. Tokens allocated to the group account earned 0.3¢ per token for each member of the group, whether or not he had contributed to the group account. As the production function is linear, these parameters remain constant regardless of how much is contributed.

More generally, for there to be a public goods problem in these linear games, a few conditions must be satisfied. First, the return from the public good to the individual must be lower than the return from the private good (0.3<1). This ensures that individuals do not have an individual incentive to contribute, and that the dominant strategy equilibrium in the stage game is thus to contribute zero tokens. Furthermore, the social benefit from contributing toward the public good must be greater than the social cost (0.3*4=1.2>1). This ensures that contributing toward the public good is socially efficient.

The game is finitely repeated for ten periods, to allow for convergence to (and learning of) the equilibrium. In the finitely repeated game, backward induction results in the unique Nash equilibrium of zero contributions. Deviations from that equilibrium are attributed to cooperation, altruism, reciprocity or various other-regarding preferences.

A number of precedents set in this original article have been used in subsequent research. Many papers use a group size of four, although some have gone as low as two and others as high as 100. Most experiments have participants 'allocate' tokens between multiple funds rather than 'contribute' towards a public good, as this experiment did. Participants typically have multiple tokens to allocate rather than simply one. Most papers use repetition with fixed groups, and many choose ten periods.

The results from this wide variety of experiments are quite robust. First, on average, contributions to the public good begin at about half the endowment of tokens. Second, there is considerable variation in the decisions of individuals. Third, those contributions reduce over time until the contributions in the final round are 10–20 per cent of the endowment. An example of this pattern of contributions is depicted in Figure 1. A number of interesting papers have hypothesized and tested for the source of these regularities. Some explanations include errors (Palfrey and Prisbrey, 1997), confusion (Andreoni, 1995b), strategies and learning (Andreoni and Croson, 2008), and reciprocity or conditional cooperation (Croson, 2007), among others.

Figure 1
Average contributions to public account in VCM. Source: Croson (2007).
Variations in the parameters have been explored as well; individual papers manipulate group size (Isaac and Walker, 1988b), the ratio of the return from the public good to the return from the private good (Isaac and Walker, 1988b), the existence of communication (Isaac and Walker, 1988a), fixed groups (Andreoni and Croson, 2008), anonymity (Laury, Walker and Williams, 1995) and framing (Andreoni, 1995a). Recent work in this area extends the paradigm to incorporate more realistic assumptions, including heterogeneity of players (Buckley and Croson, 2006), endogenous group formation (Croson, Fatas and Neugebauer, 2005), and punishment/reward (Fehr and Gächter, 2000). Data has been collected from various subject pools, including children (Krause and Harbaugh, 2000) and residents of Asian slums (Carpenter, Daniere and Takahashi, 2004). (For a fascinating look into underappreciated but related psychology literature, see research on social loafing, reviewed in Karau and Williams, 1993.)

In summary, the VCM captures the pure tension between individual gains and social efficiency. It is thus used in many settings and by many researchers to investigate the causes (and consequences) of this tension, as well as to describe behaviour in the world.
The provision point mechanism (PPM)

One concern with the VCM is that in equilibrium the public good is not provided at the socially efficient level. Bagnoli and Lipman (1989) discuss a logical response to this problem: add a threshold (or provision point) to the production process. The threshold needed to provide the public good is announced. If at least that much is allocated to the group account, then the public good is produced; if not, no public good is produced.

It is straightforward to see that a VCM can be ‘discretized’ to the PPM by adding a threshold. With the appropriate parameters (discussed below) this game now has a set of efficient Nash equilibria in which the public good is exactly provided. There are also inefficient equilibria of this game, in which the public good is not provided, but this mechanism nonetheless represents a theoretical improvement over the VCM.

There are some parameter values necessary for the existence of these efficient equilibria. In particular, imagine the threshold is $T$, the value from private consumption is 1 and individual endowments are $E_i$. Define $v_i$ as an individual's value from the public good. For an efficient equilibrium there must exist a set of contributions $\{\sigma_i\}$ such that $\sum \sigma_i = T$.

Furthermore, the individual rationality constraints must be satisfied $(\forall i) \sigma_i \leq \min \{E_i, v_i\}$ and providing the public good must be efficient $T \leq \sum v_i$.

Additional assumptions are needed before this mechanism is completely described. When the threshold is not reached, the resources contributed to it can be returned or can be lost. This feature has been called the ‘money back guarantee’ in psychology, and in economics is the refund (Isaac, Schmidtz and Walker, 1989; Bagnoli and McKee, 1991). The existence of a refund does not affect the set of efficient equilibria, but does change the set of inefficient equilibria. With no refund, there is one (unique) inefficient equilibrium of zero contribution. With a refund, there are many (weak) inefficient equilibria in which some is contributed towards the public good, but not so much that any player can supplement to reach the threshold. Those contributions are then refunded, making the contributors indifferent between these strategies and contributing zero.

The second dimension is the disposition of resources above the threshold. This is referred to as the rebate (Marks and Croson, 1998). Experiments have been run including no rebate (excess contributions are lost), proportional rebates (excess contributions are returned proportionally based on contributions), and utilization rebates (excess contributions are used to provide the public good in a VCM fashion). None of these changes the set of equilibria.

While the PPM has the advantage of the existence of efficient equilibria, it has the disadvantage of too many equilibria. For example, in a typical parameterization used by Croson and Marks (1998), five players each had 55 tokens to allocate. Tokens allocated to the private account earned 1¢ each. If there were at least 125 tokens allocated to the public account, each participant in the group received 50¢. These parameters satisfy the conditions above; the collective benefit from the public good (5 people × 50¢=$2.50) is greater than the social cost of provision ($1.25). There exists a set of allocations such that the public good is provided; one is the unique symmetric equilibrium in which each player allocates 25 tokens, the threshold is exactly met, and each participant receives their value of 50¢, strictly greater than their costs of 25¢.

Unfortunately, this is not the only efficient equilibrium. In particular, the set of allocations $\{25, 25, 25, 24, 26\}$ is also an equilibrium, as is $\{25, 25, 25, 26, 24\}$, although player 4 prefers the former and player 5 the latter. All told, there are 4,052,751 efficient equilibria using these parameters. Thus the main problem in the PPM is not one of cooperation; avoiding the inefficient outcome as in the VCM. It's a problem of coordination, of choosing which of the many efficient equilibria the group will play.

The coordination problem is difficult enough in the stage game. However, in the lab this game is typically finitely repeated. In the repeated game, the number of potential equilibria grows exponentially, as any sequence of stage-game equilibria are themselves an equilibrium of the repeated game.

In practice, almost no instances of the inefficient equilibria are observed. Group contributions tend to cycle around the efficient equilibrium level, although they are almost equally likely to be above the threshold as below. Examples of group contributions in the PPM can be seen in Figure 2.

Figure 2

Group contributions to public account in PPM, four groups. Source: Croson and Marks (2000).
Further research has investigated other dimensions of the PPM. These include the effect of subject pool (Cadsby and Maynes, 1998), binary versus continuous giving (Cadsby and Maynes, 1999), heterogeneous valuations (Croson and Marks, 1999), identifiability of contributions (Croson and Marks, 1998), incomplete information (Marks and Croson, 1999), and framing (Sonnemans, Schram and Offerman, 1998).

The PPM has a number of important and interesting properties. It allows for efficient equilibria, thus to some extent ‘solving’ the public goods problem. However, this solution brings costs: too many equilibria and the need to coordinate among them. This distinction, between the cooperation motive of the VCM and the coordination motive of the PPM is a critical and often-overlooked one.

The common pool resource game

The structure of the CPR game is based on work by Gordon (1954) and Hardin (1968) on the tragedy of the commons. In the typical tragedy, ranchers graze their herds either on their
private land or on the commonly owned land in each village. Since grazing on the commons is free, individuals prefer it to using their own land, which can be used to grow cash crops. However, grazing imposes a negative externality on others; if my cows eat the grass, there is less left for your herd. The CPR game, thus, is a *continuous taking* game; each unit of grass that I take exerts a negative externality on the rest of the village.

Unlike the VCM, the externalities imposed are typically nonlinear, with public costs initially being lower than private benefit, but rising until the two cross. Thus the game has internal equilibria, in which more grazing than is optimal is predicted. (These games are similar to a class of *rent-seeking* games, which have recently been experimentally explored. Rent-seeking games are beyond the scope of this article; but see Önçüler and Croson, 2005, for some recent work.)

In the first CPR economics experiment, Walker, Gardner and Ostrom (1990) arranged subjects into groups of eight. Each participant was given a homogeneous endowment and was told he could allocate this endowment between two markets. Like the VCM, the private market paid a fixed amount, 5¢ per token. The public market (the common pool) had externalities for other group members’ consumption. Unlike the VCM this externality was negative rather than positive. Also unlike the VCM, the externality was nonlinear, with increasing social cost. Conceptually, allocating resources to the public market captures the idea of grazing the herd on public land.

When $x_i$ is the amount player $i$ allocates to the public market, the earnings from the public market for player $i$ are:

$$x_i / \sum x_i \left( 23 \sum x_i - 0.25 (\sum x_i)^2 \right).$$

The negative squared term creates the nonlinearity. If no one is allocating resources to the public market, an individual earns more from that market than the private one (the first token allocated there earns 22.5¢ versus 5¢ in the private market). However, this return quickly diminishes, so the value from investing in the public market falls below the value from investing in the private market as the number of tokens increases. This captures the negative externalities. For each token that player $i$ invests in the public market, the marginal value of player’s $j$’s investment in that market is lowered.

The self-interested, symmetric Nash equilibrium in this game is for each player to invest eight tokens in the public market (for a total investment of 64 tokens). (When each participant invests nine tokens in the public market, the return for that marginal token is exactly 5¢. The authors assume that, when indifferent participants choose not to impose negative externalities on others, thus the equilibrium of eight tokens is used.) This equilibrium prediction is parallel to the prediction of full free-riding in the VCM. In contrast, the symmetric, socially efficient solution is for each participant to invest five tokens in the public market. This is not an equilibrium, however, since each individual privately captures more by investing further in the public market. This capturing is at the expense of the other players, who suffer the negative externality imposed. So five tokens is the socially optimal level, and is parallel to the prediction of full contributing in the VCM.

If behaviour in the CPR were parallel to that in the VCM, we should see allocations to the common market of between eight tokens (the equilibrium) and five tokens (the social optimum). As in the VCM, the stage game described above is repeated finitely many times, either 20 or 30 rounds, depending on the particular parameters. (A parallel literature in CPR games examines *dynamic* versions of the game, in which the resource replenishes itself round to round, with the replenishment rate being dependent on the harvesting rate observed. These are sometimes referred to as *renewable* CPR games. Equilibria in these dynamic games are more complicated, and Herr, Gardner and Walker, 1997, experimentally compare the different games.)

The results from the experiment can be seen in Figure 3. The solid line represents the equilibrium prediction, while the dotted line represents the social welfare maximizing outcome. Unlike the VCM, where contributions lay between these two, here contributions lie on the opposite side of the equilibrium. This indicates excessive allocation to the public market, and excessive negative externalities, over and above the equilibrium prediction.

Figure 3
This result of less-than-Nash levels of cooperation is replicated in other experiments, reviewed in Ostrom, Gardner and Walker (1994). Other work also reviewed there examines other questions in CPR games, including probabilistic destruction, communication, monitoring and sanctions, voting and heterogeneity.

One lingering puzzle remains: why are subjects more generous/cooperative than the equilibrium in the VCM and less generous/cooperative than the equilibrium in the CPR game? A number of studies have investigated this question by adding complexity to the VCM to make it resemble the CPR (for example, the stream of research on nonlinear VCM games below). Others investigate framing, suggesting it is the difference between providing a positive externality in the VCM and a negative externality in the CPR game. Unfortunately no study has offered either a definitive experiment or compelling data to explain why the outcomes from these games differ.
In addition to the games described above, a small literature explores different types of public goods games. A number of papers examine nonlinear VCMs, with internal equilibria (see Laury and Holt, 2008, for a review). Here the production of public good is nonlinearly related to the amount allocated to the public account. This yields an internal social optimum and Nash equilibrium level of contributions. As before, parameters are set so that the public good is under-provided in equilibrium.

Others have explored markets with externalities rather than public goods per se (for example, Plott, 1983). Still other researchers combine these games in creative ways, for example a PPM with a VCM for excess contributions (as in the utilization rebate of Marks and Croson, 1998), or a PPM with a VCM for under-contributions (as in Vesterlund, Duffy and Ochs 2005).

Finally, a number of papers have experimentally tested other proposed mechanisms for solving the public goods problem. For example, Chen and Plott (1996) provide a test of the Groves–Ledyard mechanism (a mechanism designed to elicit individuals values for public goods). Reviews of experiments using incentive-compatible mechanisms can be found in Chen (2008). These literatures are less developed than the previous three games, a disadvantage when trying to summarize a stream of research but an advantage when seeking a new contribution.

Commonalities and puzzles

The underlying similarity between all public goods experiments is the existence of externalities. These externalities can be positive or negative, and they can be linear, nonlinear or involve thresholds. The decisions participants make can be described as giving or taking. These varying situations affect the equilibrium predictions of the games. Individuals are ‘cooperative’ in the VCM; they contribute more towards the public good than equilibrium behaviour would predict. There are many explanations for why this may be the case, including altruism, reciprocity (conditional altruism), warm-glow and errors, but no one causal factor has emerged as dominant.

In the PPM, the issue is not one of cooperation but coordination. On average the efficient equilibrium outcomes describe the data. However, there is also ‘gaming’, with groups sometimes failing to provide the public good as one individual attempts to move towards a more attractive equilibrium. Thus, while outcomes from these mechanisms are more efficient than those from the VCM, the coordination problem is severe and unsolved.

Finally, individuals harvest more than the Nash equilibrium predictions in CPR games. This result contrasts with the VCM; here individuals are more competitive than the equilibrium prediction. The source of these differences is still unexplored and represents an excellent direction for future research.

Summary

The tension between self-interest and social efficiency is one we experience every day. Experiments like those discussed in this article have been developed to explore how humans resolve this tension. Results from these experiments highlight the impact of different public goods structures, institutional arrangements and repeated interactions on human behaviour. Ultimately they help us to design mechanisms to better provide public goods, and allow for a deeper understanding of human motivations in the wide set of activities involving externalities for others.

How to cite this article

The development by Paul Samuelson (1954; 1955) of the modern theory of public goods must be counted as one of the major breakthroughs in the theory of public finance. In two very short papers Samuelson posed and partly solved the central problems in the normative theory of public expenditure:

1. (a) How can one define analytically goods that are consumed collectively, that is, for which there is no meaningful distinction between individual and collective consumption?
2. (b) How can one characterize an optimal allocation of resources to the production of such goods?
3. (c) What can be said about the design of an efficient and just tax system which will finance the expenditures of the public sector?

None of these questions was entirely new to the literature of public finance. Indeed, more than 250 years ago David Hume (1739) noted that there were tasks which, although unprofitable to perform for any single individual, would yet be profitable for society as a whole, and which could therefore only be performed through collective action. The theme was later taken up by Hume's friend Adam Smith, who maintained that one of the duties of the state consisted in erecting and maintaining certain publick works and certain publick institutions, which it can never be for the interest of any individual or small number of individuals, to erect and maintain; because the profit would never repay the expense to any individual or small number of individuals, though it may frequently do much more than repay it to a great society. (Smith, 1776, pp. 687–8)
Apart from this insight, however, the progress made over the next centuries, certainly with regard to problems (a) and (b), was rather modest. From the point of view of the history of ideas, this is hardly surprising. What is required is a satisfactory theory of market failure. But this presupposes a clear understanding of the optimality properties of the market allocation of resources, which was not established until the modern development of Paretian welfare economics in the late 1930s. More was undoubtedly achieved with respect to problem (c), reflecting the fact that problems of tax incidence had been a central area of theoretical analysis ever since the time of the classical economists, and that criteria of just taxation had developed independently of any analysis of the expenditure side of the public budget. Still, Samuelson's formulation was in every respect a great leap forward, presenting an integrated solution to all three problems, and determining the research agenda for the years to come. It is therefore natural to begin by setting out the basic elements of his model. In a short article it is of course impossible to do justice to the large literature in this field. For more comprehensive surveys the reader is referred to the textbooks by Atkinson and Stiglitz (1980, lectures 16–17) and Myles (1995, ch. 9), and the article by Oakland (1987).

The Samuelson model

The aim of the model is to derive conditions for optimal resource allocation in an economy in which there are two types of goods, private and public. It is worth emphasizing that these terms do not prejudge the respective tasks of the private and public sectors; the analysis at this stage is institution-free and can best be considered as representing the problems of a planner who knows the production possibilities of the economy, the preferences of the consumers and his or her own ethical values. The definition of the two types of goods is technological, not institutional.

The nature of the two types of goods is defined by the equations which give the relationship between individual and aggregate consumption. For private goods the total quantity consumed is equal to the sum of the quantities consumed by the individuals, so that

\[
x_j = \sum_{i=1}^{J} x_{ij}, \quad (j = 0, \ldots, J)
\]

(1)

where the superscript refers to individuals and the subscript to commodities. For public goods the corresponding relationship is one of equality between individual and total consumption, namely

\[
x_k = x^i_k, \quad (i = 1, \ldots, I; k = J + 1, \ldots, J + K).
\]

(2)

Individual preferences, represented by utility functions, are then defined over the quantities consumed of private and public goods, so that we can write the utility of individual \(i\) as

\[
U^i = U^i\left(x^i_0, \ldots, x^i_j, x^i_{j+1}, \ldots, x^i_{j+K}\right) = U^i\left(x^i_0, \ldots, x^i_j, x_{j+1}, \ldots, x_{j+K}\right), \quad (i = 1, \ldots, I).
\]

(3)

The definition (2) has given rise to some confusion and controversy. Are there actually any goods which can be described by this definition? The usual answer is that there are some cases of ‘pure’ public goods, like national defence, which can indeed be so described; in such cases consumer benefits are directly related to the total availability of the good in question, and the consumption benefits of any one individual do not depend on the benefits enjoyed by others. This property of public goods is usually referred to as non-rivalry in consumption.
consumption: given the supply of the good in question, the consumption possibilities of one individual do not depend on the quantities consumed by others as they do in the case of private goods. However, many goods that one naturally thinks of as public turn out on closer inspection to have elements of rivalry. A road may satisfy the definition of a public good as long as volume of traffic is low, but with higher density and consequent congestion this will no longer be the case. Accordingly, several studies have been devoted to the analysis of ‘impure’ public goods, combining in some way the properties of private and public goods in the original Samuelson definition; we shall return to this below. It should be observed, however, that the Samuelson formulation does not assume that the benefits derived from the supply of the public good are the same for all, even though availabilities are the same. Neither does it assume that the benefits from public goods are independent of the quantities consumed of private goods. And the elements of rivalry in the road congestion example may be captured by introducing externalities in the consumption of a private good – car use – whose benefits depend on the supply of a public good – the road. Thus, the original Samuelson formulation offers great flexibility of interpretation, and we have been provided with an answer to the first of the main problems noted above.

We now turn to the problem of optimality of resource allocation and begin by characterizing a Pareto optimum for this kind of economy. Since the interesting special features of the model are on the consumption side only, we assume that the conditions for efficient production are satisfied, so that the production possibilities for the economy can be summarized in the transformation or production possibility equation

\[
F(x_0, \ldots, x_j, x_{j+1}, \ldots, x_{j+k}) = 0.
\]

The problems of Pareto optimality may now be formulated as follows: of all allocations satisfying equation (4), find the allocation which maximizes utility for consumer 1, given arbitrary but feasible utility levels for all other consumers. As shown by Samuelson (1955), the solution can be given an instructive graphical solution in the two-dimensional case. We therefore begin with the case where there are two consumers and one private and one public good. In the upper panel of Figure 1 we have drawn the production possibility curve as well as an indifference curve corresponding to the fixed level of utility for consumer 2; since the two curves intersect, there are obviously a number of allocations which satisfy these two constraints. In the lower panel the curve ab shows the consumption possibilities for consumer 1, the points a and b corresponding to the points of intersection in the upper panel. For any point on \(U^2\) between a and b, it must be the case that the two individuals consume the same amount of the public good, while consumer 1’s private good consumption is equal to the vertical difference between the production possibility curve and consumer 2’s indifference curve. The best allocation from 1’s point of view is then given by the tangency between his indifference curve and the consumption possibility curve in the lower panel. This determines the optimum supply of the public good \(x_1^*\) and consumer 1’s consumption of the private good \(x_0^*\) as well as the consumption of consumer 2 \(x_2^*\).

Figure 1

Pareto optimality with one private and one public good
The slope of the consumption possibility curve must of course be equal to the difference of the slopes of the two curves from which it is derived. The tangency point can therefore be characterized in terms of marginal rates of substitution and transformation as

$$\text{MRS}^1 = \text{MRT} - \text{MRS}^2, \text{ or } \text{MRS}^1 + \text{MRS}^2 = \text{MRT}.$$
In more precise mathematical terms this condition can be rewritten (if we let subscripts denote partial derivatives) as

\[
\frac{U_1^1}{U_0^1} + \frac{U_2^1}{U_0^2} = \frac{F_1}{F_0},
\]

(5)

In words: the sum of the marginal rates of substitution should be equal to the marginal rate of transformation between the public and the private good. Or, since the private good may be taken as a numeraire commodity, the sum of the marginal willingness to pay for the public good should be equal to the marginal cost of production. The intuition should be clear: an extra unit of supply benefits both consumers simultaneously; to find the total marginal benefit we have to take the sum of the marginal benefits accruing to all consumers. Problem (2) has been solved.

The mathematical derivation of the corresponding condition in the general case need not occupy us here. To extend the analysis to more than two consumers, we have only to add more terms on the left-hand side of (5). An increase in the number of public goods simply requires us to introduce similar conditions for every such good. To generalize to an arbitrary number of private goods, we note that for any given allocation of public goods, the allocation of private goods should be a Pareto optimum relative to this, so that the usual marginal conditions must hold. This gives us two sets of first order conditions for Pareto optimality, namely:

\[
\frac{U_j^i}{U_0^i} = \frac{F_j}{F_0}, \quad (i = 1, \ldots, i, \ j = 1, \ldots, J)
\]

(6)

\[
\sum_{j=1}^{J} \frac{U_j^i}{U_0^i} = \frac{F_k}{F_0}, \quad (k = j + 1, \ldots, j + K).
\]

(7)

In the two-dimensional case the first order conditions could be taken to describe a true maximum because the diagrams introduced the required convexity–concavity conditions. In the more general case one has to assume quasi-concavity of the utility functions as well as convexity of the transformation surface for the second order conditions to be satisfied. There is of course an element of arbitrariness in the concept of Pareto optimality, corresponding to the arbitrary location of consumer 2’s indifference curve in Figure 1. The model can be closed by assuming the existence of a social welfare function, and the usual assumption is that this is of the Bergson–Samuelson type, where the arguments of the function are the individual utility levels. Maximizing the welfare function \(W(U_1^1, \ldots, U_J^1)\) gives as the optimality conditions first (6) and (7) – since a welfare optimum must be a Pareto optimum – and then a set of conditions for optimal distribution of consumption between individuals. These can be written as
The marginal social utility of consumption should be the same for all. (Note that although the conditions as stated here refer to the consumption of private good 0, they can be converted, by using conditions (6), to express the equality of the marginal social utility of consumption in terms of any private good.)

Suppose now that private goods are allocated through a system of perfectly competitive markets, and that the allocation of resources to public goods also satisfies the efficiency conditions (7) as the result of some decision procedure which is yet to be specified. Imagine further that at least part of the provision of public goods is undertaken by the public sector, and that taxes are needed to finance this. What is the ideal tax system for this purpose? We wish the tax system to satisfy conditions (8), but these are conditional on the remaining first-order conditions being satisfied. Under competitive conditions the marginal rates of substitution will be equal to consumer prices, if we take commodity 0 to be the numeraire good, while marginal rates of transformation will correspond to producer prices. Thus, conditions (6) will be satisfied in a competitive economy provided that consumer prices are equal to producer prices. But this means that there must be no distortionary taxation; the only taxes that are consistent with a fully optimal solution are lump-sum taxes in amounts independent of all components of demand and supply for consumers and firms. This insight is of course well known from the standard competitive model with private goods only, but it is worth restating in the present context as the answer to problem (c).

This exposition of the basic elements of the Samuelson model can be used to put his contribution into historical perspective. Earlier writers on public finance, for example Mazzola (1890), Sax (1924) and Pigou (1928), did in fact apply marginal utility theory to the problem of the optimal supply of public goods, emphasizing the optimality rule that marginal benefit at the optimum should be equal to marginal cost. They failed, however, to develop a definition of public goods that could be used to characterize the difference between such goods and private goods. For the same reason they were also vague about the nature of the marginal benefit and how to measure it in the absence of market prices. Finally, although there is much interesting discussion by the older writers of the ability to pay and benefit theories of taxation, the efficiency aspect of taxation played a very minor part in their writings, and so they were unable to face the basic problem of how to reconcile the objectives of a just distribution and economic efficiency. With the Samuelson formulation all these issues had been clarified, and the foundation had been laid for further progress.

**Distortionary taxation**

The above optimality rules hold for the case where taxation is non-distortionary, that is, where taxes are imposed to raise revenue and to redistribute incomes without disturbing the efficiency properties of the price mechanism. For a variety of reasons such taxes are hardly feasible, and it is interesting to consider the modifications that will have to be made if taxes are distortionary. Pigou (1928) argued that the cost of tax distortions should be taken into account in balancing the costs and benefits of public goods supply:

> Where there is indirect damage, it ought to be added to the direct loss of satisfaction involved in the withdrawal of the marginal unit of resources by taxation, before this is balanced against the satisfaction yielded by the marginal expenditure. (Pigou, 1928, p. 34)

As pointed out by Atkinson and Stern (1974), however, this argument is not necessarily correct. Their analysis is an interesting exercise in the theory of the second best. To abstract from problems of redistribution, consider the case where all individuals are identical. There are two private goods, numbered 0 and 1, and one public good, identified as commodity 2. The representative consumer maximizes his or her utility function $U(x_0, x_1, x_2)$ subject to the budget constraint

$$x_0 + p_1 x_1 = 0.$$  \hspace{1cm} (9)

Thus, there is no lump-sum income, and commodity 0 serves as the numeraire. Given the optimum of the consumer, the government maximizes the sum of the utility functions (a special case of the welfare function in the previous section) subject to the constraint that the resource cost of public goods supply equals the tax revenue. Thus, the government maximizes $JU(x_0, x_1, x_2)$ subject to
\[ t_1 x_1 = p_2 x_2. \]  

(10)

Here \( I \) is as before the number of consumers, \( t_1 \) is the tax per unit of commodity 1 such that \( P_1 = p_1 + t_1 \). The small \( p \)'s denote producer prices, which for convenience are taken to be constant, corresponding to constant unit costs of production in terms of the numeraire. The government determines \( t_1 \) and \( x_2 \) simultaneously.

The analytical details of the model need not concern us here. To understand the result, one should note that from the formulation of the consumer's problem it follows that demand for the taxed good depends on the supply of the public good, so that the demand function can be written as \( x_1 = x_1(P_1, x_2) \). Thus, when the supply of the public good is increased, there will be two effects on the demand for private goods. One is the effect via increased availability of the public good, another is the price effect via increased taxation. It can be shown that the condition corresponding to the Samuelson eq. (7) in this case becomes

\[
\sum_i MRS^i = \frac{p_2 - t_1(\partial x_1 / \partial x_2)}{1 + (t_1 / x_1)(\partial x_1 / \partial t_1)}.
\]  

(11)

If there is no distortionary taxation, the right-hand side becomes simply \( p_2 \), which is the marginal rate of transformation, and we are back to the original Samuelson case. An increase in the tax rate lowers the demand for the taxed good, and the corresponding term in the denominator shows that this 'blows up' the cost of the public good: this is the effect alluded to by Pigou. On the other hand, the additional term in the numerator can in principle be of either sign and may therefore reverse Pigou's conclusions. Suppose that \( \partial x_1 / \partial x_2 \) is positive, meaning that increased supply of the public good increases the demand for the taxed good. Then the relevant social marginal cost of the public good may in fact be lower than the pure resource cost. The point is that in this case the effect of the public good on the demand for the private good serves to counteract the tax effect. The commodity tax is distortionary because it lowers consumption and production of the taxed good. If an increase of the amount of the public good serves to push the quantity of the taxed good back towards its first best optimal level, this could lower the economic cost of production.

This analysis has inspired a considerable literature about the concept of the marginal cost of public funds (MCF). To start from the insight provided by the formula (11), it has been suggested that practical calculations of the optimal amount of public expenditure should be based on the formula

\[ \sum_i MRS^i = MCF \cdot MC, \]

where MC corresponds to \( p_2 \) and the presumption is that \( MCF > 1 \). The use of the MCF for practical cost–benefit analysis of public goods provision – one of the more important applications of the pure theory of public goods – would therefore tend to depress the provision of public goods below the level indicated by the Samuelson rule.

This conclusion may be disputed, however. First, it is not clear that eq. (11) supports the hypothesis that the marginal cost of public funds exceeds 1. Even if we assume, which seems reasonable, that the tax elasticity is negative, complementarity between private and public goods (\( \partial x_1 / \partial x_2 > 0 \)) might lead the right-hand side of (11) to become less than \( p_2 \). However, since the sign and magnitude of the complementarity term must be expected to differ between different types of public sector projects, there is a good case for considering this term to be project specific and therefore not to include it in a general measure of the cost of distortionary tax finance. In this view, it is the tax elasticity of demand that is important for the MCF.

Second, there is one feature of the Atkinson–Stern analysis which calls for particular caution in practical application. This is the assumption that the government optimizes with respect to both public goods supply and the tax rate. In principle, therefore, their results are valid only for an optimal tax system, although it can be shown that the formal expression for the MCF is the same also for a non-optimal tax system (see, for example, Sandmo, 1998). More importantly, however, in the more realistic case where there are many tax rates
which have not been chosen optimally, there is no reason to expect that the MCF will be the same for all sources of tax finance. It will therefore be misleading to speak about the marginal cost of public funds, as if it were a general characteristic of the whole complex system of direct and indirect tax rates.

Third, in order to focus on the efficiency aspects of the problem, Atkinson and Stern made the assumption that all consumers are identical. But one of the reasons why we have distortionary taxation is that they are not, and that governments try to achieve some measure of redistribution through the design of the tax system. As shown by Sandmo (1998), an explicit modelling that takes account of the redistributive objective leads to a measure of the marginal cost of public funds where the efficiency loss from taxation may, depending on the distributional preferences embedded in the government's policies, be partly or wholly offset by distributive gains.

**Types of public good**

In line with the original Samuelson formulation we have so far limited the discussion to pure public consumption goods. Various alternative formulations have been discussed in the literature, and we shall briefly discuss some of these.

We have already observed that many consumption goods that may be classified as public turn out also to have important elements of ‘privateness’. This has two aspects. In the first case it may be argued that a public good like a national park cannot really be enjoyed by the individual without expenditure on private goods such as hiking equipment, and that even such an apparently clear case of a public good should be analysed as a mixed case of a private and a public good. To some extent this argument is based on a misunderstanding of the theory. There is no presumption that the benefit that an individual derives from the availability of a public good be independent of his or her consumption of private goods. Still, it may sometimes be useful to model the interaction between private and public goods consumption in a more explicit manner than is done in the standard formulation. One way this can be done is to take as the point of departure the consumption technology approach and assume that there are some final goods such as road trips and nature hikes that are intrinsically private but that are produced by the individual consumer by means of private and public goods inputs. The second aspect of mixed goods is that the benefits enjoyed by any one individual may depend on the consumption of others, as in the cases of a crowded road or a congested national park. This aspect, too, may be handled by the consumption technology approach by letting other people's consumption of complementary private goods enter every individual's production function for the final good in question. This would be a special case of the Samuelson formulation when in addition it is assumed that some private goods create externalities in consumption. Thus, the advantage of the consumption technology approach to the theory of public goods lies not in greater generality, but in a formulation that captures in a more intuitive fashion a natural way of thinking about public goods. An additional advantage is that the theory becomes more closely related to the practice of cost–benefit analysis, where willingness to pay is typically computed not by observing preferences directly, but by calculating the private cost reductions that would follow from an increase in the provision of a public good. The theory is further elaborated in Sandmo (1973); for an alternative formulation of similar ideas see Bradford and Hildebrandt (1977).

Not all public goods are naturally analysed as consumption goods. One of the classical examples, the lighthouse, is more easily interpreted as a producer good or a factor of production. Public factors of production were first introduced into the theoretical literature by Kaizuka (1965), who derives the efficiency conditions analogous to Samuelson's for the production case. Sandmo (1972) shows how the formulation can be used to derive shadow prices for such goods when the private sector is competitive.

The Samuelson formulation implies that the availability of any public good is the same for all individuals and independent of their decisions about private goods consumption – although, as we have noted, the benefit is not. This ignores the fact that many public goods are available only to individuals residing in a particular location, and that an individual may therefore select the amount available of the public good by changing his or her place of residence. This was first pointed out by Tiebout (1956) in a paper which has since given rise to a rich literature on the important topic of local public goods and, more generally, local public finance. We shall return below to the demand-revealing aspects of mobility between communities. But it is worth noting here that, although the original application of the basic idea was to individual choice among residential communities, there are possibilities of application to other interesting areas as well. In the labour market, workers’ choice among firms might be affected by public good aspects of the working environment which are specific to the individual firm. Following Buchanan (1965), ‘clubs’ has become the generic term for voluntary associations of individuals whose purpose is to provide the members with a public good. Internationally, country-specific public goods might influence the pattern of international migration; in this perspective, almost all public goods would be local, and the original formulation becomes a special case characterized by geographical immobility of the population. For surveys of the theory of clubs and local public goods the reader is referred to Rubinfeld (1987) and Scrocher (2002).

At the other end of the scale from local public goods are global public goods, goods that provide benefits to the whole of the world's population. Examples of such goods are international security, global environmental quality and scientific knowledge. One might perhaps think that in this case the theory is directly applicable, since the complications associated with geographical mobility are ruled out by assumption. On the other hand, additional problems arise because the world is not one jurisdiction but composed of a number of independent nation-states. In the original Samuelson formulation, the economy is at its production possibility frontier; this is evidently a strong assumption even for a national economy, and it becomes even more unrealistic when applied to the world as a whole. Moreover, Samuelson assumed redistribution in the form of individualized lump-sum taxes and transfers; this also is an assumption which is much farther from reality when considered in a global context. Even the assumption of redistribution via progressive taxation, which is a more realistic description of national redistribution policy, is far from the economic realities of the international community of countries.
see Sandmo (2003). If one takes the viewpoint of global welfare maximization and assumes that there are perfect lump-sum transfers both within and between countries, the Samuelson optimality conditions must hold for the world as a whole. In particular, there will be global production efficiency, and the social marginal utility of income must be the same for all individuals. However, if for some reason the international transfers are not made, then production efficiency is in general not desirable. If one assumes that the global welfare function displays inequality aversion, poor countries should not be required to contribute as much to the production of global public goods as their comparative advantage would otherwise call for. But the model also points to a serious problem of incentives, because each country, in deciding how much to contribute to the production of global public goods, finds itself in a strategic situation similar to that of the single individual in the nation state, who has an incentive to be a free rider on the contributions of others (see below). At least if one assumes that national governments are motivated by a fairly narrow concept of national self-interest, there is likely to be an under-supply of global public goods.

Equilibria with public goods

We have concentrated on the theory of public goods as an extension of welfare economics; the central question has been how to characterize optimal or efficient allocations in economies with public goods. But just as in the case of private goods it is interesting to go on from there to consider the equilibrium allocations that would follow from particular institutional arrangements in the economy and to compare these with the optimality conditions. Thus, the theory of public goods ought to be positive as well as normative, a view emphasized strongly in the influential contributions by Buchanan (for example, 1968).

The first clear formulation of a theory of public expenditure which can be given a positive interpretation was presented by Erik Lindahl (1919), who in turn was inspired by Wicksell (1896); an important modern exposition is that of Johansen (1963). In this formulation, individuals bargain over the level of public goods supply simultaneously with the distribution of the cost between them. The bargaining equilibrium is Pareto optimal, implying that the efficiency conditions (7) are satisfied. In addition, each individual pays a price in terms of private goods which is equal to his or her marginal willingness to pay. Formally, let \( \pi^j_i + k \) be the price which individual \( i \) pays for public good \( k \), and let \( P^j + k \) be the producer price or marginal cost. Then the Lindahl equilibrium will be characterized by the condition

\[
\sum_j \pi^j_i + k = P^j + k, \quad (k = 1, \ldots, K).
\]

Thus, at first glance the concept of a Lindahl equilibrium seems to establish an analogue to competitive markets for private goods with the interesting difference that prices should differ from one individual to another, depending on their marginal willingness to pay. This also ties in with older notions of the benefit theory of taxation, according to which taxes were seen as payments for public goods, to be levied in accordance with the benefits which each individual derived from them.

At the technical level it may be noted that there is an interesting ‘duality’ between the definitions of private and public goods on the one hand and the properties of equilibrium prices on the other. In terms of quantities, for private goods the sum of individual quantities consumed adds up to the quantity produced, while for public goods individual consumption equals aggregate production. In terms of prices, on the other hand, for private goods each consumer price equals the producer price, while for public goods individualized consumer prices add up to the producer price.

There is, however, one crucial difference between a Lindahl equilibrium and a competitive equilibrium for private goods. With private goods, individuals facing given prices have clear incentives to reveal their true preferences by equating their marginal rates of substitution to relative prices. Without paying, the individual is excluded from enjoying the benefits of consumption. With public goods this no longer holds. Because individuals have the same quantity of public goods available to them whether they pay or not, they have an incentive to misrepresent their preferences and be free-riders on the supply paid for by others. Moreover, this problem is likely to be particularly severe when the number of individuals is large, since an individual contribution will then make little difference to the total supply. The connection between Lindahl equilibria and the game theoretic concept of the core was discussed by Foley (1970); see also the survey by Milleron (1972).

The equilibrium of the Lindahl model is compatible with individual incentives to reveal preferences truthfully; for this reason Samuelson (1969) has referred to the individual Lindahl prices as pseudo-prices and to the equilibrium as a pseudo-equilibrium. In this case one would conjecture that, because all individuals have the same incentives to understate their true marginal willingness to pay, the Lindahl mechanism would result in equilibrium levels of public goods supply which would be too low relative to the optimum. But there is really no need to associate the problem of preference revelation with this procedure alone; as another extreme, one might think of the case where individuals are asked to state their preferences on the assumption that the cost to them is completely independent of their stated willingness to pay, but there is a positive association between this and the quantity.
public goods: The New Palgrave Dictionary of Economics

public goods provision that are both realistic and reasonably simple. A positive theory, on the other hand, must to a greater extent model economic and political institutions, and there is no single institution corresponding to the competitive market in the private goods case which can serve as a unifying benchmark for the analysis. Moreover, development of the positive theory of public goods must necessarily be closely tied to the concerns of local communities.

The Samuelson theory of public goods has been of decisive influence for the theory of public expenditure, which was developed in a number of directions during the second half of the 20th century. The extensions and reinterpretations of the original theory to the cases of public factors of production, mixed (public–private) goods and local and global public goods have significantly increased the applicability of the theory. Much has also been achieved to enrich our understanding of the incentive problems that arise in actual allocation.

The point of view taken in most of the literature considered here is that the incentive revelation problem requires decisions on public goods supply to be taken by some governmental body. However, starting with Olson (1965), there has emerged a literature on the voluntary provision of public goods. This literature is perhaps most naturally interpreted as concerned with relatively small groups, in which the incentive to free ride is limited, and not with public goods provision on a national scale. In the framework of this theory, as formulated for example by Bergstrom, Blume and Varian (1986), the decision to contribute to a public good is formulated in the standard framework of consumer demand theory. Consumers allocate their incomes between private goods and contributions to public goods, which are made under assumption that the contributions of all other consumers are taken as given, and one can then study the properties of the resulting Nash equilibrium. Particular attention has been given to the effect on contributions of a redistribution of income; as first shown by Warr (1983), under some assumptions this will change individual contributions in such a way that the aggregate supply of the public good is unaffected.

Perspectives

The Samuelson theory of public goods has been of decisive influence for the theory of public expenditure, which was developed in a number of directions during the second half of the 20th century. The extensions and reinterpretations of the original theory to the cases of public factors of production, mixed (public–private) goods and local and global public goods have significantly increased the applicability of the theory. Much has also been achieved to enrich our understanding of the incentive problems that arise in actual allocation mechanisms for public goods supply; however, it is probably fair to say that the normative theory of public goods has become much more satisfactory from a theoretical point of view than the positive theory. This state of affairs may in fact be unavoidable. The normative theory has little need to model institutional details and can thus be given a more unified appearance. A positive theory, on the other hand, must to a greater extent model economic and political institutions, and there is no single institution corresponding to the competitive market in the private goods case which can serve as a unifying benchmark for the analysis. Moreover, development of the positive theory of public goods must necessarily be closely tied to the progress of the positive theory of public sector behaviour in general; it will be interesting to see whether this theory can be developed to provide descriptive models of public goods provision that are both realistic and reasonably simple.

Numerous empirical studies have investigated the contribution of public infrastructure (the stock of
cpyically provided physical capital) to private economic productivity and growth. Using aggregate time-

test data to estimate a production function with private capital, labour and public capital as inputs, the
authors found substantial elasticities of private output with respect to public infrastructure. The result did
not withstand scrutiny. Studies using disaggregated data (by region and industry), employing
econometric diagnostics testing for nonstationarity, fixed effects and endogeneity, and using natural-

taggregate production functions; Cobb–Douglas functions; cost functions; output elasticity of capital;
productivity growth; public infrastructure

Public infrastructure (the stock of publicly provided physical capital comprising highways, sewage and
sanitation systems, water systems, school buildings, hospitals and so forth) comprises an important
component of the US economy. In 2004, there were just under seven trillion dollars of public capital in
the United States, including 1.7 trillion dollars of highways and streets. By comparison, the stock of
private capital stood at 27 trillion dollars.

Public infrastructure has figured in several related economic enquiries. What are the causes of private-
sector productivity growth and decline? What causes lesser developed regions or countries to grow? Do
country growth rates tend to converge over time? Research into each of these questions has examined
the role of public infrastructure.

The contribution of public infrastructure to economic productivity and growth has been the focus of
many empirical studies in recent years. The idea that public infrastructure should be considered an input
in the aggregate production function, together with labour and private capital, was introduced in early
public infrastructure: The New Palgrave Dictionary of Economics

Theoretical models, but it was not taken into account in empirical work until the late 1980s. The increased attention to empirical analysis was linked to concerns about the decrease in productivity observed in the United States after 1970. In Europe much of the infrastructure literature has examined the role of public investment in boosting the growth of less developed regions.

Theoretical framework

The most widely used framework for studying the impact of public infrastructure on productivity and growth has been estimation of aggregate production functions where public capital is considered a production input along with the standard inputs, labour and private capital. The general form of the aggregate production function can be written as follows:

\[ Y_{rt} = A_{rt} F(L_{rt}, K_{rt}, Kg_{rt}) \]

where \( Y \) is a measure of output, \( L \) represents labour, \( Kp \) is the stock of private capital, \( Kg \) is the stock of public capital, \( A \) is total factor productivity and the subscripts allow for regional and time variation. Although the production function can take many functional forms, most empirical studies have estimated a Cobb–Douglas production function. Under that specification, and taking a logarithmic transformation, the estimating equation can be written as follows:

\[ \ln Y_{rt} = a_{rt} + \alpha \ln K_{rt} + \beta \ln Kg_{rt} + \gamma l_{rt} + \epsilon_{rt} \]

where the variables are measured in natural logarithms, and \( \epsilon \) is an error term.

The aim of an important part of the public infrastructure literature is to estimate the output elasticity of public capital \( \beta \), so as to measure its contribution to private productivity. An alternative approach to obtaining similar parameters, based on the duality of production and cost functions, is to estimate a cost function.

Empirical evidence

The first widely known results were those obtained by Aschauer (1989), who estimated a production function using aggregate post-war time series data for the United States. He estimated an output elasticity of public capital of 0.39, larger than the corresponding value for private capital (0.35). These estimates imply large returns for public investment (above 60 per cent, double of those for private capital), and were challenged by many authors, who considered them implausibly high. Some authors attributed the high output elasticity of public capital found by Aschauer (and by Munnell, 1990a) to a spurious correlation between output and public capital due to a common time trend. Aaron
(1990) and Tatom (1991) corrected for the common time trend by first-differencing the data and obtained small and statistically insignificant coefficients.
The incorporation of state or metropolitan level data adding cross-section information to the time-series data opened up new possibilities for handling the spurious correlation and getting more accurate estimates of the contribution of public capital. Eberts (1986) focused on the manufacturing sector for 38 metropolitan areas and obtained a significant but much smaller estimate of the output elasticity of public capital, with a value of 0.03. Munnell (1990b) and Garcia-Milà and McGuire (1992) pooled state and time variation and obtained public capital elasticity estimates that range between 0.04 to 0.15. These estimates struck researchers as being more reasonable; however, they were subject to criticism because of endogeneity problems related mainly to omission of state-specific characteristics and to reverse causality.
Holtz-Eakin (1994), Evans and Karras (1994), and Garcia-Milà, McGuire and Porter (1996) used panel-data techniques not only to take into account state-specific productivity differences in the estimation, but also to explore non-stationarity of the data and possible endogeneity of the production factors. In all cases the estimates of the output elasticity of public infrastructure dropped dramatically compared with the time-series and pooled-data estimates, with values close to zero (and sometimes even negative) and not statistically significant.
By disaggregating by industry, Fernald (1999) avoided the endogeneity problem: if road infrastructure grew as a result of overall economic growth, and therefore the causality were reversed, one would not expect to find a relationship between increases in road infrastructure and the productivity of some industries but not others. He found that an increase in road infrastructure enhances productivity growth of vehicle-intensive industries much more than other industries. Fernald concluded that the US interstate building of the late 1950s and 1960s was one important factor in explaining the productivity increases up to the early 1970s, but the impact of road-building after the main network was built was small. A productivity burst because of road-building is a one-time effect and cannot be historically repeated. This is also the view of Hulten and Schwab (1993), who argue that, once the basic network is constructed, which has a major impact on the economy of the country, additional road construction has little, if any, effect on private productivity.
The results of Mas et al. (1996) support the idea that the impact of infrastructure investment is greater at earlier stages of development of the infrastructure network. They examine regions in Spain over the period 1964–91 and find that the output elasticity of productive infrastructure is 0.14 in the first ten years of the sample, but falls as more recent years are added to the sample, with a value of 0.08 when the whole period is considered. As the highway network in Spain was not yet completed in 1991, their results for Spain are compatible with those obtained for the United States, where the highway network was virtually complete, which showed that highway construction produced little or no effect.
Another possible response to the endogeneity problem is to estimate aggregate cost functions. The estimation of aggregate cost functions avoids the endogeneity bias if one can assume that prices of inputs are exogenous. Although it is reasonable to assume that individual firms are input price takers, it may not be plausible to assume that input prices are exogenous when considering aggregate (state or national level) cost functions. In spite of this shortcoming, there are several interesting papers that estimate aggregate cost functions and obtain, through the duality between cost and production functions, estimates of the output elasticity of private and public inputs. Berndt and Hansson (1992), Lynde and
Richmond (1992), Nadiri and Mamuneas (1994), and Morrison and Schwartz (1996) are good examples of cost function estimations. They differ in the functional specification, the geographical and industrial scope, and the scope of public infrastructure, but in all cases they find that public capital reduces costs and therefore improves productivity. The size of the effect tends to be quite small, along the lines of the production-function estimates obtained by Eberts (1986), Munnell (1990b) and Garcia-Milà and McGuire (1992).

A very different way to avoid endogeneity bias is to look for a natural experiment related to infrastructure investment. The idea is to compare the economic performance of two otherwise similar areas except that in one area, the control group, there has not been any highway construction whereas the other area, the treated group, has experienced highway construction. Rephann and Isserman (1994) apply matching techniques to analyse the effectiveness of US interstate highways as an economic development tool. Results vary significantly depending on the characteristics of the counties considered. Counties close to a large city or containing small cities (more than 25,000 residents) benefit from new investments in interstate highways, while rural counties without these characteristics do not experience economic growth when interstate highways are built within them. Chandra and Thompson (2000) exploit the fact that in the United States much interstate highway construction was designed to link major metropolitan areas. Thus, the rural counties in between the metropolitan areas through which the interstates run can be considered the treatment group, while the counties adjacent to the treatment group, which in essence just missed having an interstate highway run through them, can be considered as a suitable control group. The authors find that counties that have a new interstate highway running through them experience an increase in overall earnings, while earnings fall in the adjacent counties. The authors conclude that interstate highway construction affects the spatial allocation of economic activity, but has no net effect on the economic development of non-metropolitan areas as a whole.

The question of whether investment in public capital yields a net positive social return has also been addressed. Morrison and Schwartz (1996) calculate a measure of the net social return to public infrastructure investment as the difference between the cost savings to manufacturing firms minus the cost to society of the public capital investment. Their results range from small positive values to negative estimates of the net social return depending on how the price of public capital is adjusted for taxation and for the marginal cost of public funds. Haughwout (2002) examines the impact of public infrastructure on both productivity and consumer utility in a sample of large US cities. He finds that the local benefits of public capital are largely realized by households rather than firms and that the aggregate benefits of large investments in public infrastructure are not likely to be sufficient to offset the costs.

Concluding remarks

Based on the aggregate analysis, we can conclude very little. The most credible aggregate production–function estimates of the impact of public infrastructure on private output hover around zero, as do estimates of the net social benefit of public infrastructure investment. However, when the focus is on sub-aggregates such as particular industries or certain areas or incomplete networks, researchers tend to find that public capital investment boosts private output and productivity for some industries, some areas, and some networks. What is clear from the accumulated evidence is that public infrastructure is not a panacea for all that ails economies, but rather a tool that when properly targeted can be effective at
enhancing growth.

Abstract

The theory of public utility pricing provides clear recommendations when the regulator and utility have the same information about the underlying economic environment – the structure of demand and the production process. In reality, the utility has private information about the underlying economic environment, and the incentives created by the regulatory process can cause it to exploit this information by producing in an inefficient manner. This insight complicates virtually all aspects of the theory of public utility pricing, and has led to theoretical characterizations of the public utility price-setting process as the solution to a mechanism design problem.

Article

Public utilities typically provide goods and services using a physical or virtual network infrastructure under a legal monopoly status. Public utilities can be privately owned, government-owned and customer-owned. Products provided by public utilities include electricity, natural gas, water, sewage treatment, waste disposal, public transport, telecommunications, cable television and postal delivery services. In the United States, all the different ownership forms can exist within the same industry. For example, in the electricity supply industry, there are privately owned, investor-owned and municipally owned utilities, and cooperative utilities owned by their customers. Many explanations have been offered for the public utility industry structure. The standard economic efficiency argument is that the industry is natural monopoly, meaning that a single cost-minimizing firm...
is the least-cost way to serve the current level of demand. However, this logic relies on the implicit assumption that the single firm will produce in a cost-minimizing manner, which is unlikely to occur under government ownership or government regulation, for the reasons discussed below. In addition, although the current level of demand may be served at least cost by one cost-minimizing firm, this is unlikely to be that case for all future levels of demand as the number of customers or their purchasing power grows. Recognizing that public safety and health concerns argue for universal access to many of these services and the fact that the demand is very inelastic with respect to its own price leads to political economy explanations for this public utility industry structure. As Waterson (1988) notes, a government-owned or -regulated monopoly may better ensure that all customers have access to these services at reasonable prices.

Over the 100 years or more of state and federal regulation of public utilities in the United States there has been debate over what constitutes a reasonable price for goods and services of public utilities. A price that recovers the firm's operating costs including return on its capital stock is generally considered to meet the legal standard of a reasonable price. This form of price regulation in the United States is often referred to as ‘cost-of-service’ regulation. However, as Joskow (1974) has persuasively demonstrated, the price-setting process for privately owned utilities in the United States does not guarantee the firm a fixed rate of return on its capital stock or full operating cost recovery. In that sense, to call this regulatory price-setting process ‘cost-of-service’ regulation is a misnomer. Joskow (1974, p. 325) states: ‘The rate of return aspect of regulation is merely a method by which a regulatory commission justifies its approval of price increases or major changes in rate structures. Without such triggering mechanisms the rate of return constraint is essentially inoperative.’ When the cost-of-service regulatory process operates it sets a price that allows the public utility an opportunity to recover its operating costs and the regulated rate of return on its capital stock through prudent operation. If the firm earns a higher rate of return at this price because of superior management, then it is allowed to keep the revenue. If the firm earns a lower rate of return because of poor management, then shareholders must accept a lower rate of return. Only when the regulatory commission has overwhelming evidence that the higher or lower rate of return is due to extraordinary events beyond the control of the firm and not anticipated at the time the regulatory commission set the price will it make *ex post* adjustments to alter the public utility's regulated rate of return. A well-known example of an extraordinary event is a price change for fossil fuels used to produce electricity. The extreme volatility in oil, natural gas and coal prices since 1977 has led many regulatory commissions in the United States to implement fuel price adjustment clauses that automatically pass through in any input fuel price changes in the price of electricity. Baron and De Bondt (1979) discuss the impact of these fuel adjustment mechanisms on the investment and operating decisions of regulated electricity and natural gas utilities. The terms and conditions surrounding this promise of full cost recovery through prudent operation is often referred to as the ‘regulatory contract’ between the regulatory commission and the public utility. This implicit contract requires the utility to serve all demand at the price set by the commission in exchange for a price that allows the utility the opportunity to recover its operating costs and a reasonable return to its capital stock. A major challenge to this regulatory contract is determining when imprudent operation is the cause of a failure to achieve full cost recovery.

For a number of reasons, unexpected events outside the control of the regulatory commission or utility and *ex post* opportunism by the regulator are often very difficult to distinguish from valid reasons for the regulatory commission to disallow price increases. Utilities typically require substantial investments in a
network infrastructure that has limited alternative uses. The future demand for the public utility's services is uncertain, so there is a substantial risk that investments in network infrastructure will not be needed to serve the demand that exists when the investment is completed. Several aspects of the regulatory process in the United States are designed to address the problem of the regulator setting a price that is insufficient to provide a reasonable return on past investments. The concept of a ratebase and the requirement that the regulatory commission sets a price that recovers operating costs and a reasonable return on the entire ratebase limits opportunistic behaviour on the part of the regulatory commission. To a first approximation, the ratebase is the sum of all past investments judged as prudent and therefore worthy of cost recovery by the regulatory commission. Phillips (1993, ch. 8) provides a detailed discussion of this concept. The requirement that the entire ratebase earns the regulated rate of return ensures that the current regulatory commission compensates the utility for investments that previous commissions have deemed prudent.

Gilbert and Newbery (1994) construct a dynamic model of the regulatory price-setting process where the commitment to allow the firm to earn a reasonable rate of return on a ratebase composed of past prudent investments results in a socially efficient level of investment by the regulated firm. Lyon and Mayo (2005) investigate the empirical relevance of regulators’ opportunistic behaviour by examining the investment behaviour of regulated electric utilities and the propensity of the relevant state regulatory commissions to disallow investments by these utilities from entering the ratebase. Lyon and Mayo (2005) find little evidence that these cost allowances by the state regulatory commissions were due to opportunistic behaviour, and instead argue they were motivated by a desire to punish poorly managed firms.

**Optimal pricing of public utility services with full information**

Prices that adhere to the implicit regulatory contract of allowing full cost recovery only impose one restriction on the set of possible prices. For the case of a single-product utility that must set the same price for all customers, this restriction implies that the regulated price is equal to average total cost. However, virtually no public utilities sell a single product or are required to set a single price for all customers, so that regulatory commissions are free to pursue additional goals, besides the promise of cost recovery, in setting regulated prices.

This section discusses methods for setting economically efficient prices – those that maximize some social welfare function – under the simplifying assumption that the utility and the regulatory commission have the same amount of information about the utility's production process and demand. The remainder of this section assumes symmetric information between the regulated utility and the regulatory commission, so the commission can credibly set a price that only recovers the firm's minimum cost of serving its demand. Although the assumption of symmetric information about the production process and nature of demand between the utility and regulatory commission is unrealistic, the literature on optimal pricing for public utilities described in this section relies on this assumption. Two-part tariffs relax the assumption that a single uniform price is charged to all customers for each unit of output. If the production of the good or service is subject to increasing returns to scale, setting price equal to the marginal cost of the last unit sold violates the legal requirement that the firm has an opportunity to recover total production costs. Coase (1946) addresses this problem by considering a
regulated public utility producing a homogenous product with a monthly fixed cost of production, $F$, and a constant marginal cost, $c$. Coase (1946) argues that the total surplus maximizing two-part tariff sets the price of each unit consumed, $p$, equal to $c$ and the fixed charge for each customer equal to $F/N$, where $N$ is the number of customers served by the public utility.

If consumers differ in their willingness to pay for the product, then the surplus accruing to some consumers can be increased by the commission setting multi-part tariffs that charge different marginal prices for different ranges of monthly consumption. If the level of the monthly fixed charge necessary to recover total monthly fixed costs causes some consumers not to purchase the product, then a multi-part tariff can increase total consumer surplus. Assuming the marginal cost of a minute of telephone service is two cents per minute, setting a low monthly fixed charge and charging two cents per minute for the first 200 minutes of phone calls in the month and four cents per minute for all minutes above 200 minutes per month can allow the phone company to increase the number of consumers that benefit from having a telephone service without violating the promise of cost recovery. In this way, those consumers with the highest willingness will select through their consumption choice the higher marginal price, while those with the lowest willingness will select the lower marginal price, and virtually all consumers will pay a monthly fixed charge that does not cause them to disconnect from the telephone network.

Brown and Sibley (1986, ch. 4) discuss consumer and producer welfare properties of multi-part tariffs. The nature of the goods and services sold by public utilities often allows them to segment customers and to charge different prices for the same product. In addition, virtually all public utilities are multi-product firms, which implies that the regulatory process involves setting prices for all goods sold by the firm. Both of these circumstances provide opportunities for regulatory commissions to pursue objectives beyond the promise of cost recovery.

Consider the case of a homogenous product with increasing returns to scale in production that is sold to $M$ different sets of consumers and a regulatory commission that can set a single price for each set of customers. Deriving the total surplus maximizing prices for all customer types subject to the constraint on cost recovery fits into the framework considered by Ramsey (1927). Let $CS_i(p_i)$ equal the consumer surplus accruing to consumers of type $i$ and when they face price $p_i$, and $PS_i(p_i)$ equal the producer surplus from serving consumers of type $i$. Ramsey prices maximize the objective function

$$TS = \sum_{i=1}^{M} [CS_i(p_i) + PS_i(p_i)]$$

subject to the cost recovery constraint,

$$F \leq \sum_{i=1}^{M} PS_i(p_i),$$

where $F$ is the firm's fixed cost. Let $c$ equal the marginal cost of production and $\varepsilon_i(p_i)$ the own-price elasticity of the demand by customers of type $i$ at price $p_i$. The solution to this constrained optimization problem yields the inverse elasticity pricing rule:

$$\frac{(p_i^* - c)}{p_i^*} = -\frac{k}{\varepsilon_i(p_i^*)}, \quad i = 1, 2, ..., M$$

where $k$ is some positive constant and the $p_i^*$, $i=1,2,\ldots,M$, are called Ramsey prices. These prices raise the revenue necessary to achieve full cost recovery with the smallest total surplus loss. Those consumer
types with relatively more inelastic demands for the goods pay higher markups above marginal cost than other consumer types.

This same Ramsey-pricing logic can be applied to the case of multi-product public utilities. However, the simplicity of inverse elasticity pricing rule is complicated by the fact that customers can substitute across the products that the public utility offers. For example, in the pricing of postal delivery services, a business mailer has the option to use different US postal service products to communicate with its customers. To set Ramsey prices, the regulatory commission must know the multi-product cost function for postal products and the consumers’ surplus associated with each postal product, which depends on the price charged for other postal products that the consumer can use as a substitute. As shown in Brown and Sibley (1986, ch. 3), both own-price and cross-price elasticities of demand now determine the total surplus maximizing markups that solve the Ramsey-pricing problem.

The properties of the regulatory pricing mechanisms described in this section rely on the assumption that the public utility's cost function is the minimum cost way to produce each vector of outputs.

Specifically, let $T$ equal the public utility's technology set, the pairs of vectors of input quantities, $x$, and output quantities, $q$, such that $q$ can be produced using $x$. If $w$ is the vector of input prices, then the minimum cost function is equal to

$$
C(q) = \min_{x \geq 0} w'x \text{ subject to } (x, q) \in T.
$$

Although a price-taking profit-maximizing firm would like to produce along its minimum cost function, the structure of the regulatory process could cause a privately owned profit-maximizing regulated utility not to produce along its minimum cost function. Averch and Johnson (1962) present an example of a regulatory mechanism that causes a profit-maximizing firm not to produce in a least-cost manner. This work led to a massive theoretical and empirical literature exploring the distortions from minimum cost behaviour caused by regulatory price-setting processes.

State-owned utilities are likely to have even less incentive to produce in a least-cost manner. Besides the incentives provided by the regulatory price-setting process, earning revenues in excess of operating costs is just one of the many objectives that managers of state-owned companies must balance. As Waterson (1988, ch. 4) notes, state-owned utilities are often asked to pursue political or social goals that conflict with maximizing profits and therefore minimizing production costs.

Economists have begun to recognize the distinction between a public utility's observed cost function and its minimum cost function. The observed cost function, $CO(q)$, gives the firm's actual cost of producing output vector $q$ given the incentives provided by the regulatory process. For example, in the case of a state-owned utility, political constraints could require a firm's management to hire a certain number of workers for each level of output despite the fact that it is technologically feasible to produce using fewer workers at each output level. In general, the value of the firm's observed cost function is greater than the value of its minimum cost function for the same level of output, and this difference can be substantial. There is a vast empirical literature documenting violations of the assumption of cost-minimizing behaviour by public utilities. Christensen and Greene (1976) is a well-known example in the electricity
supply industry and Evans and Heckman (1984) is one for the telecommunications industry. There are few empirical studies of regulated utility behaviour where the assumption of cost-minimizing behaviour is not rejected.

Optimal pricing of public utility services with asymmetric information

Public utility regulation has long been recognized as an example of agency relationship where the regulator (the principal) attempts to provide incentives for the public utility (the agent) to serve its demand in a least-cost manner at a price that only recovers observed costs. This link between the utility's production costs and the price it is allowed to charge creates the opportunity for the public utility to exploit its superior information about the production process and the demand it faces. This recognition has led researchers and regulatory policymakers to consider ways to either break this link between the price charged and the firm's observed cost or to design incentive mechanisms that exploit the link between the regulated price and the firm's observed cost.

Price-cap regulation attempts to break this link by committing to change the price the utility is allowed to charge according to a formula that cannot be altered for a sustained period of time. For a profit-maximizing firm, the price-cap mechanism creates the same incentive to minimize cost as the assumption of price-taking behaviour. In the United Kingdom (UK) this form of regulation is also called RPI minus X price-cap regulation because the rate at which prices are allowed to change on an annual basis is equal to rate of change in the retail price index (RPI) minus an X-factor chosen by the regulatory commission. Armstrong, Cowan and Vickers (1994, ch. 3) describe the details of choosing an X-factor for a specific firm and extensions of this basic regulatory framework.

The major challenge associated with price-cap regulation is balancing the desire to commit to a pre-specified pattern for the X-factors for as long as possible against the fact that the longer duration of the commitment to this pattern of X-factors the greater the likelihood that the commitment will run afoul of the regulatory contract or political concerns. The experience of many public utilities in the UK privatized during the 1990s provides an instructive example of this phenomenon. According to Armstrong, Cowan and Vickers (1994), the regulator for the water industry and the regulator for the electricity distribution sector initially committed to a five-year initial duration for values of the X-factors. However, in both these industries the regulator was forced to abandon these commitments before the end of the five-year period because of what was argued to by the water utilities to be inadequate revenues and what was argued by many consumers as excessive revenues in the case of the electricity distribution sector. Wolak (1998) discusses practical problems associated with implementing price-cap mechanisms and why they often evolve into an extremely ineffective form of cost-of-service regulation.

The development of game theoretical models of private information environments has led economists to derive optimal prices in this ‘second-best’ world. Baron and Myerson (1982) derive the total surplus maximizing prices when the public utility has private information about its production process not observable by the regulatory commission. The Baron–Myerson model assumes that the commission offers the firm a menu of prices and fixed fees that depend on the public utility's report of its private information. This report determines what price and fixed fee the firm is able to charge to its customers and therefore the revenues it is allowed to earn.
Recognition that informational asymmetries between the regulatory commission and utility can lead to significant distortions from minimum cost production and regulated prices that recover revenues substantially higher than these minimum costs has led to an explosion of theoretical work on the design of optimal regulated prices in this private information environment. Laffont and Tirole (1993) provide a comprehensive presentation of this literature.

Wolak (1994) attempts to quantify the cost of this private information in the regulatory process. Using a sample of California water distribution utilities, he estimates a full or symmetric information solution to the utility and regulatory commission interaction and a private or asymmetric information model of this interaction based on the Baron–Myerson (1982) model. Wolak (1994) finds that the asymmetric information model of the regulatory process provides a superior fit to observed data relative to the symmetric information model in addition to computing various estimates of the cost of the informational asymmetry between the firm and regulatory commission.

**Concluding comments**

The explicit recognition of the impact of the private information possessed by the firm on the price set by the regulatory commission has increased the realism of the assumptions underlying models of the public utility price-setting process. Unfortunately, the form of the optimal price-setting mechanism derived from these models depends crucially on the source of informational asymmetries between the firm and the regulatory commission, as well as many other details of the economic environment. This implies that much more empirical work on actual regulatory price-setting processes is needed to implement these theoretical advances in actual regulatory practice.

Public works to relieve unemployment is an idea as old as the pyramids. From the cathedrals of the Middle Ages to the dams of the Tennessee Valley Authority, recent centuries abound with examples of such government-supported schemes. However, it is only fairly late in the history of economic theory that economists started devoting some analytical thought to this problem. In fact, it was around the turn of the 20th century, with the appearance on the Continent of the first systematic work on business cycles, that economists stopped looking at unemployment as a ‘pathological’ problem to be tackled primarily as one of charity and relief. Even down to the British 1909 Report of the Poor Law Commission a majority still considered unemployment as no challenge to economic theory: if properly applied, in the long run, the normal laws of value and distribution would see to a solution to this problem. A notable exception to this general neglect is, of course, the heated discussions that took place between early 19th-century classical economists during the so-called ‘general glut controversy’. In the course of that well-known debate on the self-adjusting capacities of the economic system, public works as a means to combat unemployment came many times to the forefront of the argument. Ricardo, James Mill and Say fairly easily won the day against public works. However, though dissenters like Malthus, Lauderdale, Bentham and Sismondi rejected Ricardo's doctrine on the stability of the economic system and Say's rigmarole about the equality of supply and demand, they involved themselves in a logically very damaging acceptance of the dominant Turgot–Smith saving-is-investment doctrine, together with the aggravating assumption that hoarding cannot take place. Trapped in such contradictory statements, these dissenting authors never managed to put their case convincingly either against Ricardo's self-
adjustment doctrine or, of course, in favour of contra-cyclical public works. Showing very little interest in ‘immediate and temporary effects [and fixing his] whole attention on the permanent state of things’ (1952, vol. 7, p. 120), Ricardo was left in a very strong theoretical position to dismiss arguments in favour of credit expansion and/or public works to reduce unemployment. Furthermore, his lack of a theory of output (that is, his full-capacity utilization assumption) allowed Ricardo to close in an even tighter way a line of argument that was to dominate economic theory for nearly a century, and economic policy for an even longer period. Anticipating nearly word for word Churchill's 1929 Budget Speech and what was to be known in the 1920s and 1930s as the ‘Treasury View’, in 1821 Ricardo already observed in the Commons:

When [I] heard the honourable members talk of employing capital in the formation of roads and canals, they appeared to overlook the fact that the capital thus employed must be withdrawn from some other quarter. (1952, vol. 5, p. 32)

This ‘Ricardian view’ on public investment was to be perpetuated down the 19th century; after having been defended and illustrated by most classical economists, and notably by Mill, it even survived the marginalist revolution: Marshall never advanced much beyond it and Böhm-Bawerk subscribed substantially to its conclusions.

However, during the 1880s, Foxwell and Hobson were among the first to take up the challenge again. More preoccupied with the social effects of the ‘irregularity of employment’ linked with price fluctuations, than with strictly theoretical questions, they both called for abandoning the charity and relief approach and for turning the fight against unemployment into a major objective of economic policy. Foxwell concludes his analysis by favouring (unlike most leading economists) a slightly rising price level ‘for more regular employment’. Hobson, for his part, suggests solutions to prevent under-consumption crises at the root of unemployment by a redistribution of income to encourage ‘high consumption’. Despite a few attempts by local authorities to provide relief work to the unemployed, nothing systematic surfaced in Britain in the realm of economic policy despite growing concern about unemployment.

In the history of public works doctrine, the Minority Report of the Poor Law Commission (Royal Commission on the Poor Law and the Unemployed, 1909) clearly marks a watershed: for the first time ever the minority commissioners advocated a systematic counter-cyclical policy of public works and investment to smooth out cyclical fluctuations and to stabilize employment and the level of economic activity. However, this fundamental turnabout was not confined to Sidney and Beatrice Webb, largely responsible (with A.L. Bowley for the statistical material) for drafting the Minority Report. In the same year as the Report, Beveridge in Unemployment, a Problem of Industry broadly supported its main conclusion, and a few years later the Webbs in their volume The Prevention of Destitution (1911) offered a more elaborate version of their original argument.

However, the first modern refutation of the ‘Ricardian view’ by a professional economist is due to Pigou in his 1908 inaugural lecture as Marshall’s successor at Cambridge. Worked out again in his Wealth and Welfare (1912) and Unemployment (1913), Pigou's argument became the standard pre-Keynesian case for public works: without having to resort to the notion of budget deficit, Pigou is able to demonstrate that public spending can increase aggregate employment and does not simply divert it from the private
... it is probable that only part of the extra taxes people pay would be taken from funds they would otherwise have devoted at that time directly or indirectly to wage payment. Hence, the true result of relief works and so on is not to leave the aggregate amount of unemployment in the country unaltered, but to diminish that amount. (1908, pp. 27–8)

In other words, and in the modern parlance of the balanced budget multiplier, the taxpayer's marginal propensity to consume is smaller than 1, while the government's marginal propensity to consume is unity: the net effect of such a tax increase is clearly expansionary. Pigou's failure to assess his argument quantitatively (in a multiplier-like fashion), his scepticism about the degree of labour mobility between the private and the public sectors and the resulting weak impact of his argument on policymakers do not detract however from his originality. Public works, even without any budget deficit, can lessen unemployment.

This became a standard argument for most economists, well before the First World War. Robertson gave his 'cordial support' to Pigou's analysis and, for the first time brought forward in his Industrial Fluctuation the symmetrical idea that, through public works, governments would ‘in times of depression [use] savings [that] are not otherwise so applied’ (1915, p. 253).

With the notable exception of Hawtrey in the 1920s, most British economists followed Pigou's lead even if they were bitterly arguing about the best way to close the gap between saving and investment. Hawtrey for his part never departed from his early critical position against the Minority Report outlined in Good and Bad Trade (1913, p. 260). He reiterated many times, most notably in his 1925 article, that the public works doctrine ‘overlook[s] the fact that the Government by the very fact of borrowing for its expenditure is withdrawing from the investment market savings which would otherwise be applied to the creation of capital’ (1925, p. 104). As an adviser to the Chancellor of the Exchequer, and despite the broad professional consensus in favour of public works, Hawtrey won the day in the British Treasury. Under successive Conservative and Labour Governments, the ‘Treasury View’ remained official wisdom for years (for a detailed discussion of that evolution see Hutchison, 1953, pp. 409–23 and Winch, 1969, pp. 94–113). Similarly, during the 1932 US presidential election Roosevelt kept attacking the outgoing Hoover administration for not balancing the budget. It is only with the rearmament in Germany and with the Second World War in other Western countries that the ‘Treasury View’ all but disappeared from the politicians’ standard set of arguments.

In his famous 1931 multiplier article, Kahn managed once and for all to dispose of this ‘Treasury View’. Kahn's intentions were, however, empirical, not theoretical. He set out not so much to point out the then generally accepted argument that an increase in government investment would generate ‘secondary employments’ but to provide ‘a stronger case’ for public works than that which ‘had always been recognized' by giving a precise estimate of this multiplier effect. The ratio of secondary employment to primary employment was thus given its first formal expression (1931, p. 12)

However, and to dispel a very common confusion, with a multiplier equation strictly in the Pigovian tradition, Kahn did not anticipate the theoretical core of Keynes's General Theory, that is, the principle of effective demand. In Kahn's model, even if additional public spending has a multiplier effect on output and employment, such public works do not affect the discrepancy between saving and investment: as for Pigou and Robertson, previously, ‘unused’ savings are simply brought back into
circulation. In short, for Kahn ‘the whole point of a policy of public works is that it enables an increase in the rate of home investment … without that fall in the rate of interest that would be necessary if we were relying on private enterprise’ (1931, p. 26).

In the *General Theory*, with his principle of effective demand, Keynes added a new theoretical dimension to Kahn's multiplier approach to the public works doctrine. An increase in public investment not only leads to an increase in employment and output but generates an excess of income over that required for consumption (via a marginal propensity to consume smaller than 1) so that the volume of savings will increase until saving once again equals investment. Furthermore, it is clear that since saving and investment are brought into equality by variations in the level of income, and not by changes in interest rate, there need not be full employment. In Keynes's theoretical framework, public works and government investment are thus no longer seen as temporary remedies to cyclical fluctuations in private investment, but as a necessary component of an aggregate demand the deficiencies of which are no longer automatically cared for, even in the long run, by an interest-rate mechanism.

This proposition (and the income-adjustment principle underlying it) could of course find no place in the traditional analytical framework. However, systematic short-term counter-cyclical public works policies were soon to be integrated by mainstream economists within the so-called neoclassical synthesis and played in most countries a major role in post-war economic policies. Victim of its success during the 1950s and 1960s, this Keynesian (as opposed to Keynes’s) public works doctrine ran into serious practical and theoretical problems in the early 1970s. The growing size of public sectors, the inflationary wave resulting largely from an excessive use of expansionary fiscal policies and a rapidly growing theoretical dissatisfaction of the economic profession with the neoclassical synthesis brought back the ‘Treasury View’ onto the theoretical agenda. However even if with the successive advent of the monetarist school and the ‘governmental impotence’ theorem of the New Classical School, the ‘crowding out’ hypothesis is currently enjoying a new lease of life, few economists and even fewer politicians would dispute today the importance of modulating government spending in the course of the cycle.

Pufendorf, Samuel von (1632–1694)

Arild Sæther

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Pufendorf studied in Leipzig and Jena. His first work, *Elementorum Jurisprudentiae Universalis* (1660), earned him a professorship at Heidelberg. In 1668 he moved to Lund. His works *De Naturaet Gentium* (1672) and *De Officio Hominis et Civis* (1673) were translated, spread all over Europe, and entered the curricula at most Protestant universities. Pufendorf's natural law writings include ethics, jurisprudence, government and political economy. A society in which individuals exchange to satisfy their needs brings with it growth, commerce, markets, prices and money. This theory laid the foundation for the progress of economics as a science.

Article

Pufendorf was born in Dorfchemitz, Saxony, Germany on 8 January 1632. He matriculated at Leipzig University in 1650. First he studied theology, but found it dogmatic and turned to philosophy, philology and history. After two years he moved to Jena, concentrating on mathematics, the Cartesian demonstrative method and the natural law writings of Grotius and Hobbes.

After completing his Magister degree in 1658 he secured an engagement as a tutor in the family of the Swedish ambassador in Copenhagen. Shortly thereafter hostilities broke out between the two Nordic rivals. Disregarding diplomatic privileges, the Danes seized the Swedish retinue and accused Pufendorf of espionage. During eight months of harsh captivity, with no access to learned books, he reflected on his university studies and wrote down a system of jurisprudence. After his liberation, he journeyed with his pupils to the Netherlands, where his work was published in 1660 as *Elementorum Jurisprudentiae*
Pufendorf, Samuel von (1632–1694) : The New Palgrave Dictionary of Economics

Universalis (Elements of Universal Jurisprudence). This work is considered the first useful textbook on natural law and it earned Pufendorf an enviable reputation and a professorship at the University of Heidelberg.

Here he published, anonymously, his historical and political work De Statu Imperii Germanici (On the Constitution of the German Empire). It contains a devastating criticism of the condition of public law within the Empire resulting from the Thirty Years’ War, and suggested a path to its regeneration through a European commonwealth of sovereign states based on natural and international law. The imperial censor banned the book, but it was reprinted time and again, translated into several languages, and distributed across Europe. By 1710, some 300,000 copies had been printed in Germany alone.

Pufendorf’s reputation was now extended to non-academic circles. He achieved both fame and criticism. In 1668 Pufendorf moved to the newly established university in Lund, Sweden. In 1672 he published his magnum opus De Natura et Gentium (On the Law of Nature and Nations) in eight books, and the year after an abridged popularized version, De Officio Hominis et Civis (On the Duty of Man and Citizen), in two books.

In all, 44 editions of his major work have been published. It has been translated into English, French, German and Italian. His popularized version became, in modern parlance, an international bestseller. It has been translated into nine European languages, published in more than 150 editions in tens of thousands of copies. For more than 100 years they were among the most read academic books. The classicists Locke, Montesquieu, Rousseau, Hutcheson, Hume, Smith and countless more all studied and built on his works. Due to Pufendorf’s works and reputation, natural law became part of university studies in jurisprudence, philosophy and ethics at most Protestant universities.

A new war resulted in the closing of Lund University in 1677. Pufendorf became royal historiographer in Stockholm. In the following years, he introduced empirical studies of the archives, and published 33 volumes of historical studies. He is regarded as a progenitor of 19th-century historicism.

In 1688 Pufendorf moved to Berlin as historiographer and judicial councillor at the court of Prussia. He continued his works on historical and theological issues. He died on 16 October 1694 of blood poisoning, contracted on a return journey from Stockholm, where he had been elevated to the nobility as a baron. He is buried in St. Nikolai Church in Berlin.

Pufendorf attempted in his works on natural law to mediate and unify Hobbes’s natural law doctrine of ‘egoism’ and ‘a war of all against all’ with Grotius’s natural law doctrine of ‘man’s inclination towards society’. His writings include ethics, jurisprudence, government, and political economics. These are seen as integral parts of a totality.

The foundation for his treatment is his theory of human behaviour, where the driving force is the interaction between man’s self-interest and his existence as a social being. Man seeks society with his fellow man for the fulfilment of his own needs and desires. Man’s sociable inclination is not innate; it must be cultivated. He also used his theory of the social man to create his historical account of the rise of property when society changes from hunting and gathering through agriculture to a commercial society. Individuals in a commercial society will need goods and services produced by others, because their own time and resources will fail to give them many necessary goods. On the other hand, individual men can contribute many things to the use of others. However, this will come to nothing if these individuals could not exchange and barter their different goods and services. When a society based on private property grew, it therefore brought with it commerce, the growth of markets, the creation of prices and the introduction of money. The theoretical foundation of a commercial society, in which all individuals

Pufendorf, Samuel von (1632–1694) : The New Palgrave Dictionary of Economics

attempt to satisfy their own needs and thereby satisfy the need of others, is therefore the cornerstone in his natural law theory.

Price is divided into ordinary and eminent. The former is found in the properties of goods and services in so far as they afford service and pleasure for man. The latter is found in money as a common standard for their measurement. The price of a good or service is determined by the interaction between ‘the aptitude’ (utility) of it and the scarcity of it: in modern parlance, demand and supply. The price will rise towards a level where it covers the normal costs that accrue during production and transport. Lack of need (demand) lowers the price, but price will also be lowered if the number of suppliers increases. Pufendorf therefore comes very close to a Marshallian demand-and-supply analysis. In addition, the price will change if the quantity of money changes. Pufendorf seems to recognise the Snob and Veblen effects, externalities and differences in the elasticity of demand.

Pufendorf also presents his views concerning the state and the distribution of power, the state's right to tax, and the principles of taxation. Here he discusses weighted voting, qualified majorities and what has been known as single-peaked preferences.

It was the diffusion of these theories through popularization which laid the foundation for the progress of economics as a science.

Purchasing power parity (PPP) is a theory of exchange rate determination. It asserts (in the most common form) that the exchange rate change between two currencies over any period of time is determined by the change in the two countries’ relative price levels. Because the theory singles out price level changes as the overriding determinant of exchange rate movements, it has also been called the ‘inflation theory of exchange rates’.

The PPP theory of exchange rates has somewhat the same status in the history of economic thought and in economic policy as the quantity theory of money: by different authors and at different points in time it has been considered an identity, a truism, an empirical regularity or a grossly misleading simplification. The theory remains controversial, as does the quantity theory of money, because strict versions are demonstrably wrong while soft versions deprive it of any useful content. In between there is room for theory and empirical evidence to specify the circumstances under which and the extent to which PPP provides a useful, though not exact, description of exchange rate behaviour.

The analogy with the quantity theory of money holds particularly in the effects of monetary disturbances. The latter theory fails to hold exactly when disturbances are primarily monetary, for instance in the course of hyperinflations, because changes in the expected rate of inflation generate systematic movements in velocity that break the one-to-one link between money and prices. In the same way, monetary disturbances cause exchange rate movements that at least temporarily deviate from PPP, implying changes in the exchange rate-adjusted relative price levels or ‘real’ exchange rates. It is true that when the economy, following a major monetary disturbance, has settled down again the cumulative changes in
money, prices and the exchange rate will tend to be close to each other. In that sense PPP holds. The same is decidedly not true, however, in the course of the disturbance. And in the long run, just as changes in real income or financial innovation bring about trend changes in velocity that destroy the one-to-one relationship between the money supply and prices, there also are trend deviations from PPP: productivity growth differentials between countries, for example, lead to trend changes in real exchange rates.

Statement of the theory

Let $p_i$ and $p_i^*$ represent the price of the $i$th commodity at home and abroad, stated in home and foreign currency respectively, and $e$ the exchange rate. The exchange rate is quoted as the number of units of domestic currency per unit of foreign money. Further, let $P$ and $P^*$ be the price level at home and abroad quoted in the respective currencies. The strong or absolute version of PPP relies on the ‘law of one price’ in an integrated, competitive market. If we abstract from all frictions, the price of a given good will be the same in all locations when quoted in the same currency, say dollars: $P_1 = eP_1^*$. Consider now a domestic price index $P = f(p_1, \ldots, p_n)$ and a foreign price index $P^* = g(p_1^*, \ldots, p_n^*)$. If the prices of each good, in dollars, are equalized across countries, and, if the same goods enter each country’s market basket with the same weights (that is, the homogeneous-of-degree-one $g(\cdot)$ and $f(\cdot)$ functions are the same), then by definition absolute PPP prevails. The law of one price in this special case extends not only to individual goods but also to aggregate price levels. Spatial arbitrage then takes the form of the strong (or absolute) version of PPP:

$$
\frac{P}{P^*} = e \quad \text{and} \quad \frac{P}{P^*} = \frac{\text{price of a standard market basket of goods}}{\text{price of the same standard basket}}
$$

(1)

where the RHS is the common multiple of the price of each good in one currency and in the other. Specifically, if $P_i / P_i^* = k$ for all $I$, we then have $e = P / P^* = k$. Note now the implication of absolute PPP. Whatever the monetary or real disturbances in the economy, because of instantaneous, costless arbitrage the prices of a common market basket of goods in the two countries, measured in a common currency, will be the same or $P / P^* = 1$ at all times. There can be no objection to (1) as a theoretical statement. Objections arise, however, when it is interpreted as an empirical proposition. In fact the (spot) prices of a given commodity will not necessarily be equal in different locations at a given time. Transport costs and other obstacles to trade, especially tariffs and quotas, do exist and hence the location of delivery does matter. Therefore we would not expect the price even of an ounce of gold of a specified fineness always to be the same in New York and in Calcutta. The fact that prices of the perfectly homogeneous commodity are not equalized across space at every point in time does not suggest market failure; it may simply reflect the inability to shift commodities costlessly and instantaneously from one location to the other. Information costs and impediments to trade stand in the way of strictest spatial equalization of price. But these impediments to trade do not preclude the possibility that common currency prices of any given good in different locations should be closely related and, indeed, arbitrated. They just will not be literally equalized. Impediments to trade and imperfection of competition, of course, also make possible spatial price differentiation, thus further limiting strong PPP. The weak (or relative) version of PPP therefore restates the theory in terms of changes in relative price levels and the exchange rate: $\hat{e} = \theta \frac{P}{P^*}$ where $\theta$ is a constant reflecting the given obstacles to trade. Given these obstacles an increase in the home price level relative to that abroad implies an equi-proportionate depreciation of the home currency:

$$
\hat{e} = \hat{P} - \hat{P}^*
$$

(2)

where $\hat{a}$ denotes a percentage change.

Equation (2) is the statement of PPP as it was applied by Gustav Cassel to an analysis of exchange rate changes during the First World War.

The general inflation which has taken place during the war has lowered this purchasing power in all countries, though in a different degree, and the rates of exchange
should accordingly be expected to deviate from their old parities in proportion to the inflation of each country. At every moment the real parity is represented by this quotient between the purchasing power of the money in the one country and the other. I propose to call this parity ‘purchasing power parity’. As long as anything like free movement of merchandise and a somewhat comprehensive trade between the two countries takes place, the actual rate of exchange cannot deviate very much from this purchasing power parity. (Cassel, 1918, p. 413)

Absolute PPP in (1) was stated in terms of the relative prices in different currencies and locations of a given and common basket of identical goods. Going from there to relative PPP as in (2) may merely be a way of circumventing the qualifications arising from transport costs or obstacles to trade. But often more is involved because the shift, in practice, leads to a use of PPP in terms of particular price indices such as consumer price indices (CPIs), wholesale price indices (WPIs), or gross domestic price (GDP) deflators. Once that is done we go beyond the law of one price because the shares of various goods in the different national indices may not be the same and the goods that enter the respective indices may not be strictly identical as is clearly the case for non-tradable goods.

Once shares in the indices differ or commodities are not strictly identical, the appeal to the law of one price can no longer serve as support for PPP. Now PPP can hold, even in the weak form, only if the disturbances satisfy the conditions of the homogeneity postulate of monetary theory. The homogeneity postulate asserts that a purely monetary disturbance, with all equilibrium relative prices left unchanged, will lead to an equi-proportionate change in money and all prices, including the price of foreign exchange. In this very special experiment PPP holds even if the law of one price does not apply. The constancy of real variables under the assumption of a purely monetary disturbance (that is, an unanticipated, non-recurrent increase in money) assures that once the economy has adjusted the exchange rate depreciation matches the inflation of any individual price or the price of any market basket so that (2) applies. To appreciate the difference of this experiment from absolute PPP, note that under these conditions (2) could even be stated in terms of indices of non-tradable goods prices.

PPP theory as a theory of equilibrium must be supplemented by an adjustment mechanism. In the case of identical commodities the theory is simply that of spatial arbitrage. But when the goods are not strictly identical more is required. A high degree of substitution in world trade is generally assumed to be the mechanism through which exchange rate-adjusted prices are kept in line internationally. A further point concerns causation. In much of the literature, especially in the writings of Cassel, exchange rates adjust to prices. But there is an important alternative tradition that singles out exchange rate depreciation as an independent source of inflation.

Criticism of PPP focuses on systematic ways in which relative price changes destroy the strict validity of PPP. Keynes, although strongly supporting the idea of PPP as a broad guide, recognized these possible departures from purely monetary disturbances:

If on the other hand these assumptions are not fulfilled and changes are taking place in the ‘equation of exchange’, as economists call it, between the services and products of one country and those of another, either on account of movements of capital, or reparation payments, or changes in the relative efficiency of labour, or changes in the urgency of the world’s demand for that country’s special products, or the like, then the equilibrium point between purchasing power parity and the rate of exchange may be modified permanently. (Keynes, 1923, p. 80)

This limitation of PPP led Samuelson to argue: ‘Unless very sophisticated indeed, PPP is a misleading, pretentious doctrine, promising what is rare in economics, detailed numerical prediction’ (1964, p. 153).

History

Versions of the PPP theory have been traced to the Salamanca School in 16th-century Spain and to the writings of Gerard de Malynes appearing in 1601 in England. The Swedish, French and English bullionists in the second part of the 18th century and in the early 19th century present further statements of PPP. Particularly noteworthy is the Bullion Report in England:

Whether this 13 1/2 per cent, which stands against this country by the present exchange on Lisbon, is a real difference of exchange, occasioned by the course of trade and by the remittances to Portugal on account of government, or a nominal and apparent exchange occasioned by something in the state of our currency, or is partly real and partly nominal, may perhaps be determined by what your committee have yet to state. (Great Britain, 1810, p. ccxxii)

During the 19th century classical economists, including in particular Ricardo, Mill, Goschen and Marshall, endorsed and developed more or less qualified PPP views. This history is reviewed and discussed in Viner (1937), Schumpeter (1954), Holmes (1967) and Officer (1984).

Even though PPP theory was well established by the time of the First World War, the forceful use and development of the theory by the Swedish economist Gustav Cassel has made
him the outstanding protagonist of the theory. He turned the theory into a paradigm, with all the necessary trappings: an alleged challenge to gold standard orthodoxy, a catchy name, a formula, and the claim of empirical support for the new view.

Cassel's first contributions to the subject were published in 1916 in the *Economic Journal*. He presented the inflation theory of exchange rates and proceeded to a demonstration using price level and exchange rate data for the belligerent countries, the United States, and Sweden. J.M. Keynes as the editor appended a footnote drawing attention to the contribution and noting his surprise that, war disturbances notwithstanding, PPP should hold. A further challenge was the implication of PPP that the pre-war par with gold might not be re-established or, more guardedly, might require a powerful deflation in a country like Britain.

Cassel never abandoned an uncompromising PPP view of exchange rates even though he already in 1918 started recognizing the possibility that exchange rates might transitorily diverge from PPP. A decade later he made a clear statement of his final position:

The fact that the rate of exchange corresponding to Purchasing Power Parity possesses such a remarkable stability is a sufficient reason for regarding Purchasing Power Parity as the fundamental factor determining the rate of exchange and for classifying all other factors that may influence the rate and perhaps make it deviate from the Purchasing Power Parity as factors of secondary importance, most suitably grouped under the head of ‘disturbances’. (Cassel, 1928a, p. 16)

He identified three groups of disturbances: actual and expected inflation or deflation, new hindrances to international trade, and shifts in international movements of capital. Although these disturbances are recognized, their quantitative effect on deviations from PPP is invariably seen as 'confined within rather narrow limits' (Cassel, 1928a, pp. 28–9). In insisting on the proposition that deviations from PPP are limited and transitory, Cassel neglected to pay close attention to the determinants of purchasing power disparities. Even though he recognized that inflation first leads to undervaluation, and stabilization leads later to an overvaluation (Cassel, 1928b, p. 26), he never took these ideas further. His emphasis was on PPP. But he pointed out with some merit (Cassel, 1928b) that, without some quantifiable concept of PPP, a sensible discussion of over and undervaluation could hardly begin.

Keynes (1923, ch. 3) took up PPP, crediting Ricardo with the invention and Cassel with the name. Keynes recognized PPP as an important empirical possibility. Giving it all the right qualifications he still endorsed it for all practical purposes:

This theory does not provide a simple or ready-made measure of the ‘true’ value of the exchanges. When it is restricted to foreign-trade goods, it is little better than a truism. When it is not so restricted, the conception of purchasing power parity becomes much more interesting, but is no longer an accurate forecaster of the course of the foreign exchanges. Thus defined ‘purchasing power parity’ deserves attention, even though it is not always an accurate forecaster of the foreign exchanges. The practical importance of our qualifications must not be exaggerated. (Keynes, 1923, pp. 77–8)

Cassel received support for PPP from the monetary disturbances of the 1913–28 period. Extensive PPP studies were conducted for the US government (see Young, 1925) and for the League of Nations. PPP emerged in the discussion of the resumption of the pre-war gold par in Britain in 1925, and Jacques Rueff used wage-based PPP to calculate an appropriate par for France's stabilization under Poincaré in 1926–8. But while it became a regular tool of applied macroeconomics, there was also plenty of controversy. Viner (1937) challenged the doctrinal view that classical economists had a concept of PPP, arguing that without the notion of a price level PPP could not be conceived. In fact Viner had little patience with PPP. The opposition is easily recognized today: Viner and other critics always reacted to the overstated claim that PPP must hold as a matter of fact or of theory, pointing out that only a purely monetary disturbance provided the theoretical or practical experiment in which PPP would apply. For them PPP as a theory was simply misstated and as a practical proposition overrated.

A new wave of interest in PPP emerged at the end of the Second World War, when once again exchange rates had to be set following the wartime suspension of trade and convertibility. Renewed interest in PPP followed in the late 1950s and early 1960s. Yeager (1958) and Haberler (1961) emphasized the practical usefulness of PPP and highlighted the role of high price elasticities in international trade as the factor supporting PPP. High elasticities in world trade would ensure that real disturbances had only small effects on relative prices, thus establishing more nearly the conditions under which exchange rate movements predominantly reflect differences in monetary experiences.

In the late 1930s Harrod had drawn attention to the fact that divergent international productivity levels could, via their effect on wages and home goods prices, lead to permanent deviations from Cassel's absolute version of PPP. This idea had already been developed by Ricardo and has now become central to work on international real income comparisons. Balassa (1964) and Samuelson (1964) elaborated similar ideas to argue that there are systematic trend deviations from PPP. This ‘productivity bias’ to PPP is discussed in more detail below.

PPP had yet another intellectual upturn with the move to flexible exchange rates in the early 1970s. The then fashionable ‘monetary approach to the balance of payments’ developed by Robert Mundell (1968; 1971), Harry Johnson and their students readily adapted to become a PPP-based monetary approach to the exchange rate (see Frenkel and Johnson, 1975; 1978; Mussa, 1979). The exchange rate under strict PPP conditions was interpreted as a monetary phenomenon. The absolute version of PPP in (1) above combined with the quantity theory of money for each country ($M_V = P_Y$ and $M^n V^n = P^n Y^n$) yielded the key equation determining exchange rates by relative money supplies, velocities and real incomes:
Empirical research on the 1920s and on the very early data of the 1970s initially seemed to lend support to PPP and the monetary approach. But large movements in real exchange rates of the 1970s led to the currently dominant PPP scepticism. The new direction following the Mundell–Fleming model (Mundell, 1968; Fleming, 1962) of the 1960s emphasized fluctuations in real exchange rates or the terms of trade (import prices relative to export prices) arising from the discrepancies between flexible, forward-looking asset markets and asset prices, and short-run sticky prices and wages. Work on exchange rate dynamics (Dornbusch, 1976) developed these ideas about transitory deviations from PPP in a rational expectations context.

Concern with PPP continued to be very active in the late 1970s and the early 1980s. The real exchange rates of the main currencies underwent large, persistent fluctuations with important effects on trade flows and resource allocation. At the same time currency experiments in Latin America involved dramatic real appreciations with ruinous consequences for several countries. Sometimes in history there was bafflement as to how, all things considered, PPP could work so closely. This time, however, the surprise was on the other side: how could real exchange rates get that far out of line? We now review in more detail the theory and the evidence for deviations from PPP.

**Purchasing power disparities**

Qualifications to PPP take one of several forms. Departures from PPP can be ‘structural’ in the sense that they arise systematically in response to new and lasting changes in equilibrium relative prices. Alternatively, they occur in a ‘transitory’ fashion as a result of disturbances to which the economy adjusts with differential speeds in goods and assets markets. These qualifications imply that even the weak or relative form of PPP cannot be expected to hold closely.

These disparities arise primarily for the following reasons. First, the terms of trade may change as a consequence of changes in trade patterns. Second, economic growth systematically affects the relative price of home and tradable goods. Third, monetary and exchange rate changes bring about transitory deviations in real price ratios and in PPP as a consequence of imperfectly flexible wages and prices.

**Structural departures**

The literature is replete with qualifications to PPP singling out particular real disturbances that change equilibrium relative prices. Thus it has been recognized since Ricardo that real prices of home goods are high ‘in countries where manufactures flourish’. It also has been argued that the ‘price level is high in borrowing countries’. The Ricardo–Harrod–Balassa–Samuelson theory provides a framework for these ideas.

Consider a Ricardian model where the law of one price applies to tradable goods and where there is also a home good. With perfect competition and constant returns, prices are given by unit labour costs. We define as $R$ the relative consumer price levels of two countries measured in a common currency:

$$ R = \frac{P}{P^*}. $$

With identical homothetic tastes and the law of one price the international component of price indices is the same in both countries and hence cancels out in (4a). The relative price level is then determined by the relative prices of home goods in the two countries, measured in a common currency. Let $h$ and $h^*$ be the levels of productivity in tradable goods (at the competitive margin) relative to home goods in each country. It is easily shown (see Dornbusch, Fischer and Samuelson, 1977) that the relative price level then reduces to:
A uniform rise in tradable goods productivity at home would bring about a rise in the relative price level of the home country or a real appreciation. The mechanism is the following: with the law of one price applying to tradable goods, increased productivity in the tradable goods sector increases wages in that industry and hence raises economy-wide wages. But, without accompanying productivity gains in the home goods sector, costs and prices there must rise and hence the growing country’s relative price level increases as shown by (4b).

In (4b) above the national productivity relatives $h$ and $h^*$ are measured in the tradable goods sector at the competitive margin. Shifts in technology, tastes, commercial policies or labour force growth will all change the equilibrium competitive margin and hence will change the real exchange rate. Thus real factors, as the literature since Ricardo has recognized, will introduce systematic departures from PPP. For example, a shift in world demand towards the home country’s goods would raise the relative wage and reduce the range of goods produced by the home country. The rise in the relative wage, given productivity, raises the relative price level of the home country. Likewise an increase in spending relative to income (that is, borrowing or a current account deficit) will lead to a rise in the relative price level of the spending country.

A variant of the Ricardian productivity differential model as an explanation for the relatively low price of non-tradables in poor countries has been advanced by Kravis and Lipsey (1983) and Bhagwati (1984). They rely on differences in factor endowments and factor rewards rather than differences in production functions. In the poor labour-abundant country, the labour-using non-tradable services can be produced at a lower cost than in the rich, capital-abundant country. Whichever is the model, this effect, as we discuss below, has found ample support in empirical research on international real income and price comparisons.

**Transitory deviations**

There is no difficulty in accepting that prices of close substitutes or even identical goods could diverge across space at any point in time. This would be the case because, in the shortest time period, transportation and information costs make arbitrage difficult or even impossible. These difficulties would explain that PPP holds up to a constant and white noise error (see Aizenman, 1986). But in fact we have to explain relatively persistent and often large deviations from PPP. These can arise from divergent speeds of adjustment of the exchange rate compared with wages and prices. Particularly when flexible exchange rates behave like asset prices while wages are determined by long-term contracts, there is room for relative prices to show relatively persistent deviations from PPP.

Theoretical approaches to support the relative stickiness of prices can rely on the presence of long-term labour contracts combined with oligopolistic pricing in goods markets. A model of imperfect competition is essential because the less-than-perfect degree of substitution is a key ingredient in PPP deviations. Less-than-perfect substitution means that we are not dealing with the law of one price and arbitrage but with firms’ decisions to set relative prices. A suggestive framework is the Dixit–Stiglitz (1977) model of product diversification with imperfect competition. Given constant returns and labour as the only factor each firm will set prices as a fixed and common markup over wages. In the world market for the products of a particular industry the relative price of domestic and foreign variants of the product is determined by relative unit labour costs measured in a common currency:

$$\frac{p}{e p^*} = \frac{w}{w^* e}$$

where $w$ and $w^*$ denote unit labour costs at home and abroad in the respective currencies. Given sluggish wages, for contract reasons or otherwise, exchange rate movements will be one-for-one reflected in changes in the real exchange rate.

The assumption that firms base their pricing entirely on home cost, as appears in this model, leaves no room for the alternative of spatial price differentiation. There is as yet no definitive or even large body of literature that develops the industrial organization aspects of pricing under flexible and volatile exchange rates (see Dornbusch, 1987).

**Early empirical evidence**
There is little doubt that the prices of primary commodities traded on major organized exchanges in different locations are fully arbitrated when literally all adjustments for contracts (maturity, delivery terms and location, and so on) are made. But much available evidence suggests that PPP in the strong or weak version does not apply in the same fashion to manufactured goods. This lack of close conformity with PPP is as true for individual commodity prices as it is for aggregate price indices. Moreover, the absence of a very tight PPP relation appears to hold especially during major monetary dislocations. Studies of high-inflation episodes appear to offer support for PPP in that they show close cumulative movements of internal prices and the exchange rate. But even here the evidence is deceptive, as becomes clear when one looks at relative prices, which do show large variations. Indeed, particularly during high inflation the differing frequencies of adjustments of wages, prices and the exchange rate introduce considerable variability in relative prices which disappears only in the most intense stages of hyperinflation where all pricing comes to be based on the exchange rate. Kravis and Lipsey (1978) and Isard (1977) have shown tests of the law of one price at the level of narrowly defined manufactured goods. These studies established that for the same good (or highly substitutable goods) there are quite definitely persistent price discrepancies between domestic and export prices, between domestic and import prices, and between export prices to different markets.

Empirical studies on time series PPP relationships for aggregate price indices since the mid-1960s also show evidence of persistent deviations. Once relative prices are not strictly constant PPP will perform differently depending on the particular price index chosen for comparison. Commonly the choice is among CPIs, WPIs, and GDP deflators. WPIs are often ruled out on the argument that conceptually they are poorly defined, being neither producer nor consumer price indices. The preference is most often given to CPIs and GDP deflators, which have a clear methodological definition. As a measure of the departure from PPP, research shows that, for the post-Bretton Woods period since 1971 or so, bilateral comparisons of exchange-rate-adjusted inflation rates (that is, comparisons of inflation rates measured in a common currency) reveal that the correlation coefficients are much lower than unity, which is the theoretical value implied by the weak form of the PPP hypothesis.

The strong deviations from PPP can likewise be found by looking at relative prices, in which case one would compare the variability of relative price indices (the standard deviation expressed as a fraction of the mean), measured in a common currency and using the United States as the numeraire country. The data for these relative price variability measures show a large increase in variability in the shift from fixed (Bretton Woods period) to flexible (post-Bretton Woods) exchange rates, suggesting that real exchange rates are approximately as volatile as nominal exchange rates (Baxter and Stockman, 1989).

The evidence on deviations from PPP leaves little doubt that they have been large and persistent. To pin down the major sources of these movements, however, is significantly more difficult. Among the chief explanations are capital flows induced by internationally divergent monetary–fiscal mixes interacting with sluggish wages and prices. Thus it would appear that a country that shifts in the direction of tight money and easy fiscal policy, for example, will experience real appreciation.

Besides these dominant macro-shocks there is, of course, a host of other factors. Jacob Frenkel has observed in this context:

> The experience during the 1970s illustrates the extent to which real shocks (oil embargo, supply shocks, commodity booms and shortages, shifts in the demand for money, differential productivity growth) result in systematic deviations from PPP ... It should be noted, however, that to some extent the overall poor performance of the purchasing power parities doctrine is specific to the 1970s. During the floating rate period of the 1920s, the doctrine seems to have been much more reliable. (Frenkel, 1981, pp. 694–5)

The lack of solid empirical evidence in support of PPP extends to the assumption that divergent price developments ‘cause’ exchange rate depreciation. From the study of experiences of high inflation it is clear that in some instances capital flight and exchange depreciation precipitated increases in inflation. In fact Nurkse (1944) makes much of the point that expectations acting via capital flight on the exchange rate, and not actual money and prices, often initiate an inflationary episode.

With respect to structural PPP deviations, there is some evidence that establishes that over time real exchange rates, rather than showing constancy or a tendency to fluctuate around a constant level, in fact exhibit a distinct trend. Productivity levels or real incomes influence systematically the relative prices of tradable and non-tradable goods within a country and hence international relative price levels across countries and across time. In the context of an international income comparison project, Kravis and associates have constructed indices of relative national price levels using an absolute price comparison approach. Drawing on a detailed sample of prices they construct matched sets of the price of individual commodity groups in a particular country relative to a reference country. For commodity i the relative price is $p_i / p_i^*$, where the p's are measured in the respective countries’ currencies with an asterisk denoting the reference country. Using an arithmetic average with weights $a_i$, given by final expenditure shares, a PPP index is defined:

$$
\text{PPP} = \sum_{i} a_i \left( \frac{p_i}{p_i^*} \right).
$$
The expenditure shares $a_i$ used in the weighting may be those of either one of the countries or some other appropriate weighting scheme. The Kravis real price level of a country (relative to the reference country) is defined as the PPP index in (6) divided by the actual exchange rate:

$$\text{Kravis real price level} = \frac{\text{PPP}}{e}. \quad (7)$$

This real price level definition represents a measure of the deviation from the law of one price at the aggregate level. Kravis and Lipsey (1983, p. 21) report the results of a cross-section study of 34 countries where the 1975 real price level as defined in (7) of the sample of countries (relative to the United States) is explained by the countries real income compared with that of the United States. The evidence shows that the higher a country's relative income is, the higher is its relative price level. Work by Hsieh (1982) using a time series approach further supports the extensive evidence on divergent productivity trends as a source of structural PPP deviations. It must be noted, though, that the evidence on structural deviations continues to be challenged by Officer (1984).

**Implications of purchasing power disparities**

The possibility that exchange rate movements do not conform to tight PPP patterns poses important issues for macroeconomic measurement, linkages, and policy. We review here several implications.

**Real income comparisons**

With strict PPP based on the law of one price, the purchasing power of a given income in one country and currency can be compared with the purchasing power of the income of any other country by simply measuring incomes in a common currency. If one income is 20 times larger than the other, measured in the same currency at actual exchange rates, then its command over goods and services is 20 times larger. But the fact that PPP does not hold leads to systematic biases in the comparisons. Specifically, as the work of Kravis and associates (1978; 1982; 1983) has shown, the real income of poor countries is severely underestimated when actual exchange rates are used to make the comparison. The low relative price of non-tradables in poor countries (due to the productivity differential discussed earlier) yields for poor countries true purchasing power of income significantly above what exchange rate-converted income suggests. Note that the biases are particularly large for countries whose incomes are only a small fraction of the US levels, so that productivity differential effects play a maximal role. The poorer a country, the lower is the real price level. An interesting point is that these real price level differences apply both to goods and to services. One reason they also apply to goods is that these always have a local retail component which, on account of labour costs (though perhaps not transport), will tend to be low in poor countries. For low-income countries actual real income is two to three times what exchange rate-converted incomes suggest. These structural deviations from PPP, of course, would be invariant under a purely monetary disturbance so that the weak form of PPP still applies.

**Interest rate linkages and PPP**

Under perfect international mobility of capital and risk-neutral speculation there is a linkage between nominal interest rates and the anticipated rate of depreciation, which is given by the open economy Fisher equation:

$$i = i^* + \pi \quad (8a)$$
where $i$ and $i^*$ are the nominal interest rates at home and abroad and $x$ is the anticipated rate of depreciation of the home currency. Adding and subtracting anticipated inflation rates on both sides yields an equation in terms of inflation-adjusted or real interest rates:

$$r^* = r - \frac{\bar{R}}{R}.$$  

(8b)

Real interest parity, according to (8b), prevails when the real interest differential equals the expected rate of real appreciation, $\bar{R}/R$. From the real interest parity condition it is clear that under exact PPP the real exchange rate is constant. In the absence of restrictions on capital flows, real interest rates must therefore be strictly equalized across countries. The real interest parity equation has two interesting implications. A first one is the linkages between the level of real exchange rates and monetary policy. Suppose that in a medium-term macroeconomic context, following a disturbance, the actual real exchange rate adjusts only gradually to the trend level $R'$ according to the process: $\frac{R}{R} = (1/\lambda) (R' - R)$. Here $1/\lambda$ is the speed of adjustment, which depends among other things on the extent to which wages and prices are sticky. Combining this process with (8b) yields an equation for the equilibrium real exchange rate:

$$R = R' + \lambda (r - r^*).$$  

(9)

The result shown here is that, when real interest rates at home exceed those abroad, the real exchange rate will be low or appreciated relative to its trend value. A tightening of monetary policy, by raising real interest rates, would thus bring about a (transitory) real appreciation. Equation (9) emerges from the dynamic Mundell–Fleming models and is often thought to explain real exchange rate movements and their tendency to return only gradually to their long-run value. A second way to look at (8b) draws on the fact that the tradable–non–tradable goods distinction has implications for real exchange rates. Suppose the law of one price holds for tradable goods and that shares in the two countries’ price indices are the same. Then, as argued before, the real exchange rate is equal to the relative price of non-tradable goods (in a common currency) in the two countries. Structural disturbances such as differential productivity growth or changes in aggregate demand will now have a systematic impact on relative non-tradable goods prices and hence real interest-rate differentials. Specifically, the country with the higher growth rate of productivity has a rising relative price of home goods and thus has a lower real rate of interest. As another example consider a country where aggregate demand is transitorily high. The real price of home goods will be high, but falling. Accordingly, the real interest rate will be higher than that abroad. Deviations from PPP, trend or short-run, thus introduce an equilibrium international interest-rate differential. PPP deviations affect interest differentials another way. In (8a) above we assumed risk neutrality. But, once risk-averse speculators are admitted, the possibility that exchange rate movements could deviate from a strict PPP pattern introduces portfolio risk associated with the currency composition of the portfolio. PPP deviations are thus one basic motive for international portfolio diversification. A risk premium will appear and among the determinants of this premium is the variability of the real exchange rate. The risk premium will be an increasing function of real exchange rate uncertainty.

Exchange rate policy

In Cassel's view even small deviations from PPP would bring about large changes in trade flows and hence a rapid discipline to move prices back into line inter-nationally. But the reversion towards PPP has often not been quick and deviations from PPP have taken more nearly the pattern of persistent swings in a country’s external competitiveness. The changes in competitiveness in turn have implied large swings in external balances, in output and in employment in the tradable goods sector. Changes in exchange rates that deviate from PPP at the same time influence the path of a country’s inflation: real depreciation increases inflation and real appreciation dampens inflation. These effects of purchasing power disparities make the exchange rate an important issue in macroeconomic policy. Countries with high inflation cannot afford a fixed exchange rate since the loss in external competitiveness would soon lead to excessive and growing external deficits and high
purchasing power parity: The New Palgrave Dictionary of Economics

unemployment. If freely fluctuating rates are deemed too unstable the policy answer is often a crawling peg. In a crawling peg regime the rate of depreciation follows a PPP path such that over time the real exchange rate remains constant (see Williamson, 1965; 1982). Such a policy is an important advance over a system of occasional devaluations (too little, too late), but it is not without risks, for two reasons. First, freezing the real exchange rate may be a bad policy when disturbances in fact call for a path of, say, real depreciation. Second, there is a trade-off between stability of the real exchange rate and price stability. A policy of fully accommodating any and all price or cost disturbances by an offsetting depreciation may in fact remove price stability altogether (see Dornbusch, 1982).

PPP issues enter exchange rate policy also when a country seeks to gain macroeconomic advantages by a deliberate policy of driving the exchange rate away from PPP. A real depreciation serves to gain competitiveness and shift employment toward the depreciating country. In the 1930s this was called a ‘beggar-thy-neighbour’ policy, and in post-Second World War Europe it became ‘export-led growth’. A policy of real appreciation, by contrast, serves to reduce inflationary pressure as the rate of increase of tradable goods prices is pushed below the prevailing rate of inflation. These macroeconomic effects of purchasing power disparities are not difficult to bring about: easy money, in the short and medium term, serves to depreciate the exchange rate and thus create employment. This policy is more effective and more lasting the more sticky wages are and the smaller the connection between wages, prices and the exchange rate is. By contrast, in an economy that is strongly indexed and in particular with exchange rate influences on indexation, an attempt at creating employment via easy money would be frustrated as exchange depreciation precipitates offsetting wage and price inflation.

Deviations from PPP have also been used as a disinflation policy. Deliberate fixing of the exchange rate or pre-announced rates of depreciation below the prevailing rates of inflation have been adopted in various countries to break inflation. The experience has been almost uniformly disappointing and worse. The resulting overvaluation very often has led to excessive external deficits, borrowing and capital flight, and ultimately only moderate success at disinflation. The cases of Chile and Argentina in the late 1970s were particularly extreme. Exchange rate policies led to extreme overvaluation. But these economies had been opened to unrestricted trade or free capital flows. The public therefore could speculate against the overvalued currency by massive imports or capital flight while the governments financed the resulting deficits by external borrowing. In the end the scheme collapsed, leaving the private sector with foreign goods or foreign assets and the governments with huge foreign debts.

PPP disparities are relevant for the exchange rate choice between flexible and fixed or managed rates. In a world where exchange rate movements conform strictly to PPP and monetary policy governs prices there is no issue. Flexible rates then allow a country to choose its preferred rate of inflation. But once disparities are possible both as a result of structural trends and perhaps as a consequence of short-term capital movements the fixed versus flexible rate choice becomes more difficult. Flexible rates are preferable because there is no risk that the government pegs a rate that no longer corresponds to equilibrium. But flexible rates suffer the handicap that disequilibrating capital flows can drive the real exchange rate away from the level warranted by the fundamentals of the goods market. In particular, if exchange rates respond more to asset markets than price levels, persistent real appreciation or depreciation become a possibility. When this occurs there is invariably a call for PPP-based foreign exchange market intervention to bring rates back to ‘fundamentals’. Explicit target zones have been proposed as a means of maintaining the advantages of flexible rates within limits to maintain approximate PPP (see Williamson, 1983).

Flexible rates are also a concern because disequilibrating capital flows can provoke large changes in the rate of inflation. A loss of confidence, whether warranted or not, induces a capital outflow and a real exchange rate depreciation, as the experience of many East Asian countries in the late 1990s has demonstrated. If domestic financial policies are linked via the budget or indexation to the exchange rate, the real depreciation can initiate a sharp increase in inflation. Much of the discussion of the merits of flexible rates has concentrated on the question of whether speculative capital flows ‘cause’ the inflation or whether they merely respond to an inflationary situation, bringing about exchange depreciation in line with prevailing inflation. The Graham–Nurkse–Robinson view asserts, contrary to Milton Friedman, that destabilizing capital flows are the central element in the outbreak of major inflation experiences. Exchange stabilization, similarly, is seen as an essential step in stopping a runaway inflation and initiating a stabilization programme.

PPP is also relevant in the context of devaluation of a fixed rate. In the monetary approach to the balance of payments a firm tenet is the proposition that a devaluation cannot exert a lasting effect on relative prices or the balance of trade. Exchange rate depreciation raises the prices of all tradable goods in the same proportion and any effect then must be limited to a temporary depression of home goods prices due to reduced absorption. As money responds to the external surplus, real absorption rises and the initial real equilibrium is restored.

This approach has the disturbing implication that devaluation does not appear to be an effective means of coping with trade or employment problems. In practice devaluation will work well when it is designed to speed up the adjustment from an initial disequilibrium in a situation where wages and prices are less than fully flexible downward. But a devaluation is likely to be ineffective if it is accompanied by a monetary expansion and wage increases, thus eliminating any real effects.

More recent developments

During the 1990s PPP attracted an enormous amount of interest. Presumably driven by the disbelief that such an intuitively appealing proposition about exchange rate behaviour had found little support in the data, researchers embarked in a ‘search’ for PPP using increasingly sophisticated time series methods. The early 1990s saw a proliferation of studies testing for PPP over the long run either by testing whether nominal exchange rates and relative prices move together (co-integrate) or by testing whether the real exchange rate has a tendency to revert to a stable equilibrium level over time (is stationary). The latter approach is motivated by the fact that the real exchange rate may be defined as the nominal exchange rate adjusted for relative national price levels and is, therefore, a measure of the deviation from PPP.

Regardless of the great interest in this area of research, the validity of long-run PPP and the properties of PPP deviations have remained the subject of an ongoing controversy. Unit root and co-integration studies generally report the absence of significant mean reversion of the real exchange rate for the recent floating experience (recent surveys include Taylor and Taylor, 2004; Sarno, 2005). However, the literature has been able to identify an important pitfall in studies of the long-run behaviour of PPP deviations. Specifically, one well-documented explanation for the inability to find clear-cut evidence of PPP is the low power of conventional tests to reject a false hypothesis of a unit root in (non-stationarity of) the real exchange rate (that is, the hypothesis that PPP is invalid) with a sample span corresponding to the length of the recent float (Frankel, 1990). Put simply, conventional time series methods would not be able to detect the reversion of exchange rates towards PPP even if PPP were indeed valid unless very long samples of data were made available. Researchers have sought to overcome the ‘power’ problem in testing for PPP in various ways. One logical reaction to tackle this problem was to test for mean reversion in the real exchange rate using long spans of data. Lothian and Taylor (1996), for example, use two centuries of data on dollar–sterling and franc–sterling real exchange rates and provide evidence supporting PPP in the recent floating period. This evidence is ‘indirect’ in the sense that PPP was found to hold over the full sample, which includes the recent float. Lothian and Taylor could not find any significant evidence of a structural break between the pre- and post-Bretton Woods period, and argue that the widespread failure to detect mean reversion in real exchange rates during the recent float may simply be due to the shortness of the sample.

Long-span studies have, however, been subject to some criticism in the literature. One criticism relates to the fact that, because of the very long data spans involved, various exchange rate regimes are typically spanned. Also, real shocks may have generated structural breaks or shifts in the equilibrium real exchange rate. This is a necessary evil with long-span studies of which researchers are generally aware. The long samples required to generate a reasonable level of power with standard univariate unit root tests may be unavailable for many currencies (perhaps thereby generating a ‘survivorship bias’ in tests on the available data) and, in any case, may potentially be inappropriate because of differences in real exchange rate behaviour both across different historical periods and across different nominal exchange rate regimes (for example, Baxter and Stockman, 1989).

In light of the evidence provided by this literature, there remain several unresolved puzzles, among which two are prominent. First, it is still controversial whether long-run PPP is valid during the recent floating exchange rate regime from 1973 or so. Second, it is puzzling why the majority of studies which favour long-run PPP, such as the long-span studies, find empirical estimates of the persistence of PPP deviations that are too high – the half-life of shocks, that is, the time it takes for a shock to the real exchange rate to dissipate by one half, ranges between three and five years – to be explained in light of conventional nominal rigidities and to be reconciled with the large short-term volatility of real exchange rates (Rogoff, 1996).

A source of potentially important bias in estimates of the half-life is caused by cross-sectional aggregation in moving from the law of one price for individual goods to PPP deviations based on price indices. Imbs et al. (2005) demonstrate how such bias is bound to be present in estimates of the real exchange half-life and provide empirical evidence that the bias is substantial. Crucini, Telmer and Zachariadis (2005) adopt a similar approach to understanding the behaviour of deviations from the law of one price and PPP by examining micro-data on absolute prices of goods. They study good-by-good deviations from the law of one price for over 5,000 goods and services between European Union countries for the years 1975, 1980, 1985 and 1990, and report that between most countries there are roughly as many overpriced goods as there are underpriced goods so that PPP holds to a good approximation, particularly after wealth differences are controlled for.

It is instructive to graph the real exchange rate and its components over a long span of time to speculate on its low-frequency properties. The top panel of Figure 1 plots the time series for prices in the UK and the United States as well as the nominal dollar–sterling exchange rate over the sample period 1791–2000, with all time series expressed in logarithms.

Figure 1
It is quite interesting how the price series move together – even without being adjusted by the exchange rate to express prices in a common currency – over such a long period. It is also apparent how the bigger and more persistent wedge between the two prices seems to occur in the post-Bretton Woods period, essentially from the 1970s onwards. This wedge also coincided with the beginning of a corresponding trend in the nominal exchange rate, exactly as one would expect under PPP. The bottom panel of Figure 1 then graphs the real exchange rate constructed from these time series (in deviation from the mean). The real exchange rate appears to have a tendency to return to its long-run mean (consistent with the PPP hypothesis), although the mean is crossed only 20 times in more than 200 years of data, indicating a remarkable degree of persistence in departures from PPP. Furthermore, the real exchange rate appears to be more persistent when it is in the proximity of the long-run mean, whereas reversion towards the mean happens more rapidly when the absolute size of the PPP deviation is large. This eyeball analysis of 200 years of real dollar-sterling exchange rate therefore suggests that this real exchange rate may be stationary, albeit persistent, and that it is very persistent in the neighbourhood of PPP, while being mean-reverting at a faster speed when the deviation from PPP gets larger. This is consistent with the existence of nonlinear dynamics in the real exchange rate, implying that the speed of mean reversion is state dependent.
In fact, the empirical literature on PPP has pursued formally the idea of nonlinearities in real exchange rate dynamics since the second half of the 1990s, providing several insights. In essence, the procedures conventionally applied by researchers to examine long-run PPP assume that the real exchange rate follows a linear process and depends on its own past values. In turn, this means that adjustment to the PPP equilibrium is assumed to be both continuous and of constant speed, regardless of the size of the past deviation from PPP. However, the presence of transactions costs may imply a nonlinear process, which has important implications for the conventional tests of long-run PPP. A number of authors have developed theoretical models of nonlinear real exchange rate adjustment arising from transactions costs in international arbitrage (for example, Dumas, 1992). In most of these models proportional or ‘iceberg’ transport costs (‘iceberg’ because a fraction of goods is presumed to ‘melt’ when shipped) create a band for the real exchange rate within which the marginal cost of arbitrage exceeds the marginal benefit. Assuming instantaneous goods arbitrage at the edges of the band then typically implies that the thresholds become reflecting barriers.

Drawing on recent work on the theory of investment under uncertainty, some of these studies show that the thresholds should be interpreted more broadly than as simply reflecting shipping costs and trade barriers per se, but also as resulting from the sunk costs of international arbitrage and the resulting tendency for traders to wait for sufficiently large arbitrage opportunities to open up before entering the market.

Taylor (2001) has shown that empirical estimates of the half-life of shocks to the real exchange rate may be biased upwards because of two empirical pitfalls. The first pitfall identified by Taylor relates to temporal aggregation in the data. Using a model in which the real exchange rate follows an AR(1) process at a higher frequency than that at which the data is sampled, Taylor shows analytically that the degree of upward bias in the estimated half-life rises as the degree of temporal aggregation increases, that is, as the length of time between observed data points increases. The second pitfall highlighted by Taylor concerns the possibility of nonlinear adjustment of real exchange rates. On the basis of Monte Carlo experiments with a nonlinear artificial data generating process, Taylor shows that there can also be substantial upward bias in the estimated half-life of adjustment from assuming linear adjustment when in fact the true adjustment process is nonlinear.

Overall, the theoretical models based on non-zero transactions costs of arbitrage in international goods markets suggest that the exchange rate will become increasingly mean-reverting with the size of the past deviation from the PPP equilibrium level. In other words, the speed at which the real exchange rate reverts to PPP depends on the size of the past deviation from PPP itself. When the real exchange rate is arbitrarily close to PPP, the real exchange rates may move randomly next period since agents have no arbitrage opportunities available in international goods markets. At the other extreme, when the real exchange rate deviates from PPP by a very large extent, it is likely that arbitrage forces will imply movements of goods and changes in prices (expressed in a common currency) that induce fast reversion to PPP.

Note that these arguments rationalize mean reversion in the real exchange rates based on ideas that relate to the law of one price in the sense that refers to tradable goods only. However, we argue that this is reasonable given that Engel (1999), in a study that measures the proportion of dollar real exchange rate movements that can be accounted for by movements in the relative prices of non-tradable goods, finds that relative prices of non-tradable goods appear to account for essentially none of the movement of dollar real exchange rates. Hence, much of the explanation for the time series properties of PPP deviations is likely to reside in the behaviour of deviations from the law of one price, that is, movements in the relative prices of tradable goods.

To turn to the empirics of nonlinear reversion to PPP, models that capture the nonlinear behaviour described above have shed light on several aspects of the behaviour of the real exchange rate. For example, Michael, Nobay and Peel (1997) apply a nonlinear model to monthly interwar data for the French franc–US dollar, French franc–UK sterling and UK sterling–US dollar as well as for the Lothian and Taylor (1996) long-span data-set described in Figure 1. Their results clearly reject the linear framework in favour of a nonlinear process. The systematic pattern in the estimates of the nonlinear models provides strong evidence of mean-reverting behaviour for PPP deviations, and helps explain the mixed results of previous studies.

Using data for the recent float alone, Taylor, Peel and Sarno (2001) provide strong confirmation that the four major real bilateral dollar exchange rates obtaining among the G5 economies are well characterized by nonlinearly mean-reverting processes. Their estimated model implies an equilibrium level of the real exchange rate in the neighbourhood of which the behaviour of the real exchange rate is close to a random walk, becoming increasingly mean-reverting with the absolute size of the deviation from equilibrium, consistent with the theoretical literature on the nature of real exchange rate dynamics in the presence of international arbitrage costs.

Impulse response functions based on these nonlinear real exchange rate models suggest that the speed of real exchange rate adjustment is typically much faster than the very slow speeds of real exchange rate adjustment often recorded in the literature. For example, the estimated half-lives (in months) for dollar–sterling and dollar–yen are the following:

<table>
<thead>
<tr>
<th>Shock (%)</th>
<th>40</th>
<th>30</th>
<th>20</th>
<th>10</th>
<th>5</th>
<th>1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dollar–sterling</td>
<td>10 20 22 26 29 32</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Dollar–yen</td>
<td>14 18 24 32 38 42</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

where the first row reports the size of the shock (in percentage terms) to the real exchange rate. The estimated half-lives of these major real dollar exchange rates illustrate the nonlinear nature of the response to shocks, with larger shocks mean-reverting much faster than smaller shocks. The dollar–sterling rate displays quite fast mean reversion, ranging from a half-life of less than one year for the largest shocks of 40 per cent to just under three years for small shocks of one percent; for shocks of five to ten per cent, the half-lives are just over two years. The dollar–yen displays higher persistence, with half-lives ranging from 14 to 42 months. These results therefore seem to shed some light on the PPP puzzles.
Only for small shocks occurring when the real exchange rate is near its equilibrium do nonlinear models consistently yield half-lives in the range of three to five years, which Rogoff (1996) terms ‘glacial’. For dollar—sterling, even small shocks of one to five per cent have a half-life less than three years; for larger shocks, the speed of mean reversion is even faster. An interesting experiment in terms of gauging the extent to which market integration and the reduction of trade costs impacts on the degree of mean reversion in real exchange rates is provided by the advent of the euro in 1999. Koedijk, Tims and van Dijk (2004) provide empirical evidence that the introduction of the euro and, more generally, the process of economic integration in Europe have accelerated convergence to PPP, consistent with a transactions-costs goods-market arbitrage view of the mean reversion properties of the real exchange rate.

The vast empirical literature briefly reviewed here suggests that there are at least three features that are potentially important in designing a suitable model for the deviations from PPP. The first feature is that the model needs to allow for the fact that adjustment towards PPP is likely to occur at different speeds via nominal exchange rates and prices. The majority of empirical studies on PPP are based on univariate representations of the real exchange rate. This approach is valid only if certain (common factor) restrictions in the process linking exchange rates and prices are satisfied. Employing a model which does not impose these restrictions increases the power of the econometrics methods employed, while allowing us to shed light on the relative importance of nominal exchange rates and prices in restoring the PPP equilibrium. The second desirable feature is that the model allows explicitly for the possibility that different monetary and exchange rate regimes generate regime shifts in the structural dynamics of PPP deviations, especially when one uses long spans of data. The third feature is that the model might be nonlinear, in accordance with the growing evidence that exchange rate dynamics displays statistically and economically important nonlinearities.

To account for these three features, Sarno and Valente (2006) extend the long-span data used by Obstfeld and Taylor (2004) and apply a general modeling methodology in which regime changes and nonlinearities in the dynamic relationship between exchange rates and prices are explicitly allowed for, without imposing common factor restrictions. They examine the G5 countries across different exchange rate regimes, including the gold standard, the Bretton Woods period, and the floating regime since the 1970s. Over the sample period examined, the economic history of the countries involved has seen a number of fundamental changes in monetary and exchange rate regimes, institutional structure and policy targets which, in addition to the continuous evolution of the financial system and various nominal and real shocks, represent serious potential pitfalls to researchers attempting to find an empirical model of the deviations from PPP that is stable over the full sample.

Sarno and Valente’s results are supportive of long-run PPP for each of the four major exchange rates examined and of a simple basic conjecture: under fixed exchange rate regimes relative prices adjust to restore deviations from long-run equilibrium, while nominal exchange rates bear most of the burden of adjustment under flexible exchange rate regimes. This is consistent with the general notion that the relative importance of exchange rates and relative prices in restoring the long-run equilibrium level of the exchange rate varies over time and is affected by the nominal exchange rate arrangement in operation. Further, the estimated half-lives of the nonlinear exchange rate models are sensibly different for fixed and floating regimes. Under fixed exchange rate regimes, shocks to the PPP equilibrium relationship may be very persistent, implying half-lives — on average across the exchange rates considered — from over five years for large real exchange rate shocks of 20 per cent to almost ten years for small shocks of 1 per cent. However, the corresponding half-lives during floating exchange rate regimes are drastically shorter, since the nominal exchange rate is allowed to operate and contribute to restoring PPP. In fact, shocks will last for less than one year on average for 20 per cent shocks. The properties of PPP deviations under floating exchange regimes implied by their model appear to be fairly consistent with standard models of open economy macroeconomics and with their dynamic properties under conventional nominal rigidities (for example, Chari, Kehoe and McGrattan, 2002). It is only under fixed exchange rate regimes, when the burden of adjustment towards PPP relies exclusively on relative prices, that we observe remarkably long half-lives of PPP shocks.

Concluding remarks

PPP remains an essential element of open economy macroeconomics for at least two reasons. First, it is a benchmark by which to judge the level of an exchange rate. Cassel argued that without PPP there would be no meaningful way of discussing overvaluation or undervaluation. That recognition has found a very concrete expression in the real exchange rate series now routinely calculated and reported by governments, international organizations and financial institutions. These series show exchange-rate-adjusted price relatives for a country relative to its trading partners. The series are constructed on the basis of GDP deflators, unit labour costs, manufacturing prices and wholesale prices for all major industrialized countries and increasingly for developing countries, too. They are used to judge changes in a country’s external competitiveness, thus implicitly assuming, as Cassel did, that movements in equilibrium relative prices are negligible. Changes in real exchange rates then (and only then) unambiguously translate into changes in competitiveness from which to expect changes in trade flows and net exports. There is no question that these data provide a useful benchmark or starting point for policy discussion.

The second use of PPP is to serve as a simple prediction model for exchange rates at medium and long horizons. Under perfectly flexible wages and prices a monetary expansion would lead to equi-proportionate increases in wages, prices and the exchange rate, leaving all real variables unchanged. This combination of the quantity theory and PPP is an important insight in guiding policy. Expansionary monetary policy can be effective only if wages and prices are less than fully flexible and will be more effective the more flexible the exchange rate is. The essential channel is the real depreciation of the exchange rate that served to create employment, at least for a while. Similarly, exchange depreciation can be effective only if money wages and prices are unresponsive. Policy can be effective only if PPP fails to hold. Macroeconomic theory goes increasingly in the direction of sound microfoundations, information, contracting, and pricing models under transactions costs to explore what the basis of PPP failure is in the short run and to determine the resulting...
extent and persistence of policy effects.

purification

Stephen Morris
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Many complete information games have equilibria only in mixed strategies, where players are required to randomize over pure strategies among which they are indifferent according to a fixed probability distribution. Harsanyi showed that, if such a game were perturbed – with each player observing an idiosyncratic independent payoff shock with continuous support – then the perturbed games will have pure strategy equilibria which will converge to the mixed strategy equilibrium as the perturbations become small. We review the strong conditions on perturbations under which Harsanyi's result holds and discuss weaker conditions on perturbations which ensure the existence of pure strategy equilibria without approximating all mixed equilibria of the unperturbed game.

Article

In a mixed strategy equilibrium of a complete information game, players randomize between their actions according to a particular probability distribution, even though they are indifferent between their actions. Two criticisms of such mixed strategy equilibria are (a) that players do not seem to randomize in practice, and (b), if a player were to randomize, why would he or she choose to do so according to probabilities that make other players indifferent between their strategies?

Since many games have no pure strategy equilibria, it is important to provide a more compelling rationale for the play of mixed strategy equilibria. Harsanyi (1973) gave a ‘purification’ interpretation of mixed strategy equilibrium that resolves these criticisms. The complete information-game payoffs are intended as an approximate description of the strategic situation, but surely do not capture every consideration in the minds of the players. In particular, suppose that a player has some small private inclination to choose one action or another independent of the specified payoffs, but this information is not known to the other players. Then the behaviour of such players will look – to their opponents and to outside observers – as if they are randomizing between their actions, even though they do not experience the choice as randomization. Because of the private payoff perturbation, they will not in fact be indifferent between their actions, but will almost always be choosing a strict best response. Harsanyi's remarkable purification theorem showed that all equilibria (pure or mixed) of almost all complete information games are the limit of pure strategy equilibria of perturbed games where players have independent small shocks to payoffs.

Reny and Robson (2004) present an analysis that unifies the purification interpretation with the ‘classical’ interpretation that players randomize because they think that there is a small chance that their mixed strategy may be observed in advance by other players. But Harsanyi's purification theorem justly provides the leading interpretation of mixed strategy equilibria among game theorists today.

I first review Harsanyi's theorem. Harsanyi's result applies to regular equilibria of complete information games with independent payoff shocks; since many equilibria of interest (especially in dynamic games) are not regular, Harsanyi's result cannot be relied upon in many economic settings of interest; I therefore briefly review what little is known about such extensions.
Harsanyi's theorem has two parts: (a) pure strategy equilibria always exist in suitably perturbed versions of a complete information game; and (b) for any regular equilibrium of a complete information game and any sequence of such perturbed games converging to the complete information game, there is a sequence of pure strategy equilibria converging to the regular equilibrium. An important literature has ignored the latter approachability question and focused on the former pure strategy existence quest, identifying conditions on an information structure – much weaker than Harsanyi's – to establish the existence of pure strategy equilibria. I conclude by reviewing these papers.

Consider two players engaging in the symmetric coordination game below.

<table>
<thead>
<tr>
<th></th>
<th>A</th>
<th>B</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>2,2</td>
<td>0,0</td>
</tr>
<tr>
<td>B</td>
<td>0,0</td>
<td>1,1</td>
</tr>
</tbody>
</table>

As well as the pure strategy Nash equilibria \((A,A)\) and \((B,B)\), this game has a symmetric mixed strategy Nash equilibrium where each player chooses \(A\) with probability \(\frac{1}{3}\) and \(B\) with probability \(\frac{2}{3}\).

But suppose that, in addition to these common knowledge payoffs, each player \(i\) observes a payoff shock depending on the action he or she chooses. Thus,
where $\varepsilon > 0$ is a commonly known parameter measuring the size of payoff shocks and $(\eta_{1A}, \eta_{1B})$ and $(\eta_{2A}, \eta_{2B})$ are distributed independently of each other, and player $i$ observes only $(\eta_iA, \eta_iB)$. Finally, assume that, for each player $i$, $\eta_i = \eta_iA - \eta_iB$ is distributed according to a continuous density $f$ on the real line with corresponding c.d.f. $F$.

This perturbed game is one with incomplete information, where a player's strategy is a function $s_i : \mathbb{R} \to \{A, B\}$. In equilibrium, each player will follow a threshold strategy of the form

$$s_i(\eta_i) = \begin{cases} A & \text{if } \eta_i \geq z_i \\ B & \text{if } \eta_i < z_i \end{cases}$$

Under such a strategy, the *ex ante* probability that player $i$ will choose action $B$ is $\pi_i = F(z_i)$, and the probability he or she will choose $A$ is $1 - \pi_i$. Thus we can re-parameterize the strategy as

$$s_i(\eta_i) = \begin{cases} A & \text{if } \eta_i \geq F^{-1}(\pi_i) \\ B & \text{if } \eta_i < F^{-1}(\pi_i) \end{cases}$$

Let us look for a strategy profile $(s_1, s_2)$ of the incomplete information game, parameterized by $(\pi_1, \pi_2)$, that forms an equilibrium of the incomplete information game. Since player 1 thinks that player 2 will choose action $A$ with probability $1 - \pi_2$ and action $B$ with probability $\pi_2$, player 1's expected payoff gain from choosing action $A$ over action $B$ is then

$$2(1 - \pi_2) + \varepsilon \cdot \eta_1 - \pi_2.$$
Thus player 1’s best response must be to follow a threshold strategy with threshold

\[ F^{-1}(\eta_1) = \frac{3\eta_2 - 2}{\varepsilon} \]

or

\[ \varepsilon F^{-1}(\eta_1) = 3\eta_2 - 2. \]

Symmetrically, we have

\[ \varepsilon F^{-1}(\eta_2) = 3\eta_1 - 2. \]

Thus, there will be a symmetric equilibrium where both players choose action B with probability \( \pi \) if and only if

\[ \varepsilon F^{-1}(\eta) = 3\pi - 2. \]

For small \( \varepsilon \), this equation has three solutions tending 0, \( \varepsilon \), and 1 as \( \varepsilon \to 0 \). These solutions correspond to the three symmetric Nash equilibria of the above complete information game, respectively: (a) both always choose A, (b) both choose B with probability \( \frac{2}{3} \), and (c) both always choose B.

Harsanyi's purification theorem generalizes the logic of this example. If we add small independent noise to each player's payoffs, then each player will almost always have a unique best response and thus the perturbed game will have a pure strategy equilibrium. There is a system of equations that describes equilibria of the unperturbed game. If that system of equations is regular, then a small perturbation of the system of equations will result in a nearby equilibrium.

I will report a statement of Harsanyi's result due to Govindan, Reny and Robson (2003), which weakens a number of the technical conditions in the original theorem.

Consider an \( I \)-player complete information game where each player \( i \) has a finite set of possible actions \( A_i \) and a payoff function \( g_i: A_i \to \mathbb{R} \) where \( A = A_1 \times \cdots \times A_I \). An equilibrium \( \alpha \in \Delta(A_1) \times \cdots \times \Delta(A_I) \) is a regular Nash equilibrium of the complete information game if the Jacobian determinant of a continuously differentiable map characterizing equilibrium is non-zero at \( \alpha \) (see van Damme, 1991, Definition 1.5.1, p. 39).

The \( \mu \)-perturbed game is then an incomplete information game where each player \( i \) privately observes a vector \( \eta_i \in \mathbb{R}^{|A_i|} \). Player \( i \)'s payoff in the incomplete information game if action profile \( a \) is chosen is then \( g_i(a) + \eta_i \), thus \( \eta_i \) is a private value shock. Each \( \eta_i \) is independently drawn according to a measure \( \mu_i \), where each \( \mu_i \) assigns probability 0 to \( i \)'s expectation of \( \eta_i \) being equal under any pair of \( i \)'s pure strategies \( a_i \) and \( a_i' \), given any mixed strategy profile of the other players; Govindan, Reny and Robson (2003) note that this weak condition is implied by \( \mu_i \) being absolutely continuous with respect to Lebesgue measure on \( \mathbb{R}^{|A_i|} \). A pure strategy for player \( i \) in the \( \mu \)-perturbation is a function \( s_i: \mathbb{R}^{|A_i|} \to A_i \).
pure strategy profile $s$ induces a probability distribution over actions $V_s \in \Delta(A)$, where

$$V_s(a) = \Pr\{\eta: s_i(\eta_i) = a_i \text{ for each } i\}$$

**Theorem:** (Harsanyi, 1973; Govindan, Reny and Robson, 2003). Suppose that $\alpha$ is a regular Nash equilibrium of the complete information game and that, for each $i$, $\mu_i^n$ converges to a point mass at $0 \in \mathbb{R}^A$. Then for all $\varepsilon > 0$ and all large enough $n$, the $\mu$-perturbed game has a pure strategy equilibrium inducing a distribution on $A$ that is within $\varepsilon$ of $\alpha$, that is,

$$|V_s(a) - \prod_{i=1}^j a_i(a_i)| \leq \varepsilon$$

for all $a \in A$.

The pure strategy equilibria are ‘essentially strict’, that is, almost all types have a strict best response. An elegant proof in Govindan, Reny and Robson (2003) simplifies Harsanyi’s original proof.

**Dynamic games**

Harsanyi’s theorem applies only to regular equilibria of a complete information game. Harsanyi noted that all equilibria of almost all finite complete information games are regular, where ‘almost all’ means with probability one under Lebesgue measure on the set of payoffs. Of course, normal form games derived from general extensive form games are not generic in this sense. This raises the question of whether mixed strategy equilibria of extensive form games are purifiable in Harsanyi’s sense.

Here is an economic example suggesting why this is an important question. Consider an infinite overlapping generations economy where agents live for two periods; the young are endowed with two units of an indivisible and perishable consumption good, and the old have no endowment. Each young agent has the option of transferring one unit of consumption to the current old agent. Each agent’s utility function is strictly increasing in own consumption when young and old, and values smoothed consumption (one when young, one when old) strictly more highly than consuming the endowment (two when young, none when old). Under perfect information, this game has a ‘social security’ subgame perfect Nash equilibrium where each young agent transfers one unit to the old agent if and only if no young agent failed to do so in the past. But suppose instead that each young agent observes only whether the previous young agent made a transfer, and restrict attention to subgame perfect Nash equilibria. Then Bhaskar (1998) has shown that there is no pure strategy equilibrium with a positive probability of transfers (in fact, this conclusion remains true if all agents only observe history of any commonly known finite length). To see why, suppose there was such an equilibrium: if the young agent at date $t$ does not transfer, then the young agent at date $t+1$ must punish by not making a transfer; but the young agent at date $t+2$ did not observe the date $t$ outcome, and so will think that the young agent at date $t+1$ deviated, and will therefore not make transfers; so the young agent at date $t+1$ would have an incentive to make transfers, and not to punish as required by the equilibrium strategy.

However, Bhaskar shows that there are mixed strategy equilibria with positive transfers. In particular, there is an equilibrium where the young always transfers in the first period or if he or she observed transfers in the previous period, and randomizes between making transfers or not if he or she did not observe transfers. This strategy profile attains the efficient outcome and involves mixing off the equilibrium path only. It is natural to ask whether this equilibrium can be ‘purified’: suppose that each young agent obtains a small ‘altruism’ payoff shock that makes transfers to the old slightly attractive. The mixed strategy might then be the limit of pure strategy equilibria where the more altruistic agents make the transfers and the less altruistic agents do not. However, Bhaskar shows that the mixed strategy equilibria cannot be purified. The logic of Harsanyi’s purification result breaks down because the equilibrium is not regular.

Very little is known in general about purifiability of mixed strategy equilibria in extensive form games. Results will presumably depend on the regularity of the equations characterizing equilibria and the modelling of payoff choices in the extensive form (for example, do shocks occur at the beginning of the game or at each decision node?). The best hope of a positive purification result would presumably be in finite dynamic games, where Harsanyi’s regularity techniques might be applied. But Bhaskar (2000) gives an example of a simple finite extensive form game where mixed strategy equilibria are not purifiable because of the non-regularity of equilibria even for generic assignment of payoffs to terminal
nodes. Mixed strategy equilibria play an important role in recent developments of the theory of repeated games. Bhaskar, Mailath and Morris (2006) report some positive and negative purification results in that context.

**Purification without approachability**

Harsanyi's purification theorem has two parts. First, the ‘purification’ part: all equilibria of the perturbed game are essentially pure; second, the ‘approachability’ part: every equilibrium of a complete information game is the limit of equilibria of such perturbed games. For the first part, Harsanyi's theorem uses the assumption of sufficiently diffuse independent payoff shocks. Only the second part required the strong regularity properties of the complete information game equilibria. Radner and Rosenthal (1982) addressed a weaker version of the purification part of Harsanyi's theorem, asking what conditions on the information system of an incomplete information game will ensure that for every equilibrium (perhaps mixed) there exists an outcome equivalent pure strategy equilibrium. Thus they did not ask that every equilibrium be essentially pure and they did not seek to approximate mixed strategy equilibria of any unperturbed game. Each agent observing a signal with an atomless independent distribution is clearly sufficient for such a ‘purification existence’ result (whether or not the signal is payoff relevant). But what if there is correlation?

A simple example from Radner and Rosenthal (1982) illustrates the difficulty. Suppose that two players are playing matching pennies and each player $i$ observes a payoff-irrelevant signal $x_i$, where $(x_1, x_2)$ are uniformly distributed on $\{ (x_1, x_2) \in \mathbb{R}_+^2 | 0 \leq x_1 \leq x_2 \leq 1 \}$. In any equilibrium, almost all types of each player must assign probability $\frac{1}{2}$ to his or her opponent choosing each action (otherwise, that player would be able to obtain a payoff greater than his or her value in the zero sum game). Yet it is impossible to generate pure strategies of the players that make this property hold true. Another illustration of the importance of correlation for purification occurs in Carlsson and van Damme (1993), where it is shown that, while small independent noise leads to Harsanyi's purification result, small highly correlated noise leads to the selection of a unique equilibrium (the comparison is made explicitly in their Appendix B).

Radner and Rosenthal (1982) show the existence of a pure strategy equilibrium if each player observes a payoff-irrelevant signal with an atomless distribution and each player $i$'s payoff-irrelevant signal and payoff-relevant information (which may be correlated) are independent of each other player's payoff-irrelevant signal. This result extends if players observe additional finite private signals which are also uncorrelated with others' atomless payoff-irrelevant signals. Their method of proof builds on the argument of Schmeidler (1973) showing the existence of a pure strategy equilibrium in a game with a continuum of players. Radner and Rosenthal (1982) also present a number of counter-exs – in addition to the matching pennies example above – with non-existence of pure strategy equilibrium. Milgrom and Weber (1985) show the existence of a pure strategy equilibrium if type spaces are atomless and independent conditional on a finite valued common state variable with payoff interdependence occurring only via the common state variable. Their result – which neither implies nor is implied by the Radner and Rosenthal (1982) conditions – has been used in many applications. Aumann et al. (1983) show that, if every player has a conditionally atomless distribution over others’ types (that is, his or her conditional distribution has no atoms for almost every type), there exists a pure strategy $\varepsilon$ -equilibrium. Their theorem thus covers the matching pennies example described above.

The existence of such purifications deals with one of the two criticisms of mixed strategy equilibria raised above: people do not appear to randomize. In particular, in any such purification the ‘randomization’ represents the uncertainty in a player's mind about how other players will act, rather than deliberate randomization. This interpretation of mixed strategies was originally emphasized by Aumann (1974).

quantal response equilibria

Jacob K. Goeree, Charles A. Holt and Thomas R. Palfrey
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A quantal response specifies choice probabilities that are smooth, increasing functions of expected payoffs. A quantal response equilibrium has the property that the choice distributions match the belief distributions used to calculate expected payoffs. This stochastic generalization of the Nash equilibrium provides strong empirical restrictions that are generally consistent with data from laboratory experiments with human subjects. We define the concept of regular quantal response equilibrium and discuss several applications from the recent literature.

Article

Economic theory relies extensively on the assumption of perfect rationality, which makes it possible to construct general models with strong (and sometimes surprising) predictions. The evaluation of these models using field data requires the incorporation of random errors representing unobserved and omitted elements, measurement error, and so on. Evaluation of these models using data from laboratory experiments also requires an error structure, since choice behaviour in the laboratory is also noisy, showing clear mistakes and inconsistencies over time.

Probabilistic choice models (for example, logit, probit) have long been used to incorporate stochastic elements in to the analysis of individual decisions, and the quantal response equilibrium (QRE) is the analogous way to model games with noisy players. These probabilistic choice models are based on quantal response functions, which have the intuitive feature that deviations from optimal decisions are negatively correlated with the associated costs. That is, individuals are more likely to select better choices than worse choices, but do not necessarily succeed in selecting the very best choice. Formally, a quantal response function maps the vector of expected payoffs from available choices into a vector of choice probabilities that is monotone in the expected payoffs.

In a strategic game environment, a player's expected payoffs from different strategies are determined by beliefs about other players' actions, so beliefs determine expected payoffs, which in turn, generate choice probabilities according to some quantal response function. A QRE imposes the requirement that the beliefs match the equilibrium choice probabilities. Thus, QRE requires solving for a fixed point in the choice probabilities, analogous to the Nash equilibrium.

In fact, QRE is a generalization of Nash equilibrium, which converges to the Nash equilibrium as the quantal response functions become very steep, and approximate best response functions. This approach provides a useful theoretical framework for looking at comparative statics effects of parameter changes that may not alter Nash predictions. The incorporation of random elements also provides a foundation for standard statistical analysis of field and laboratory data in game theoretic applications.

A motivating example: generalized matching pennies
Before providing general definitions, it is useful to begin with a simple two-person matching pennies game in which the Row player chooses Top (T) or Bottom (B) and the Column player chooses left (L) or right (R). Row wins a penny (and Column loses a penny) if the outcome is (Top, Right) or (Bottom, Left) and Column wins a penny otherwise. Thus Row's expected payoff for Top \( U_T(p_R) \) is a function of Column's probability of choosing Right \( p_R \), which is easily calculated as \( U_T(p_R) = p_R(1-p_R) = 2p_R - 1 \), and similarly, \( U_B(p_R) = 1 - 2p_R \), so the optimal decision is to choose Top if Column is more likely to choose Right, that is, if \( p_R > \frac{1}{2} \). Column's expected payoffs are computed analogously, as a function of Row's probability of choosing Top \( p_T \).

Figure 1 illustrates the best response functions in the unit square of mixed strategies in the game, with the y-axis representing the row player's Top choice probability and the x-axis representing the column player's Right choice. The best response for Row is indicated by the dark step function that jumps from 0 to 1 at \( p_R = \frac{1}{2} \). Similarly, the Column player's best response line is the step function, shown in light grey, which crosses over from left to right at a height of \( \frac{1}{2} \).

Figure 1
Players' best responses and quantal responses for a generalized matching pennies game
Using the same figure, we can represent a quantal response function, which smoothes out the discontinuous best response function, reflecting the monotone and continuous choice probability as a function of payoffs. Such a quantal response function is illustrated by Row's dark curved line that rises smoothly from the bottom-left corner to the top-right corner. The probabilistic choice equals \( \frac{1}{2} \) exactly at the point where row player is indifferent between Top and Bottom. A quantal response function is also drawn for Column. The intersection of these two quantal response functions occurs in the centre of the figure, and is the quantal response equilibrium, just as the intersection of the sharp best response function at the same point is the Nash equilibrium in mixed strategies (for each decision).

Now suppose that all payoffs stay the same except for the Top-Right outcome, which gives Row a higher payoff of 9 and Column a payoff of \(-1\) as before. The increase in Row's Top-Right payoff shifts Row's best response line leftward, as indicated by the dashed line step function in the figure, and it also shifts Row's quantal response (smooth dashed line). The new Nash equilibrium (dot at the intersection of the step functions) is still at \( p_T = 0.5 \), whereas the new QRE is at a higher level \( p_T = 0.62 \). This intuitive ‘own payoff’ effect contrasts with the Nash equilibrium prediction of no change in Row's choice probabilities (since they are determined by the requirement that Column is indifferent). The own-payoff effect predicted by regular QRE accords with data from laboratory experiments that employ an asymmetric matching-pennies structure – for example, Ochs (1995), McKelvey, Palfrey and Weber (2000), Goeree and Holt (2001), and Goeree, Holt, and Palfrey (2003).

**Definitions**

Let \( G = (N, S_1, \ldots, S_n, \pi_1, \ldots, \pi_n) \) be a normal-form game, where \( N = \{1, \ldots, n\} \) is the set of players, \( S_i = \{s_{i1}, \ldots, s_{ij(i)}\} \) is player \( i \)'s set of strategies and \( S = S_1 \times \cdots \times S_N \) is the set of strategy profiles, and \( \pi_i : S_i \rightarrow \mathbb{R} \) is player \( i \)'s payoff function. Furthermore, let \( \Sigma_i = \Delta^{J(i)} \) be the set of probability distributions over \( S_i \). An element \( \sigma = \Sigma_i \) is a mixed-strategy, which is a mapping from \( S_i \) to \( \Sigma_i \), where \( \sigma(s_i) \) is the probability that player \( i \) chooses pure-strategy \( s_i \). Let \( \Sigma = \Sigma_1 \times \cdots \times \Sigma_N \) be the set of mixed-strategy profiles. Given a mixed-strategy profile \( \sigma \in \Sigma \), player \( i \)'s expected payoff is \( \pi_i(\sigma) = \sum_{s_i \in S_i} p(s) \pi_i(s) \), where \( p(s) = \prod_{j \in N} \sigma_j(s_j) \) is the probability distribution over pure-strategy profiles induced by \( \sigma \).

Let \( P_{ij} \) denote the probability that player \( i \) selects strategy \( j \). Recall that the main idea behind QRE is that strategies with higher expected payoffs are more likely to be chosen, although the best strategy is not necessarily chosen with probability 1. In other words, QRE replaces players' strict rational choice best-responses by smoothed best responses.
quantal responses.

Definition 1: \( P_i : R^J(i) \rightarrow \Delta J(i) \) is a \textit{regular quantal-response} function if it satisfies the following four axioms.

- **Interiority**: \( P_{ij}(\pi_i) > 0 \) for all \( j = 1, \ldots, J(i) \) and for all \( \pi_i \in R^J(i) \).
- **Continuity**: \( P_{ij}(\pi_i) \) is a continuously differentiable function for all \( \pi_i \in R^J(i) \).
- **Responsiveness**: \( \partial P_{ij}(\pi_i)/\partial \pi_{ij} > 0 \) for all \( j = 1, \ldots, J(i) \) and for all \( \pi_i \in R^J(i) \).
- **Monotonicity**: \( \pi_{ij} > \pi_{ik} \) implies that \( P_{ij}(\pi_i) > P_{ik}(\pi_i) \) for all \( j, k = 1, \ldots, J(i) \).

These axioms are economically and intuitively compelling. Interiority ensures the model has full domain, that is, it is logically consistent with all possible data-sets. This is important for empirical applications of the model. Continuity is a technical restriction, which ensures that \( P_i \) is non-empty and single-valued. Furthermore, it seems a natural assumption since arbitrarily small changes in expected payoffs should not lead to jumps in choice probabilities. Responsiveness requires that if the expected payoff of an action increases, \textit{ceteris paribus}, the choice probability must also increase. Monotonicity is a weak form of rational choice that involves binary comparisons of actions: an action with higher expected payoff is chosen more frequently than an action with a lower expected payoff.

Define \( P(\pi) = (P_1(\pi_1), \ldots, P_n(\pi_n)) \) to be regular if each \( P_i \) satisfies the above regularity axioms. Since \( P(\pi) \in \Sigma \) and \( \pi = \pi(\sigma) \) is defined for any \( \sigma \in \Sigma \), \( P \circ \sigma \) defines a mapping from \( \Sigma \) into itself.

Definition 2: \textit{Let} \( P \) \textit{be regular. A \textit{regular quantal response equilibrium} of the normal-form game G is a mixed-strategy profile} \( \sigma^* \) \textit{such that} \( \sigma^* = P(\sigma^*) \).

Since regularity of \( P \) includes continuity, \( P \circ \sigma \) is a continuous mapping. Existence of a regular QRE therefore follows directly from Brouwer's fixed-point theorem.

**Theorem**: There exists a regular quantal response equilibrium of G for any regular \( P \).

**Empirical implications of regular QRE**

The axioms underlying regular QRE collectively have strong empirical implications, even without any parametric assumptions on \( P \). To illustrate the nature of these restrictions, consider again the generalized matching-pennies game, where Row's payoff is \( X \) when the outcome is (top, right). If \( X > 1 \), it is readily verified that Row's expected payoff of choosing 'top' is higher than of choosing 'bottom' when \( p_R < 2/(X+3) \) (\( p_R > 2/(X+3) \)). Monotonicity therefore implies that, if \( (p_R^*, p_T^*) \) defines a regular QRE, it must satisfy the inequalities:

\[
p_T^* \geq \frac{1}{2} \text{ if } p_R \geq 2/(X+3) \text{ and vice versa.}
\]

Likewise, Column's expected payoff of choosing 'right' is higher (lower) than of choosing 'left' when \( p_T < \frac{1}{2} \) (\( p_T > \frac{1}{2} \)). Thus \( (p_R^*, p_T^*) \) must satisfy

\[
p_R^* \geq \frac{1}{2} \text{ if } p_T \geq \frac{1}{2}, \text{ and vice versa.}
\]

The region defined by these inequalities defines the set of possible regular QRE. For the specific case of \( X = 9 \), this area is shown by the dark gray shaded area in Figure 2. The three black dots show the Nash equilibria for \( X = 9 \) (left), \( X = 1 \) (centre) and \( X = 0 \) (right).

**Figure 2**

QRE Sets for generalized matching pennies with \( X = 9 \) (dark) and \( X = 0 \) (light)
The case $-1 < X < 1$ can be analysed in a similar way. The set of regular QRE for $X=0$, for instance, is given by the light shaded area in Figure 2. Note that the Row player is predicted to choose ‘top’ more often than ‘bottom’ in any regular QRE when $X > 1$, while the reverse is true for $X < 1$. In fact, the responsiveness axiom can be used to show that if Row's payoff of the (top, right) outcome rises, Row's probability of choosing ‘top’ increases.

**Proposition:** (Goeree, Holt and Palfrey, 2005). In any regular QRE of the asymmetric matching pennies game, Row's probability of choosing Top is strictly increasing in $X$ and
**Quantal response equilibrium: a structural definition**

The original definition of QRE (McKelvey and Palfrey, 1995) adopts an approach in the spirit of Harsanyi (1973) and McFadden (1974) whereby the choice probabilities are rationalized by privately observed, mean zero random disturbances to the expected payoffs. These disturbances are assumed to be private information to the players, thereby converting the original game into a special kind of game of incomplete information. Any Bayesian equilibrium of this disturbed game is a QRE of the underlying game. The quantal response function generating the QRE is determined by the probability distribution of the random payoff disturbances.

Thus a smoothed response line can be interpreted to be the (inverse) distribution function of the differences between the disturbances, which has a value of \( \frac{1}{2} \) when the expected payoffs are equal. For example, if the disturbances are i.i.d. and normally distributed, then the quantal response functions will take the shape of a ‘probit’ curve, while if the i.i.d. disturbances are distributed according to an extreme value distribution, the quantal response functions will have a logistic form. For example, the logit QRE for the generalized matching pennies game is a pair of probabilities that solve:

\[
\rho_T = \frac{\exp(\lambda [(X + 1) \rho_R - 1])}{\exp(\lambda [(X + 1) \rho_R - 1]) + \exp(\lambda [1 - 2 \rho_R])}, \quad \rho_R = \frac{\exp(\lambda [1 - 2 \rho_T])}{\exp(\lambda [1 - 2 \rho_T]) + \exp(\lambda [2 \rho_T - 1])}
\]

where the numerators are exponential functions of the expected payoffs for the corresponding decision (\( T \) or \( R \)), and the denominators are normalizing factors that force probabilities to sum to 1. As the logit precision parameter \( \lambda \) increases, the response functions become more responsive to payoff differences, and the logit response functions converge to the sharp step functions shown in Figure 1.

The disturbances in the structural approach to QRE can be interpreted in several ways. One possibility is to interpret them literally. That is, one views the underlying game as simply a model of the average game being played, with each actual game player being a mean zero perturbation of the basic game. With this view, one can think of the payoff disturbances as reflecting the effects of unobservable components such as a player's mood or perceptual variations. A second possibility is to think of the players as statisticians, whose objective is to estimate the payoff of each strategy using some unknown set of instruments to perform the estimation. For general abstract games, a reasonable first cut is to suppose that their estimation errors are unbiased. The players then choose the strategy with the highest estimated expected payoffs, implicitly taking into account the fact that the other players are also estimating payoffs with some error, with the resulting equilibrium corresponding to QRE.

One can show that the quantal response function generated by i.i.d disturbances will always have the continuity and monotonicity properties of regular quantal response functions, and therefore will lead to regular QRE. In particular, the comparative static result of the previous section holds for the logit QRE (McKelvey and Palfrey, 1996). If disturbances are not i.i.d., however, non-monotonocities are possible. Haile, Hortacsu and Kosenok (2006) use this observation to show that, without restrictions on the disturbances, structural QRE can explain any data. One way to avoid this problem is to make the i.i.d. assumption or impose the weaker notion of *interchangeability* (Goeree, Holt and Palfrey, 2005). A second way to generate testable restrictions is to constrain the same structural assumptions to hold across different data-sets, thereby generating comparative static predictions.

Another solution is to simply work directly with the regularity axioms of Definition 1 – the resulting quantal response functions do impose empirical restrictions on the data and do not inherit the unintuitive features of the structural approach such as symmetry and strong substitutability. *Symmetry* requires that the effect of an increase in strategy \( k \)'s payoff on the probability of choosing strategy \( j \) is the same as the effect of an increase in strategy \( j \)'s payoff on the probability of choosing strategy \( k \). *Strong substitutability* implies, among other things, that, if the payoff of strategy \( k \) rises, the probability of choosing any of the other strategies \( j \neq k \) falls.

**Applications: quantal response equilibrium in normal-form games**

In an individual choice problem, the addition of ‘noise’ spreads out the distribution of decisions around the expected-payoff-maximizing decision. In contrast, expected payoffs in a game depend on other players’ choice probabilities, and this interactive element can magnify the effects of noise via feedback effects. One notable example is a coordination game where each person’s payoff is the minimum of all player’s efforts, minus a cost parameter, \( c \), times a player’s own effort. If \( c < 1 \), any common effort level is a Nash equilibrium, since a unilateral decrease below a common effort reduces the minimum and saves the cost, for a net loss of \( 1 - c \) for each unit reduction in effort. Conversely, a unilateral effort increase does not alter the minimum, so the loss is \( -c \). Therefore, \( c \) affects the downward slopes of the expected payoff function in each direction and, if there is any uncertainty about others’
decisions, low values of \( c \) make effort increases less risky. It is not surprising that reductions in the effort cost \( c \) tend to increase average efforts, both in laboratory experiments with human subjects and in a quantal response equilibrium with noisy behaviour (Anderson, Goeree and Holt, 2001). For the two-person coordination game experiments reported in Goeree and Holt (2005a), a reduction in the effort cost parameter from 0.75 to 0.25 raised average effort levels from 126 to 159 in the final five rounds. With payoffs in pennies and a precision parameter of 0.1, the logit QRE predictions for this game are 126 and 154 for the high and low effort costs. Thus the QRE tracks the strong behavioural response to the treatment change, whereas the range of Nash equilibria — from 110 to 170 — is unaffected by this change.

The Traveller’s Dilemma is another game where small amounts of noise can have large effects. As in the coordination game, the payoffs depend on the minimum of all decisions (‘claims’). This is a two-person ‘lost luggage’ problem, where the airline representative interprets unequal damage claims as evidence that the high claimant is inflated unjustly. Each player earns the minimum of the two claims, with a penalty of \( R \) subtracted from the payoff for the high claimant and added to that of the low claimant. As with the coordination game, claims must be in a specified interval, but in the Traveller’s Dilemma the unique Nash equilibrium is the lowest possible claim in this interval, irrespective of the magnitude of \( R \), as long as the benefit \( R \) from a reduction below a common claim is greater than the smallest permitted claim reduction. In contrast, intuition suggests that claims will be high when the penalty from having the higher claim is low. In the Capra et al. (1999) experiment, reductions in the penalty parameter, \( R \), induce dramatic increases in claims, moving the average from near Nash levels for high values of \( R \) to the opposite side of the range of feasible claims for low values of \( R \). This strong treatment effect is tracked well by the quantal response equilibrium with the same precision parameter that tracks other coordination game data.

In addition to these applications, the QRE has been used to explain ‘anomalous’ behaviour in a wide variety of games, including signalling games, centipede games, two-stage bargaining, and overbidding in auctions (Goeree, Holt and Palfrey, 2002). In addition, the quantal response equilibrium has proven to be quite useful in the analysis of data from political science experiments: jury voting (Guarnaschelli, McKelvey and Palfrey, 2000), voter turnout (Levine and Palfrey, 2007), and behaviour in participation games (Goeree and Holt, 2005a; Cason and Van Lam, 2005).

**Applications: quantal response equilibrium in extensive form games**

The QRE approach has also been developed for extensive form games (McKelvey and Palfrey 1998), where the analysis in done using behavioural strategies. In the extensive form QRE, players follow Bayes’ rule and calculate expected continuation payoffs based on the QRE strategies of the other players. Interiority implies that beliefs are uniquely defined at any information set and for any QRE strategy profile. Therefore issues related to belief-based refinements do not arise, and a quantal response version of sequential rationality follows immediately. When quantal response functions approach best response functions, then the limiting QRE of the extensive form game will select a subset of the sequential equilibria of the underlying game.

QRE in extensive form games will typically have different implied choice probabilities than would obtain if the same quantal response function were applied to the same game in its reduced normal form. This occurs for two reasons. First, QRE is not immune to ‘reduction’ of equivalent strategies, since duplicate strategies will generally change the quantal response choice probabilities, for much the same reason as the ‘red bus – blue bus’ example in discrete choice econometrics. Second, expected payoff differences are different when one collapses an extensive form game into its normal form: with behaviour strategies, expected payoffs are computed at the interim stage, conditioning on previous actions in the game; in contrast, normal form mixed strategies are calculated _ex ante._

**Summary**

The quantal response equilibrium approach to the analysis of games has proven to be a useful generalization of the Nash equilibrium, especially when dealing with ‘noisy decisions’ made by boundedly rational players and by subjects in experiments. It can be extended to allow for learning and cognitive belief formation in one-shot games where learning is not possible. This approach provides a coherent framework for analysing an otherwise bewildering array of ‘biases’ and anomalies in economics.

quantile regression

Moshe Buchinsky
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A semiparametric technique that has been gaining considerable popularity in economics, the quantile regression model has a number of attractive features. For example, it can be used to characterize the entire conditional distribution of a dependent variable given a set of regressors; it has a linear programming representation which makes estimation easy; and it gives a robust measure of location. Concentrating on cross-section applications, this article presents the basic structure of the quantile regression model, highlights the most important features, and provides the elementary tools for using quantile regressions in empirical applications.

Keywords

asymptotic covariance matrix; bootstrap; censored quantile regression model; design matrix bootstrapping; equivariance; generalized method of moments; heteroskedasticity; kernel estimators in econometrics; least absolute deviation; linear programming; optimal minimum distance estimator; quantile regression; semiparametric estimation; Tobit model

Article

1 Introduction

The quantile regression is a semiparametric technique that has been gaining considerable popularity in economics (for example, Buchinsky, 1994). It was introduced by Koenker and Bassett (1978b) as an extension to ordinary quantiles in a location model. In this model, the conditional quantiles have linear forms. A well-known special case of quantile regression is the least absolute deviation (LAD) estimator of Koenker and Bassett (1978a), which fits medians to a linear function of covariates. In an important generalization of the quantile regression model, Powell (1984; 1986) introduced the censored quantile regression model. This model is an extension of the 'Tobit' model and is designed to handle situations in which some of the observations on the dependent variable are censored. The quantile regression model has some very attractive features: (a) it can be used to characterize the entire conditional distribution of a dependent variable given a set of regressors; (b) it has a linear programming representation which makes estimation easy; (c) it gives a robust measure of location; (d) typically, the quantile regression estimator is more efficient than the least squares estimator when the error term is non-normal; and (e) L-estimators, based on a linear combination of quantile estimators (for example, Portnoy and Koenker, 1989) are, in general, more efficient than least squares estimators.

This article presents the basic structure of the quantile regression model. It highlights the most important features and provides the elementary tools for using quantile regressions in empirical applications. The article concentrates on cross-section applications, where the observations are assumed to be independently and identically distributed (i.i.d.).

2 The Model

2.1 Definitions and estimator

Any real-valued random variable \( z \) is completely characterized by its (right continuous) conditional distribution function \( F(z) = \Pr(z \leq \theta) \). For any \( 0 < \theta < 1 \), the quantity

\[
Q_\theta(z) = F^{-1}(\theta) = \inf \left\{ z : F(z) \geq \theta \right\}
\]

is called the \( \theta \) th quantile of \( z \). This quantile is obtained as a solution to a minimization problem of a particular objective function, the check function, given by

\[
\rho_\theta(\lambda) = \lambda(\theta - I(\lambda < 0)),
\]

where \( I(\cdot) \) denotes the usual indicator function. That is,
An estimate for the $\theta$th quantile of $z$ can be obtained from i.i.d. data $z_i$, $i = 1, \ldots, n$, by minimizing the sample analogue of the population objective function defined above. That is,

\[
\hat{Q}_\theta(z) = \arg\min_{a} \frac{1}{n} \sum_{i=1}^{n} \rho(z_i - a),
\]
or alternatively

\[
\hat{Q}_\theta(z) = \arg\min_{a} \left\{ \sum_{z_i \geq b} \theta z_i - a + \sum_{z_i < b} (1 - \theta) z_i - a \right\}.
\]

The last equation provides a clear intuition for the quantile estimates. The $\theta$th quantile estimate is obtained by weighting the positive residuals by $\theta$, while the negative residuals are weighted by the complement of $\theta$, namely, $1 - \theta$.

The extension of this idea to the case of a conditional quantile is straightforward. Suppose that the $\theta$th conditional quantile of $y$, conditional on a $K \times 1$ vector of regressors $x = (1, x_2, \ldots, x_K)$, is

\[
Q_\theta(\eta|x) = x' \beta_{\theta}.
\]

This implies that the model can be written as

\[
y = x' \beta_{\theta} + u_{\theta},
\]

and, by construction, it follows that $Q_\theta(u|x) = 0$.

This model, which was first introduced by Koenker and Bassett (1978b), can be viewed as a location model. That is,

\[
Fr(y \geq \eta|x) = F_{\theta u}(r - x' \beta_{\theta}|x),
\]

where $u_{\theta}$ has the (right continuous) conditional distribution function $F_{\theta u}(\cdot|x)$, satisfying $Q_\theta(u|x) = 0$.

Similar to the unconditional case presented above, the population parameter vector $\beta_{\theta}$ is defined by
\[ \hat{\beta}_\theta = \arg\min_{\beta} \frac{1}{n} \sum_{i=1}^{n} \rho(y_i - x_i' \beta), \]

The sample analogue for the \( \theta \) th quantile conditional quantile is defined in a similar manner. Let \((y_i, x_i), i = 1, \ldots, n,\) be an i.i.d. sample from the population. Then, \( \hat{\beta}_n \), the estimator for \( \beta_\theta \), is defined by

\[ \hat{\beta}_n = \arg\min_{\beta} \frac{1}{n} \sum_{i=1}^{n} \rho(y_i - x_i' \beta), \text{ or alternatively} \]

\[ \hat{\beta}_n = \arg\min_{\beta} \frac{1}{n} \left\{ \sum_{i: y_i > x_i' \beta} \theta \cdot (y_i - x_i' \beta) + \sum_{i: y_i < x_i' \beta} (1 - \theta) \cdot (y_i - x_i' \beta) \right\}. \]

The \( \theta \) th quantile regression problem in (2) can be also be rewritten as

\[ \hat{\beta}_n = \arg\min_{\beta} \frac{1}{n} \sum_{i=1}^{n} \left( \theta - 1 / 2 + 1 / 2 \text{ sgn} (y_i - x_i' \beta) \right) (y_i - x_i' \beta). \]

where \( \text{sgn}(\lambda) = I(\lambda \geq 0) - I(\lambda < 0).\) The last equation gives, in turn, the \( K \times 1 \) vector of first-order conditions (F.O.C.):

\[ \frac{1}{n} \sum_{i=1}^{n} \left( \theta - 1 / 2 + 1 / 2 \text{ sgn} (y_i - x_i' \beta) \right) x_i = \frac{1}{n} \sum_{i=1}^{n} \psi(x_i, y_i, \beta) = 0, \]

where \( \psi(x_i, y_i, \beta) = (\theta - 1 / 2 + 1 / 2 \text{ sgn} (y_i - x_i' \beta)) x_i.\) It is straightforward to show that under the quantile restriction \( \Omega_\rho(u \beta \mid x) = \mathbb{0} \) the moment function \( \psi(\cdot) \) satisfies

\[ E[\psi(x_i, y_i, \beta)] = E[\psi(x_i, y_i, \beta)] = 0. \]

In the jargon of the generalized method of moments (GMM) framework, this establishes the validity of \( \psi(\cdot) \) as a moment function. Consequently, using the methodology of Huber (1967), one can establish consistency and asymptotic normality of \( \hat{\beta}_n \).

For illustration and discussion below, it is convenient to define the following: Let \( y \) denote the stacked vector of \( y_i, i = 1, \ldots, n, \) and let \( X \) denote the stacked matrix of the row vectors \( x_i, i = 1, \ldots, n.\)

### 2.2 Linear programming and quantile regression

The problem in (2) can be shown to have a linear programming (LP) representation. This feature has some important consequences from both theoretical and practical standpoints.

Let the \( K \times 1 \) vector \( \beta \) be written as a difference of two non-negative vectors \( \beta^+ \) and \( \beta^- \), that is, \( \beta = \beta^+ - \beta^- \), for \( \beta^+, \beta^- \geq 0. \) Similarly let the \( n \times 1 \) residuals vector \( u \) be written as a difference of two
non-negative vectors $u^+$ and $u^-$, that is, $u = u^+ - u^-$, for $u^+, u^- \geq 0$. Furthermore, define the following quantities: $A = (X - X, I_n - I_n)$, where $I_n$ is an $n$ dimensional identity matrix, $z = (\theta^+, \theta^-, u^+, u^-)^T$, $c = (0, 0^T, \theta^T, (1 - \theta)^T, \textbf{0})$ is a $k \times 1$ vector of zeros, and $l$ is an $n \times 1$ vector of ones.

When written in matrix notation the problem in (2) takes the familiar primal problem of LP:

\[
\begin{align*}
\min & \; c'z \\
\text{subject to} & \; Az = y, z \geq 0.
\end{align*}
\]

Furthermore, the dual problem, of LP is (approximately) the same as the F.O.C. given above, namely

\[
\begin{align*}
\max & \; w'y \\
\text{subject to} & \; w'A \leq c'.
\end{align*}
\]

The duality of LP implies that feasible solutions exist for both the primal and the dual problems, if the design matrix $X$ is of full column rank, that is, \( \text{rank } (X) = K \). The equilibrium of LP guarantees then that this solution is optimal.

The LP representation of the quantile regression problem has several important implications from both computational and conceptual standpoints. First, it is guaranteed that an estimate will be obtained in a finite number of simplex iterations. Second, the parameter estimate is robust to outliers. That is, for all $y_i$ can be increased toward $\infty$, and for all $y_i$ can be decreased toward $-\infty$, without altering the solution $\hat{\beta}_\theta$. In other words, the only thing that matters is not the exact value of $y_i$ but rather on which side of the estimated hyperplane it lies. This is important for many economic applications in which $y_i$ might be censored, at say $y_i^\theta$. For example, for the right-censored model $\hat{\beta}_\theta$ will not be affected as long as for all $i$ we have $y_i^\theta - x_i' \hat{\beta}_\theta > 0$.

### 2.3 Equivariance properties

The quantile regression estimator has several important equivariance properties which help facilitate the computation procedure. That is, data-sets that are based on certain transformations of the original data set lead to estimators which are simple transformations of the original estimator. Denote the set of feasible solutions to the problem defined in (2) by $\hat{E}(\theta, y, X)$. Then for every $\hat{\beta}_\theta = \hat{E}(\theta, y, X)$ we have (see Koenker and Bassett, 1978b: Theorem 3.2):

\[
\hat{\beta}(\theta, y, X) = \lambda \hat{E}(\theta, y, X), \text{for } \lambda \in [0, \infty), \hat{\beta}(1 - \theta, y, X) = \lambda \hat{E}(\theta, y, X), \text{for } \lambda \in (-\infty, 0), \hat{\beta}(\theta, y + \gamma, X) = \hat{E}(\theta, y, X) + \gamma, \text{for } \gamma \in \mathbb{R}^K, \hat{E}(\theta, y, X) = A^{-1} \hat{E}(\theta, y, X), \text{for nonsingular } K \times k \text{ matrix } A
\]

These properties help in reducing the number of simplex iterations (of any LP algorithm) required for obtaining $\hat{\beta}_\theta$. For example, suppose that $\hat{\beta}_\theta^0$ is a good starting value for $\hat{\beta}_\theta$ (for example, the least-squares estimate from the regression of $y$ on $x$, or an estimate obtained from only a small subset of the data available). Let $\hat{\beta}_\theta^R$ denote the quantile regression estimate from the $\theta$ th quantile regression of $y^R - y - \lambda \hat{\beta}_\theta^0$ on $x$. Then $\hat{\beta}_\theta = \hat{\beta}_\theta^R + \hat{\beta}_\theta^0$. In many cases it is faster to obtain the two estimates $\hat{\beta}_\theta^R$ and $\hat{\beta}_\theta^0$ than to estimate $\hat{\beta}_\theta$ directly.

### 2.4 Efficient estimation

The quantile regression estimator described above is not the efficient estimator for $\beta_\theta$. An efficient estimator can be obtained by solving
That is, each observation is weighted by the conditional density of its error evaluated at zero. This estimation procedure requires the use of an estimate for the unknown density \( f_u(\cdot|x) \). Below we provide details about the estimation of the asymptotic covariance matrix, which, in turn, also provides information about possible estimates for \( f_u(\cdot|x) \). (For a more complete discussion of this estimator, see Newey and Powell, 1990.)

### 2.5 Interpretation of the quantile regression

How can the quantile's coefficients be interpreted? Consider the partial derivative of the conditional quantile of \( y \) with respect to one of the regressors, say \( j \), that is, \( \frac{\partial}{\partial x_j} Q_\theta(y|x) \). This derivative may be interpreted as the marginal change in the \( \theta \)th conditional quantile due to a marginal change in the \( j \)th element of \( x \). If \( x \) contains \( K \) distinct variables, then this derivative is given simply by \( \beta_{\theta} \), the coefficient on the \( j \)th variable. It is important to note that one should be cautious not to confuse this result with the location of an individual in the conditional distribution. In general, it need not be the case that an observation that happened to be in the \( \theta \)th quantile of one conditional distribution will also be at the same quantile if \( x \) had changed. The above derivative reflects changes in the conditional distribution but has nothing to say about the location of an observation within the conditional distribution.

Note that an estimate for the \( \theta \)th conditional quantile of \( y \) given \( x \) is given by \( Q_\hat{\theta}(\cdot|x) = \hat{\beta} \cdot x \). Hence, if one were to vary \( \theta \) between 0 and 1 and estimate a different quantile regression estimate for each \( \theta \), one can trace the entire conditional distribution of \( y \), conditional on \( x \).

### 3 Large sample properties of \( \hat{\beta} \)

We denote the conditional distribution function of \( u_\theta \) by \( F_u(\cdot|x) \) and the corresponding density function by \( f_u(\cdot|x) \).

**Assumption A.1:** The distribution functions \( F_u(\cdot|x) \) are absolutely continuous, with continuous density functions \( f_u(\cdot|x) \) uniformly bounded away from 0 and \( \infty \) at the point 0, for \( l = 1, 2, ... \)

**Assumption A.2:** There exist positive definite matrices \( \Delta_\theta \) and \( \Lambda_0 \) such that

1. (i) \( \lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} x' z' \Delta_\theta = \Lambda_0 \)
2. (ii) \( \lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} f_u(0|x) x' z' = \Delta_\theta \) and
3. (iii) \( \max_{i=1, \ldots, n} \|z_i\| / \sqrt{n} \to 0 \).

**Assumption A.3:** The parameter vector \( \beta_\theta \) is in the interior of the parameter space \( \mathcal{F}_\theta \).

Assumption A.1 requires that the conditional density of \( u_\theta, \) conditional on \( x_i \), be bounded and that there be no mass point at the conditional \( \theta \)th quantile at which \( \beta_\theta \) is estimated.

Assumptions A.2 and A.3 provide regularity conditions very similar to those used for the usual least-squares estimator. Assumptions A.1 and A.2 are sufficient for establishing that \( \hat{\beta}_\theta \to \beta_\theta \) as \( n \to \infty \), while Assumption A.3 is needed in addition for establishing the asymptotic normality of \( \hat{\beta}_\theta \) in the following theorem.

**Theorem 1:** Under Assumptions A.1–A.3

1. (i) \( \sqrt{n}(\hat{\beta}_\theta - \beta_\theta) \sim N(0, \theta(1 - \theta)\Delta^{-1}_\theta \Lambda_0 \Delta^{-1}_\theta) \),
2. (ii) if in addition \( f_u(0|x) = f_u(0) \) with probability 1, then \( \sqrt{n}(\hat{\beta}_\theta - \beta_\theta) \sim N(0, \omega^2_\theta \Delta^{-1}_\theta) \), where \( \omega^2_\theta = \theta(1 - \theta) f_u(0) \).

The result in (i) uses the fact that the \((y_i, x_i)\) are independent, but need not be identically distributed. This is the case when \( f_u(\cdot|x) \) depends on \( x \), as is the case, for example, with heteroskedasticity. The result in (ii) simplifies the result in (i) when \((y_i, x'_i)\) are i.i.d.

### 3.1 Estimation of the asymptotic covariance matrix

Several estimators for the asymptotic covariance matrix are readily available. Some of the estimators are valid under Theorem 1(i), while others are valid only under the independence assumption of...
Theorem 1(ii). In the following, we refer to the former as the general case, while the latter is referred to as the i.i.d. case. Note that under either cases $\Lambda_0$ can be easily estimated by its sample analogue, namely, 

$\hat{\Lambda} = n^{-1} \sum_{i=1}^{n} \hat{\epsilon}_i$.

3.1.1 The i.i.d. case

In this case the problem centers around estimating $\omega_\theta^2$, or more specifically around estimating $1/\int u_\theta(g)$. Let $\hat{u}_\theta(\theta_1), \cdots, \hat{u}_\theta(\theta_n)$ be the ordered residuals from the $\theta$-th quantile regression.

*Order estimator:* Following Siddiqui (1960), an estimator for $1/\int \hat{u}_\theta(g)$ is provided by

$$
\frac{1}{\int \hat{u}_\theta(g)} = \frac{\left(1 - \Phi\left(\hat{u}_\theta(\theta_n) - \hat{u}_\theta(\theta_1)\right)\right)^2}{4h_n^2},
$$

for some bandwidth $h_n = \Theta(1)$. Bofinger (1975) provides an optimal choice for the bandwidth, that minimizes the mean squared error, based on the normal approximation for the true $\int u_\theta(\cdot)$:

$$
h_n = n^{-1/5} \left\{ \frac{4.5 \Phi^{-1}(4/5)}{(2 \Phi^{-1}(1/2))^2 + 1} \right\}^{1/5}.
$$

where $\Phi$ and $\phi$ denote the distribution function and density function of a standard normal variable, respectively.

*Kernel estimator:* The density $\int u_\theta(g)$ can be estimated directly by

$$
\hat{f}_{u_\theta}(g) = \sum_{i=1}^{n} \kappa(g - \hat{u}_\theta(\theta_i)),
$$

where $\kappa(\cdot)$ is some kernel function $\kappa(\cdot)$ and $\kappa_n = \Theta(1)$ is the kernel bandwidth. It can be optimally chosen using a variety of cross-validation methods (for example, least-squares, log likelihood, and so on).

*Bootstrap estimator for $\omega_\theta^2$: This estimator relies on bootstrapping the residual series $\hat{u}_\theta, \hat{u}_\theta, \cdots, \hat{u}_\theta$. Specifically, one can obtain $B$ bootstrap estimates for $u_\theta$, the $\theta$'s quantile of $u_\theta$, say $\hat{u}_{\theta,1}^*, \cdots, \hat{u}_{\theta,B}^*$, from $B$ bootstrap samples drawn from the empirical distribution $\hat{F}_\theta$. An estimator for $\omega_\theta^2$ is obtained then by

$$
\hat{\omega}_\theta^2 = \frac{\sum_{\theta=1}^{B} \left(\hat{u}_{\theta}^* - \hat{u}_{\theta}^*\right)^2}{\hat{B}}
$$

where $\hat{B} = \frac{1}{B} \sum_{\theta=1}^{B} \hat{u}_{\theta}^*$.
3.1.2 The general case

There are several alternative estimators for the general case. Here we provide two possible estimators that have been proven accurate in a variety of Monte Carlo studies (for example, Buchinsky, 1995).

**Kernel estimator:** Powell (1986) considered the following kernel estimator for $\Delta \theta$

$$\hat{\Delta}_\theta = (z_n \eta)^{-1} \sum_{i=1}^{n} \kappa(\hat{u}_i) x_i \xi_i,$$

where $\kappa(\cdot)$ is some kernel function and $\epsilon_n = \Omega(1)$ is the kernel bandwidth. Note that the top left-hand element of the matrix $\hat{\Delta}_\theta$ is an estimate of the density $f(\theta|\cdot)$. Hence, the same cross-validation methods discussed before can be used to optimally choose $c_n$.

**Design matrix bootstrap estimators:** There are several alternative ways for employing the bootstrap method of Efron (1979). The most general method is what is termed the design matrix bootstrapping, whereby one re-samples from the joint distribution of $(y, x)$. Specifically, let $(y_i, x_i)$, $i = 1, \ldots, n$, be a randomly drawn sample from the empirical distribution of $(x, y)$, denoted $F_{xy}$. Let $\hat{\theta}_B$ denote the quantile regression estimate based on the bootstrap sample. If we repeat this process $B$ times, then an estimate for $V_\theta = \sigma(1 - \theta) \Delta \theta^{-1} \Lambda \theta^{-1}$ is given by

$$\hat{V}_\theta = \frac{B}{n} \sum_{j=1}^{B} (\hat{\theta}_B - \bar{\theta}_B)(\hat{\theta}_B - \bar{\theta}_B)'$$

where $\bar{\theta}_B = \frac{1}{B} \sum_{j=1}^{B} \hat{\theta}_B$. The estimate $\hat{V}_\theta$ is a consistent estimator for $V_\theta$ in the sense that the conditional distribution of $\sqrt{n}(\hat{\theta}_B - \bar{\theta}_B)$, conditional on the data, weakly converges to the unconditional distribution of $\sqrt{n}(\hat{\theta}_B - \bar{\theta}_B)$.

One important caveat about bootstrapping is in order. If one already uses the bootstrap method, it can be used more efficiently and effectively, taking advantage of the higher-order refinement properties of the method. For example, one can directly construct confidence intervals, test statistics, and so forth, based on the bootstrap estimates without having to first compute an estimate for $V_\theta$. The number of bootstrap repetitions required for the particular application may be different. Nevertheless, the exact number of repetitions can be computed using the method proposed by Andrews and Buchinsky (2000).

4 Set of quantile regressions

The model presented in (1) considered only the estimation for a single quantile $\theta$. In practice one would like to estimate several quantile regressions at distinct points of the conditional distribution of the dependent variable. This section outlines the estimation of a finite sequence of quantile regressions and provides its asymptotic distribution.

4.1 Estimation and large sample properties

Consider the model given in (1) (dropping the $i$ subscript) for $p$ alternative $\theta$'s:

$$y = x' \alpha \theta + u \theta \quad \text{where} \quad Q_{\theta_j}(u \theta_j | x) = 0,$$

for $j = 1, \ldots, p$. Without loss of generality assume that $0 < \theta_1 < \theta_2 < \cdots < \theta_p < 1$. Estimating the $p$ quantile regressions amounts to running $p$ separate regressions for $\theta_1$ through $\theta_p$. Let the stacked...
vector of $\beta$'s $\tilde{\beta}_\theta = (\tilde{\beta}_{\theta_1}, \ldots, \tilde{\beta}_{\theta_p})'$ denote the population's true parameter vector and let $\hat{\beta}_\theta = (\hat{\beta}_{\theta_1}, \ldots, \hat{\beta}_{\theta_p})'$ denote its corresponding estimate.

**Theorem 2.** Under Assumptions A.1–A.3

1. (i) \[ \sqrt{n}(\tilde{\beta}_\theta - \beta) \overset{P}{\to} N(0, \Lambda_\theta), \] \[ \Lambda_\theta = \{(\Lambda_{\theta_{ij}}, \Lambda_{\theta_{ik}})\}_{k=1}^p, \] where

2. (ii) if in addition $f \cdot u_{\theta}(0) = u_{\theta}(0)$ for $j = 1, \ldots, p$ with probability 1, then \[ \sqrt{n}(\tilde{\beta}_\theta - \beta) \overset{P}{\to} N(0, \Lambda_\theta), \] \[ \Lambda_\theta = \{(\Lambda_{\theta_{ij}}, \Lambda_{\theta_{ik}})\}_{k=1}^p \] and

**4.2 Crossing of quantiles**

Note that the estimated conditional quantiles, conditional on $x$, are given by $x'\hat{\beta}_{\theta_1}, \ldots, x'\hat{\beta}_{\theta_p}$. Since the estimates $\hat{\beta}_{\theta_j}$ for the $p$ quantiles are obtained from separate quantile regressions, it is possible that for some vector $x_0$, $x'\tilde{\beta}_{\theta_j} > x'\tilde{\beta}_{\theta_k}$, even though $\theta_j < \theta_k$, that is, conditional quantiles may cross each other. This may not be of any practical consequence, since there may not be such a vector within the relevant range of plausible $x$'s. Nevertheless, in any empirical application these potential crossing need to be examined.

**4.3 Testing for equality of slope coefficients**

Under the i.i.d. assumption the $p$ coefficient vectors $\beta_{\theta_1}, \ldots, \beta_{\theta_p}$ should be the same, except for the intercept coefficients. There are a number of ways for testing the null hypothesis of i.i.d. errors. Only two testing procedures are provided here. For other alternative methods see Koenker (2005).

4.3.1 Wald-type testing

This testing procedure is based on the optimal minimum distance (MD) estimator under the null hypothesis. Denote the parameter vector under the null by $\beta_{\theta}^R$ and note that $\beta_{\theta}^R = (\beta_{\theta_1}, \ldots, \beta_{\theta_p}, \beta_{\theta_1}, \ldots, \beta_{\theta_k})'$ is a $(p + k - 1) \times 1$, with $p$ distinct intercepts, $\beta_{\theta_1}, \ldots, \beta_{\theta_p}$, and $k - 1$ common slope parameters $\beta_{\theta_1}, \ldots, \beta_{\theta_k}$.

An optimal estimate for the restricted coefficient vector $\beta_{\theta}^R$ is defined by

$$\tilde{\beta}_{\theta}^R = \text{arg min}_{\beta} \| (\tilde{\beta}_{\theta} - R\beta) - \tilde{V}_{\theta}^{-1}(\tilde{\beta}_{\theta} - R\beta) \|^2,$$

where $\tilde{V}_{\theta}$ is a consistent estimate for the covariance matrix of $\tilde{\beta}_{\theta}$, the unrestricted parameter estimate from the $p$ quantile regressions, estimated under the null (that is, under Theorem 2(ii)). The matrix $R$ is simply a $(p + k - 1) \times p \cdot k$ restriction matrix which imposes the restrictions implied by the i.i.d. assumption. A test statistic for equality of the slope coefficients is provided then by

$$W_n = n(\tilde{\beta}_{\theta} - R\hat{\beta}_{\theta}^R)' \tilde{V}_{\theta}^{-1}(\tilde{\beta}_{\theta} - R\hat{\beta}_{\theta}^R).$$

Under the null hypothesis $W_n \overset{D}{\to} \chi^2(pK - p + K + 1)$ as $n \to \infty$. So, the null hypothesis is rejected if $W_n > \chi^2_{1-\alpha}(pK - p + K + 1)$, where $\chi^2_{1-\alpha}(m)$ denotes the $1-\alpha$ quantile of a $\chi^2$-distribution with $m$ degrees of freedom.

4.3.2 GMM-type testing

An alternative testing procedure can be applied using Hansen's (1982) GMM method. Define a moment function \( \psi(x, \gamma, \beta) \) by stacking the \( p \) individual moment functions as defined in (3). While this moment function is a \( pk \times 1 \) vector, under the null there are only \( p + K - 1 \) parameters to be estimated. Hansen's GMM framework provides an estimator for \( \hat{\beta}_R \), say \( \hat{\beta}_R \), defined by

\[
\hat{\beta}_R = \arg \min_{\beta} \left\{ \frac{1}{n} \sum_{i=1}^{n} \psi(x_i, \gamma_i, \beta) \right\}^{\prime} A^{-1} \left\{ \frac{1}{n} \sum_{i=1}^{n} \psi(x_i, \gamma_i, \beta) \right\}.
\]

(4)

An efficient estimator can be obtained if \( A \) is chosen so that \( A \bar{\psi}(x, \gamma, \beta) \psi(x, \gamma, \beta) \) as \( n \to \infty \). This framework provides us with a straightforward testing procedure. Under the null hypothesis

\[
\eta \left\{ \frac{1}{n} \sum_{i=1}^{n} \psi(x_i, \gamma_i, \hat{\beta}_R) \right\}^{\prime} A^{-1} \left\{ \frac{1}{n} \sum_{i=1}^{n} \psi(x_i, \gamma_i, \hat{\beta}_R) \right\} D \chi^2(pK - \nu - K + 1),
\]

as \( n \to \infty \).

Note that, because of the linearity of the conditional quantiles, the GMM testing provides a test statistics which is (asymptotically) equivalent to that provided by the MD testing.

### 5 Censored quantile regression

An important extension to the quantile regression model was suggested by Powell (1984; 1986). This extension considers the case in which some of the observations are censored. This model is essentially a semiparametric extension to the well known 'Tobit' model and can be written as

\[
y_i = \min\left\{ y_i^0, x_i \hat{\beta} + u_i \right\},
\]

for \( i = 1, \ldots, n \), where \( y_i^0 \) is the (known) top coding value of \( y_i \) in the sample, for \( i = 1, \ldots, n \). (For simplicity of presentation it will be assumed that \( y_i^0 = y_i^0 \) for all \( i = 1, \ldots, n \).)

This model can be written as a latent variable model. That is, we have \( y_i^0 = x_i \hat{\beta} + u_i \), where \( Q_\Theta(y|x) = C \) and \( y_i = y_i^0 I(y_i \leq y_i^0) \). It is easy to see that the observed conditional \( \Theta \) th quantile of \( y_i \), conditional on \( x_i \), is given by \( Q_\Theta(y|x_i) = \min\left\{ y_i^0, x_i \hat{\beta} \right\} \).

Hence, Powell suggested the following estimator for \( \hat{\beta}_\Theta \)

\[
\hat{\beta}_\Theta = \arg \min_{\beta} \frac{1}{n} \sum_{i=1}^{n} \rho_\Theta(y_i - \min\left\{ y_i^0, x_i \hat{\beta} \right\}),
\]

(5)

where \( \rho_\Theta(y) \) is the same check function as defined above. Note that in order to obtain a consistent estimator of \( \hat{\beta}_\Theta \) it is necessary that \( x_i \hat{\beta} < y_i^0 \) for at least a fraction of the sample. Intuitively, the larger the fraction, the more precise the estimator will be.
Powell (1986) showed that, under certain regularity conditions, similar to those established by Huber (1967), the estimator is asymptotically normal. That is, \[ \sqrt{n}(\hat{\beta}_n - \beta_0) \overset{D}{\rightarrow} N(0, \Lambda_C) \] as \( n \to \infty \), where

\[ V_C = \theta(1 - \theta)\Delta_C^{-1} \Lambda_C \Lambda_C \Delta_C^{-1} = E\left[ f_u(y)I(y' \beta > y) xx' \right] \text{and} \Delta_C = E\left[ K(x' \beta < y) xx' \right]. \]

As in the basic quantile regression model, if \( f_u(y')y - f_u(y) \) with probability 1, then \( V_C \) simplifies to \( V_C = \omega_C^{-1} \Delta_C \), where \( \omega_C = \theta(1 - \theta) f_u(y) \).

It is important to note that if \( y' \beta = y \) for all observations, then the censored quantile regression estimate coincides with the basic quantile regression.

The simple intuition for this estimation procedure is that \( \beta \) can be estimated only from that part of the sample for which it is observed, that is, for that fraction of the sample for which \( y' \beta \leq y \). As a result, we note that the asymptotic covariance is ‘adjusted’ for that fact. That is, the term \( K(x' \beta < y) \) is included in both \( \Delta_C \) and \( \Delta_C \).

A considerable drawback of the censored quantile regression model is that it does not have the attractive LP representation and the objective function is not globally convex in \( \beta \).

6 Concluding remarks

The main goal of this article is to provide the basic structure of the quantile regression model. Versions of this model have been widely used in the empirical literature in a variety of situations not covered by this article. Furthermore, there have been substantial advancements in the theoretical literature as well. This literature includes quantile regression for nonlinear models, time-series models, and others. There are also a number of empirical studies that have used quantile regression extensively, in a variety of data configurations and economic contexts. For a brilliant in-depth exposition of a wide variety of topics related to quantile regression, interested readers should refer to Koenker (2005).

The New Palgrave Dictionary of Economics Online

quantity theory of money

Milton Friedman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

After formally setting out the quantity theory of money, including the distinction between the nominal quantity of money and the real quantity of money, and various quantity equations, this article considers the Keynesian challenge to the theory (which seemed vindicated during the economically successful 1950s and 1960s) and the revival of belief in the quantity theory in the 1970s as rapid monetary growth was accompanied by stagflation and rising interest rates. It deals with the natural rate hypothesis and the theory of rational expectations, surveys the empirical evidence, and ends with a consideration of policy implications.

Keywords

American Economic Association; anticipated inflation; arbitrage; Bretton Woods System; buffer stocks; cash-balance version of the quantity equation; commodity standards; credit; deflation; demand for money; demand–supply analysis; deposit–currency ratio; deposit–reserve ratio; easy money; excess balances; expectations; export subsidies; fiat money; fiscal policy; Fisher, I.; foreign exchange controls; free banking; Friedman, M.; full employment; Great Depression; high-powered money; human vs. non-human wealth; Hume, D.; hyperinflation; import controls; income velocity; interest rate; Keynes, J. Article

Lowness of interest is generally ascribed to plenty of money. But … augmentation [in the quantity of money] has no other effect than to heighten the price of labour and commodities … In the progress toward these changes, the augmentation may have some influence, by exciting industry, but after the prices are settled … it has no manner of influence.

[T]hough the high price of commodities be a necessary consequence of the increase of gold and silver, yet it follows not immediately upon that increase; but some time is required before the money circulates through the whole state…. In my opinion, it is only in this interval of intermediate situation, between the acquisition of money and rise of prices, that the increasing quantity of gold and silver is favourable to industry…. [W]e may conclude that it is of no manner of consequence, with regard to the domestic happiness of a state, whether money be in greater or less quantity. The good policy of the magistrate consists only in keeping it, if possible, still increasing … (David Hume, 1752).

In this survey, we shall first present a formal statement of the quantity theory, then consider the Keynesian challenge to the quantity theory, recent developments, and some empirical evidence. We shall conclude with a discussion of policy implications, giving special attention to the likely implications of the worldwide fiat money standard that has prevailed since 1971.

1 The formal theory

(a) Nominal versus real quantity of money

Implicit in the quotation from Hume, and central to all later versions of the quantity theory, is a distinction between the nominal quantity of money and the real quantity of money. The nominal quantity of money is the quantity expressed in whatever units are used to designate money – talents, shekels, pounds, francs, lira, drachmas, dollars, and so on. The real quantity of money is the quantity expressed in terms of the volume of goods and services the money will purchase. There is no unique way to express either the nominal or the real quantity of money. With respect to the nominal quantity of money, the issue is what assets to include – whether only currency and coins, or also claims on financial institutions; and, if such claims are included, which ones should be, only deposits transferable by cheque, or also other categories of claims which in practice are close substitutes for deposits transferable by cheque. More recently, economists have been experimenting with the theoretically attractive idea of defining money not as the simple sum of various categories of claims but as a weighted aggregate of such claims, the weights being determined by one or another concept of the ‘moneyness’ of the various claims.

Despite continual controversy over the definition of ‘money’, and the lack of unanimity about relevant
Theoretical criteria, in practice, monetary economists have generally displayed wide agreement about the most useful counterpart, or set of counterparts, to the concept of ‘money’ at a particular times and places (Friedman and Schwartz, 1970, pp. 89–197; Barnett, Offenbacher and Spindt, 1984; Spindt, 1985).

The real quantity of money obviously depends on the particular definition chosen for the nominal quantity. In addition, for each such definition, it can vary according to the set of goods and services in terms of which it is expressed. One way to calculate the real quantity of money is by dividing the nominal quantity of money by a price index. The real quantity is then expressed in terms of the standard basket whose components are used as weights in computing the price index – generally, the basket purchased by some representative group in a base year.

A different way to express the real quantity of money is in terms of the time duration of the flow of goods and services the money could purchase. For a household, for example, the real quantity of money can be expressed in terms of the number of weeks of the household’s average level of consumption its money balances could finance or, alternatively, in terms of the number of weeks of its average income to which its money balances are equal. For a business enterprise, the real quantity of money it holds can be expressed in terms of the number of weeks of its average purchases, or of its average sales, or of its average expenditures on final productive services (net value added) to which its money balances are equal. For the community as a whole, the real quantity of money can be expressed in terms of the number of weeks of aggregate transactions of the community, or aggregate net output of the community, to which its money balances are equal.

The reciprocal of any of this latter class of measures of the real quantity of money is a velocity of circulation for the corresponding unit or group of units. For example, the ratio of the annual transactions of the community to its stock of money is the ‘transactions velocity of circulation of money’, since it gives the number of times the stock of money would have to ‘turn over’ in a year to accomplish all transactions. Similarly, the ratio of annual income to the stock of money is termed ‘income velocity’. In every case, the real quantity of money is calculated at the set of prices prevailing at the date to which the calculation refers. These prices are the bridge between the nominal and the real quantity of money.

The quantity theory of money takes for granted, first, that the real quantity rather than the nominal quantity of money is what ultimately matters to holders of money and, second, that in any given circumstances people wish to hold a fairly definite real quantity of money. Starting from a situation in which the nominal quantity that people hold at a particular moment of time happens to correspond at current prices to the real quantity that they wish to hold, suppose that the quantity of money unexpectedly increases so that individuals have larger cash balances than they wish to hold. They will then seek to dispose of what they regard as their excess money balances by paying out a larger sum for the purchase of securities, goods, and services, for the repayment of debts, and as gifts, than they are receiving from the corresponding sources. However, they cannot as a group succeed. One man’s spending is another man’s receipts. One man can reduce his nominal money balances only by persuading someone else to increase his. The community as a whole cannot in general spend more than it receives; it is playing a game of musical chairs.

The attempt to dispose of excess balances will nonetheless have important effects. If prices and incomes are free to change, the attempt to spend more will raise total spending and receipts, expressed in nominal units, which will lead to a bidding up of prices and perhaps also to an increase in output. If prices are fixed by custom or by government edict, the attempt to spend more will either be matched by an increase in goods and services or produce ‘shortages’ and ‘queues’. These in turn will raise the effective price...
and are likely sooner or later to force changes in customary or official prices. The initial excess of nominal balances will therefore tend to be eliminated, even though there is no change in the nominal quantity of money, by either a reduction in the real quantity available to hold through price rises or an increase in the real quantity desired through output increases. And conversely for an initial deficiency of nominal balances.

Changes in prices and nominal income can be produced either by changes in the real balances that people wish to hold or by changes in the nominal balances available for them to hold. Indeed, it is a tautology, summarized in the famous quantity equations, that all changes in nominal income can be attributed to one or the other – just as a change in the price of any good can always be attributed to a change in either demand or supply. The quantity theory is not, however, this tautology. On an analytical level, it has long been an analysis of the factors determining the quantity of money that the community wishes to hold; on an empirical level, it has increasingly become the generalization that changes in desired real balances (in the demand for money) tend to proceed slowly and gradually or to be the result of events set in train by prior changes in supply, whereas, in contrast, substantial changes in the supply of nominal balances can and frequently do occur independently of any changes in demand. The conclusion is that substantial changes in prices or nominal income are almost always the result of changes in the nominal supply of money.

(b) Quantity equations

Attempts to formulate mathematically the relations just presented verbally date back several centuries (Humphrey, 1984). They consist of creating identities equating a flow of money payments to a flow of exchanges of goods or services. The resulting quantity equations have proved a useful analytical device and have taken different forms as quantity theorists have stressed different variables.

The transactions form of the quantity equation

The most famous version of the quantity equation is doubtless the transactions version formulated by Simon Newcomb (1885) and popularized by Irving Fisher (1911):

\[ MV = PT, \]

(1)

or

\[ MV + M'V' = PT. \]

(2)
In this version the elementary event is a transaction – an exchange in which one economic actor transfers goods or services or securities to another actor and receives a transfer of money in return. The right-hand side of the equations corresponds to the transfer of goods, services, or securities; the left-hand side, to the matching transfer of money.

Each transfer of goods, services or securities is regarded as the product of a price and quantity; wage per week times number of weeks, price of a good times number of units of the good, dividend per share times number of shares, price per share times number of shares, and so on. The right-hand side of equations (1) and (2) is the aggregate of such payments during some interval, with \( P \) a suitably chosen average of the prices and \( T \) a suitably chosen aggregate of the quantities during that interval, so that \( PT \) is the total nominal value of the payments during the interval in question. The units of \( P \) are dollars (or other monetary unit) per unit of quantity; the units of \( T \) are number of unit quantities per period of time. We can convert the equation from an expression applying to an interval of time to one applying to a point in time by the usual limiting process of letting the interval for which we aggregate payments approach zero, and expressing \( T \) not as an aggregate but as a rate of flow. The magnitude \( T \) then has the dimension of quantity per unit time; the product of \( P \) and \( T \), of dollars (or other monetary unit) per unit time.

\( T \) is clearly a rather special index of quantities: it includes service flows (man-hours, dwelling-years, kilowatt-hours) and also physical capital items yielding such flows (houses, electric-generating plants) and securities representing both physical capital items and such intangible capital items as ‘goodwill’. Since each capital item or security is treated as if it disappeared from economic circulation once it is transferred, any such item that is transferred more than once in the period in question is implicitly weighted by the number of times it enters into transactions (its ‘velocity of circulation’, in strict analogy with the ‘velocity of circulation’ of money). Similarly, \( P \) is a rather special price index.

The monetary transfer analysed on the left-hand side of equations (1) and (2) is treated very differently. The money that changes hands is treated as retaining its identity, and all money, whether used in transactions during the time interval in question or not, is explicitly accounted for. Money is treated as a stock, not as a flow or a mixture of a flow and a stock. For a single transaction, the breakdown into \( M \) and \( V \) is trivial: the cash that is transferred is turned over once, or \( V = 1 \). For all transactions during an interval of time, we can, in principle, classify the existing stock of monetary units according as each monetary unit entered into 0, 1, 2,… transactions – that is, according as the monetary unit ‘turned over’ 0, 1, 2,… times. The weighted average of these numbers of turnover, weighted by the number of dollars that turned over that number of times, is the conceptual equivalent of \( V \). The dimensions of \( M \) are dollars (or other monetary unit); of \( V \), number of turnovers per unit time; so, of the product, dollars per unit time.

Equation (2) differs from equation (1) by dividing payments into two categories: those effected by the transfer of hand-to-hand currency (including coin) and those effected by the transfer of deposits. In equation (2) \( M \) stands for the volume of currency and \( V \) for the velocity of currency, \( M' \) for the volume of deposits, and \( V' \) for the velocity of deposits.

One reason for the emphasis on this particular division was the persistent dispute about whether the term \textit{money} should include only currency or deposits as well. Another reason was the direct availability of data on \( M' V' \) from bank records of clearings or of debits to deposit accounts. These data make it possible to calculate \( V' \) in a way that is not possible for \( V \).

Equations (1) and (2), like the other quantity equations we shall discuss, are intended to be identities – a
special application of double-entry bookkeeping, with each transaction simultaneously recorded on both sides of the equation. However, as with the national income identities with which we are all familiar, when the two sides, or the separate elements on the two sides, are estimated from independent sources of data, many differences between them emerge. This statistical defect has been less obvious for the quantity equations than for the national income identities – with their standard entry 'statistical discrepancy' – because of the difficulty of calculating \( V \) directly. As a result, \( V \) in equation (1) and \( V' \) in equation (2) have generally been calculated as the numbers having the property that they render the equations correct. These calculated numbers therefore embody the whole of the counterpart to the 'statistical discrepancy'.

Just as the left-hand side of equation (1) can be divided into several components, as in equation (2), so also can the right-hand side. The emphasis on transactions reflected in this version of the quantity equation suggests dividing total transactions into categories of payments for which payment periods or practices differ: for example, into capital transactions, purchases of final goods and services, purchases of intermediate goods, and payments for the use of resources, perhaps separated into wage and salary payments and other payments. The observed value of \( V \) might well depend on the distribution of total payments among categories. Alternatively, if the quantity equation is interpreted not as an identity but as a functional relation expressing desired velocity as a function of other variables, the distribution of payments may well be an important set of variables.

The income form of the quantity equation

Despite the large amount of empirical work done on the transactions equations, notably by Irving Fisher (1911, pp. 280–318; 1919, pp. 407–9) and Carl Snyder (1934, pp. 278–91), the ambiguities of the concepts of 'transactions' and the 'general price level' – particularly those arising from the mixture of current and capital transactions – have never been satisfactorily resolved. More recently, national or social accounting has stressed income transactions rather than gross transactions and has explicitly if not wholly satisfactorily dealt with the conceptual and statistical problems involved in distinguishing between changes in prices and changes in quantities. As a result, since at least the work of James Angell (1936), monetary economists have tended to express the quantity equation in terms of income transactions rather than gross transactions. Let \( Y = \text{nominal income} \), \( P = \text{the price index implicit in estimating national income at constant prices} \), \( N = \text{the number of persons in the population} \), \( y = \text{per capita national income in constant prices} \), and \( y' = Ny = \text{national income at constant prices} \), so that

\[
Y = PNY = Py'.
\]

Let \( M \) represent, as before, the stock of money; but define \( V \) as the average number of times per unit time that the money stock is used in making income transactions (that is, payment for final productive services or, alternatively, for final goods and services) rather than all transactions. We can then write the
The quantity theory of money

quantity equation in income form as

\[ MV = PNY = P'y'. \]

or, if we desire to distinguish currency from deposit transactions, as

\[ MV + M'V' = PNY. \]

Although the symbols \( P \), \( V \), and \( V' \) are used both in equations (4) and (5) and in equations (1) and (2), they stand for different concepts in each pair of equations. (In practice, gross national product often replaces national income in calculating velocity even though the logic underlying the equation calls for national income. The reason is the widespread belief that estimates of GNP are subject to less statistical error than estimates of national income.)

In the transactions version of the quantity equation, each intermediate transaction – that is, purchase by one enterprise from another – is included at the total value of the transaction, so that the value of wheat, for example, is included once when it is sold by the farmer to the mill, a second time when the mill sells flour to the baker, a third time when the baker sells bread to the grocer, a fourth time when the grocer sells bread to the consumer. In the income version, only the net value added by each of these transactions is included. To put it differently in the transactions version, the elementary event is an isolated exchange of a physical item for money – an actual, clearly observable event. In the income version, the elementary event is a hypothetical event that can be inferred but is not directly observable. It is a complete series of transactions involving the exchange of productive services for final goods, via a sequence of money payments, with all the intermediate transactions in this income circuit netted out. The total value of all transactions is therefore a multiple of the value of income transactions only.

For a given flow of productive services or, alternatively, of final products (two of the multiple faces of income), the volume of transactions will be affected by vertical integration or disintegration of enterprises, which reduces or increases the number of transactions involved in a single income circuit, and by technological changes that lengthen or shorten the process of transforming productive services into final products. The volume of income will not be thus affected.

Similarly, the transactions version includes the purchase of an existing asset – a house or a piece of land or a share of equity stock – precisely on a par with an intermediate or final transaction. The income version excludes such transactions completely.

Are these differences an advantage or disadvantage of the income version? That clearly depends on what it is that determines the amount of money people want to hold. Do changes of the kind considered in the preceding paragraphs, changes that alter the ratio of intermediate and capital transactions to income, also
alter in the same direction and by the same proportion the amount of money people want to hold? Or do they tend to leave this amount unaltered? Or do they have a more complex effect?

The transactions and income versions of the quantity theory involve very different conceptions of the role of money. For the transactions version, the most important thing about money is that it is transferred. For the income version, the most important thing is that it is held. This difference is even more obvious from the Cambridge cash-balance version of the quantity equation (Pigou, 1917). Indeed, the income version can perhaps best be regarded as a way station between the Fisher and the Cambridge version.

**Cambridge cash-balance approach**

The essential feature of a money economy is that an individual who has something to exchange need not seek out the double coincidence – someone who both wants what he has and offers in exchange what he wants. He need only find someone who wants what he has, sell it to him for general purchasing power, and then find someone who has what he wants and buy it with general purchasing power. For the act of purchase to be separated from the act of sale, there must be something that everybody will accept in exchange as ‘general purchasing power’ – this aspect of money is emphasized in the transactions approach. But also there must be something that can serve as a temporary abode of purchasing power in the interim between sale and purchase. This aspect of money is emphasized in the cash-balance approach.

How much money will people or enterprises want to hold on the average as a temporary abode of purchasing power? As a first approximation, it has generally been supposed that the amount bears some relation to income, on the assumption that income affects the volume of potential purchases for which the individual or enterprise wishes to hold cash balances. We can therefore write

\[ M = kPNy = kPy', \]

where \( M, N, P, y, \) and \( y' \) are defined as in equation (4) and \( k \) is the ratio of money stock to income – either the observed ratio so calculated as to make equation (6) an identity or the ‘desired’ ratio so that \( M \) is the ‘desired’ amount of money, which need not be equal to the actual amount. In either case, \( k \) is numerically equal to the reciprocal of the \( V \) in equation (4), the \( V \) being interpreted in one case as measured velocity and in the other as desired velocity.

Although equation (6) is simply a mathematical transformation of equation (4), it brings out sharply the difference between the aspect of money stressed by the transactions approach and that stressed by the cash-balance approach. This difference makes different definitions of money seem natural and leads to placing emphasis on different variables and analytical techniques.

The transactions approach makes it natural to define money in terms of whatever serves as the medium of exchange in discharging obligations. The cash-balance approach makes it seem entirely appropriate to
include in addition such temporary abodes of purchasing power as demand and time deposits not transferable by check, although it clearly does not require their inclusion (Friedman and Schwartz, 1970, ch. 3).

Similarly, the transactions approach leads to emphasis on the mechanical aspect of the payments process; payments practices, financial and economic arrangements for effecting transactions, the speed of communication and transportation, and so on (Baumol, 1952; Tobin, 1956; Miller and Orr, 1966, 1968). The cash-balance approach, on the other hand, leads to emphasis on variables affecting the usefulness of money as an asset: the costs and returns from holding money instead of other assets, the uncertainty of the future, and so on (Friedman, 1956; Tobin, 1958).

Of course, neither approach enforces the exclusion of the variables stressed by the other. Portfolio considerations enter into the costs of effecting transactions and hence affect the most efficient payment arrangements; mechanical considerations enter into the returns from holding cash and hence affect the usefulness of cash in a portfolio.

Finally, with regard to analytical techniques, the cash-balance approach fits in much more readily with the general Marshallian demand-supply apparatus than does the transactions approach. Equation (6) can be regarded as a demand function for money, with $P, N,$ and $y$ on the right-hand side being three of the variables on which the quantity of money demanded depends and $k$ symbolizing all the other variables, so that $k$ is to be regarded not as a numerical constant but as itself a function of still other variables. For completion, the analysis requires another equation showing the supply of money as a function of these and other variables. The price level or the level of nominal income is then the resultant of the interaction of the demand and supply functions.

Levels versus rates of change

The several versions of the quantity equations have all been stated in terms of the levels of the variables involved. For the analysis of monetary change it is often more useful to express them in terms of rates of change. For example, take the logarithm of both sides of equation (4) and differentiate with respect to time. The result is

\[
\frac{1}{M} \frac{dM}{dt} + \frac{1}{V} \frac{dV}{dt} = \frac{1}{P} \frac{dP}{dt} + \frac{1}{y'} \frac{dy'}{dt}
\]

(7)

or, in simpler notation,

\[
\delta M + \delta V = \delta P + \delta y' = \delta y',
\]

(8)
where $g$ stands for the percentage rate of change (continuously compounded) of the variable denoted by its subscript. The same equation is implied by equation (6), with $g_V$ replaced by $-g_k$.

The rate of change equations serve two very different purposes. First, they make explicit an important difference between a once-for-all change in the level of the quantity of money and a change in the rate of change of the quantity of money. The former is equivalent simply to a change of units – to substituting cents for dollars or pence for pounds – and hence, as is implicit in equations (4) and (6), would not be presumed to have any effect on real quantities, on neither $V$ (nor $k$) nor $y'$, but simply an offsetting effect on the price level, $P$. A change in the rate of change of money is a very different thing. It will tend, according to equations (7) and (8), to be accompanied by a change in the rate of inflation ($g_P$) which, as pointed out in section d below, affects the cost of holding money, and hence the desired real quantity of money. Such a change will therefore affect real quantities, $V$ and $g_V$, $y'$ and $g_y'$, as well as nominal and real interest rates.

The second purpose served by the rate of change equations is to make explicit the role of time, and thereby to facilitate the study of the effect of monetary change on the temporal pattern of response of the several variables involved. In recent decades, economists have devoted increasing attention to the short-term pattern of economic change, which has enhanced the importance of the rate of change versions of the quantity equations.

(c) The supply of money

The quantity theory in its cash-balance version suggests organizing an analysis of monetary phenomena in terms of (1) the conditions determining supply (this section); (2) the conditions determining demand (section d below); and (3) the reconciliation of demand with supply (section e below).

The factors determining the nominal supply of money available to be held depend critically on the monetary system. For systems like those that have prevailed in most major countries during the past two centuries, they can usefully be analysed under three main headings termed the proximate determinants of the quantity of money: (1) the amount of high-powered money – specie plus notes or deposit liabilities issued by the monetary authorities and used either as currency or as reserves by banks; (2) the ratio of bank deposits to bank holdings of high-powered money; and (3) the ratio of the public’s deposits to its currency holdings (Friedman and Schwartz, 1963b, pp. 776–98; Cagan, 1965; Burger, 1971; Black, 1975).

It is an identity that

$$M = H \cdot \frac{D}{R} \left(1 + \frac{D}{C}\right)$$

$$\frac{D}{R} + \frac{D}{C}$$

(9)
where $H =$ high-powered money; $D =$ deposits; $R =$ bank reserves; $C =$ currency in the hands of the public so that $(D/R)$ is the deposit–reserve ratio; and $(D/C)$ is the deposit–currency ratio. The fraction on the right-hand side of (9), i.e., the ratio of $M$ to $H$, is termed the money multiplier, often a convenient summary of the effect of the two deposit ratios. The determinants are called proximate because their values are in turn determined by much more basic variables. Moreover, the same labels can refer to very different contents.

High-powered money is the clearest example. Until some time in the 18th or 19th century, the exact date varying from country to country, it consisted only of specie or its equivalent: gold, or silver, or cowrie shells, or any of a wide variety of commodities. Thereafter, until 1971, with some significant if temporary exceptions, it consisted of a mixture of specie and of government notes or deposit liabilities. The government notes and liabilities generally were themselves promises to pay specified amounts of specie on demand, though this promise weakened after World War I, when many countries promised to pay either specie or foreign currency. During the Bretton Woods periods after World War II, only the USA was obligated to pay gold, and only to foreign monetary agencies, not to individuals or other non-governmental entities; other countries obligated themselves to pay dollars.

Since 1971, the situation has been radically different. In every major country, high-powered money consists solely of fiat money – pieces of paper issued by the government and inscribed with the legend ‘one dollar’ or ‘one pound’ and the message ‘legal tender for all debts public and private’; or book entries, labelled deposits, consisting of promises to pay such pieces of paper. Such a worldwide fiat (or irredeemable paper) standard has no precedent in history. The ‘gold’ central banks still record as an asset on their books is simply the grin of a Cheshire cat that has disappeared.

Under an international commodity standard, the total quantity of high-powered money in any one country – so long as it remains on the standard – is determined by the balance of payments. The division of high-powered money between physical specie and the fiduciary component of government-issued promises to pay is determined by the policies of the monetary authorities. For the world as a whole, the total quantity of high-powered money is determined both by the policies of the various monetary authorities and the physical conditions of supply of specie. The latter provide a physical anchor for the quantity of money and hence ultimately for the price level.

Under the current international fiat standard, the quantity of high-powered money is determined solely by the monetary authorities, consisting in most countries of a central bank plus the fiscal authorities. What happens to the quantity of high-powered money depends on their objectives, on the institutional and political arrangements under which they operate, and the operating procedures they adopt. These are likely to vary considerably from country to country. Some countries (e.g., Hong Kong, Panama) have chosen to link their currencies rigidly to some other currency by pegging the exchange rate. For them, the amount of high-powered money is determined in the same way as under an international commodity standard – by the balance of payments.

The current system is so new that it must be regarded as in a state of transition. Some substitute is almost sure to emerge to replace the supply of specie as a long-term anchor for the price level, but it is not yet clear what that substitute will be (see section 5 below).

The deposit–reserve ratio is determined by the banking system subject to any requirements that are imposed by law or the monetary authorities. In addition to any such requirements, it depends on such factors as the risk of calls for conversion of bank deposits to high-powered money; the cost of acquiring
additional high-powered money in case of need; and the returns from loans and investments, that is, the structure of interest rates.

*The deposit–currency ratio* is determined by the public. It depends on the relative usefulness to holders of money of deposits and currency and the relative cost of holding the one or the other. The relative cost in turn depends on the rates of interest received on deposits, which may be subject to controls imposed by law or the monetary authorities.

These factors determine the *nominal*, but not the *real*, quantity of money. The real quantity of money is determined by the interaction between the *nominal* quantity supplied and the *real* quantity demanded. In the process, changes in demand for real balances have feedback effects on the variables determining the nominal quantity supplied, and changes in nominal supply have feedback effects on the variables determining the real quantity demanded. Quantity theorists have generally concluded that these feedback effects are relatively minor, so that the *nominal* supply can generally be regarded as determined by a set of variables distinct from those that affect the *real* quantity demanded. In this sense, the nominal quantity can be regarded as determined primarily by supply, the real quantity, primarily demand.

Instead of expressing the nominal supply in terms of the identity (9), it can also be expressed as a function of the variables that are regarded as affecting $H$, $D/R$, and $D/C$, such as the rate of inflation, interest rates, nominal income, the extent of uncertainty, perhaps also the variables that are regarded as determining the decisions of the monetary authorities. Such a supply function is frequently written as

\[
M^S = h(R, Y, \ldots)
\]

(10)

where $R$ is an interest rate or set of interest rates, $Y$ is nominal income, and the dots stand for other variables that are regarded as relevant.

(d) The demand for money

The cash-balance version of the quantity theory, by stressing the role of money as an asset, suggests treating the demand for money as part of capital or wealth theory, concerned with the composition of the balance sheet or portfolio of assets. From this point of view, it is important to distinguish between ultimate wealth holders, to whom money is one form in which they choose to hold their wealth, and enterprises, to whom money is a producer's good like machinery or inventories (Friedman, 1956; Laidler, 1985; Friedman and Schwartz, 1982).

Demand by ultimate wealth holders

For ultimate wealth holders the demand for money, in real terms, may be expected to be a function primarily of the following variables:

1. Total wealth
The analogue of the budget constraint in the usual theory of consumer choice. It is the total that must be divided among various forms of assets. In practice, estimates of total wealth are seldom available. Instead, income may serve as an index of wealth. However, it should be recognized that income as measured by statisticians may be a defective index of wealth because it is subject to erratic year-to-year fluctuations, and a longer-term concept, like the concept of permanent income developed in connection with the theory of consumption, may be more useful (Friedman, 1957, 1959).

The emphasis on income as a surrogate for wealth, rather than as a measure of the ‘work’ to be done by money, is perhaps the basic conceptual difference between the more recent analyses of the demand for money and the earlier versions of the quantity theory.

2. The division of wealth between human and non-human forms
The major asset of most wealth holders is personal earning capacity. However, the conversion of human into non-human wealth or the reverse is subject to narrow limits because of institutional constraints. It can be done by using current earnings to purchase non-human wealth or by using non-human wealth to finance the acquisition of skills, but not by purchase or sale of human wealth and to only a limited extent by borrowing on the collateral of earning power. Hence, the fraction of total wealth that is in the form of non-human wealth may be an additional important variable.

3. The expected rates of return on money and other assets
These rates of return are the counterparts to the prices of a commodity and its substitutes and complements in the usual theory of consumer demand. The nominal rate of return on money may be zero, as it generally is on currency, or negative, as it sometimes is on demand deposits subject to net service charges, or positive, as it sometimes is on demand deposits on which interest is paid and generally is on time deposits. The nominal rate of return on other assets consists of two parts: first, any currently paid yield, such as interest on bonds, dividends on equities, or cost, such as storage costs on physical assets, and, second, a change in the nominal price of the asset. The second part is especially important under conditions of inflation or deflation.

4. Other variables determining the utility attached to the services rendered by money relative to those rendered by other assets – in Keynesian terminology, determining the value attached to liquidity proper
One such variable may be one already considered – namely, real wealth or income, since the services rendered by money may, in principle, be regarded by wealth holders as a ‘necessity’, like bread, the consumption of which increases less than in proportion to any increase in income, or as a ‘luxury’, like recreation, the consumption of which increases more than in proportion.

Another variable that is important empirically is the degree of economic stability expected to prevail, since instability enhances the value wealth-holders attach to liquidity. This variable has proved difficult to express quantitatively although qualitative information often indicates the direction of change. For example, the outbreak of war clearly produces expectations of greater instability. That is one reason why a notable increase in real balances – that is, a notable decline in velocity – often accompanies the outbreak of war. Such a decline in velocity produced an initial decline in sensitive prices at the outset of both World War I and World War II – not the rise that later inflation would have justified. The rate of inflation enters under item 3 as a factor affecting the cost of holding various assets,
particularly currency. The variability of inflation enters here, as a major factor affecting the usefulness of money balances. Empirically, variability of inflation tends to increase with the level of inflation, reinforcing the negative effect of higher inflation on the quantity of money demanded.

Still another relevant variable may be the volume of trading in existing capital goods by ultimate wealth holders. The higher the turnover of capital assets, the larger the fraction of total assets people may find it useful to hold as cash. This variable corresponds to the class of transactions omitted in going from the transactions version of the quantity equation to the income version.

We can express this analysis in terms of the following demand function for money for an individual wealth holder:

\[
M^D = P \cdot f\left(y, w, R^*_M, R^*_F, R^*_E, u\right),
\]

where \(M\), \(P\), and \(y\) have the same meaning as in equation (6) except that they relate to a single wealth-holder (for whom \(y = y'\)); \(w\) is the fraction of wealth in non-human form (or, alternatively, the fraction of income derived from property); an asterisk denotes an expected value, so \(R^*_M\) is the expected nominal rate of return on money; \(R^*_F\) is the expected nominal rate of return on fixed-value securities, including expected changes in their prices; \(R^*_E\) is the expected nominal rate of return on physical assets, including expected changes in their prices; and \(u\) is a portmanteau symbol standing for other variables affecting the utility attached to the services of money. Though the expected rate of inflation is not explicit in equation (11), it is implicit because it affects the expected nominal returns on the various classes of assets, and is sometimes used as a proxy for \(R^*_E\). For some purposes it may be important to classify assets still more finely – for example, to distinguish currency from deposits, long-term from short-term fixed-value securities, risky from relatively safe equities, and one kind of physical assets from another. Furthermore, the several rates of return are not independent. Arbitrage tends to eliminate differences among them that do not correspond to differences in perceived risk or other nonpecuniary characteristics of the assets, such as liquidity. In particular, as Irving Fisher pointed out in 1896, arbitrage between real and nominal assets introduces an allowance for anticipated inflation into the nominal interest rate (Fischer, 1896; Friedman, 1956).

The usual problems of aggregation arise in passing from equation (11) to a corresponding equation for the economy as a whole – particular, from the possibility that the amount of money demanded may depend on the distribution among individuals of such variables as \(y\) and \(w\) and not merely on their aggregate or average value. If we neglect these distributional effects, equation (11) can be regarded as applying to the community as a whole, with \(M\) and \(y\) referring to per capital money holdings and per capital real income, respectively, and \(w\) to the fraction of aggregate wealth in non-human form.

Although the mathematical equation may be the same, its significance is very different for the individual wealth-holder and the community as a whole. For the individual, all the variables in the equation other
than his own income and the disposition of his portfolio are outside his control. He takes them, as well as the structure of monetary institutions, as given, and adjusts his nominal balances accordingly. For the community as a whole, the situation is very different. In general, the nominal quantity of money available to be held is fixed and what adjusts are the variables on the right-hand side of the equation, including an implicit underlying variable, the structure of monetary institutions, which, in the longer run, at least, adjusts itself to the tastes and preferences of the holders of money. A dramatic example is provided by the restructuring of the financial system in the US in the 1970s and 1980s. In practice, the major problems that arise in applying equation (11) are the precise definitions of \( y \) and \( w \), the estimation of expected rates of return as contrasted with actual rates of return, and the quantitative specification of the variables designated by \( u \).

**Demand for business enterprises**

Business enterprises are not subject to a constraint comparable to that imposed by total wealth of the ultimate wealth-holder. They can determine the total amount of capital embodied in productive assets, including money, to maximize returns, since they can acquire additional capital through the capital market. A similar variable defining the ‘scale’ of the enterprise may, however, be relevant as an index of the productive value of different quantities of money to the enterprise. Lack of data has meant that much less empirical work has been done on the business demand for money than on the aggregate demand enterprises. As a result, there are as yet only faint indications about the best variable to use: whether total transactions, net value added, net income, total capital in nonmoney form, or net worth.

The division of wealth between human and non-human form has no special relevance to business enterprises, since they are likely to buy the services of both forms on the market.

Rates of return on money and on alternative assets are, of course, highly relevant to business enterprises. These rates determine the net cost of holding money balances. However, the particular rates that are relevant may differ from those that are relevant for ultimate wealth-holders. For example, the rates banks charge on loans are of minor importance for wealth-holders yet may be extremely important for businesses, since bank loans may be a way in which they can acquire the capital embodied in money balances.

The counterpart for business enterprises of the variable \( u \) in equation (11) is the set of variables other than scale affecting the productivity of money balances. At least one subset of such variables – namely, expectations about economic stability and the variability of inflation – is likely to be common to business enterprises and ultimate wealth-holders.

With these interpretations of the variables, equation (11), with \( w \) excluded, can be regarded as symbolizing the business demand for money and, as it stands, symbolizing aggregate demand for money, although with even more serious qualifications about the ambiguities introduced by aggregation.

**Buffer stock effects**

In serving its basic function as a temporary abode of purchasing power, cash balances necessarily fluctuate, absorbing temporary discrepancies between the purchases and sales they mediate. Though always recognized, this ‘buffer stock’ role of money has seldom been explicitly modelled.
Recently, more explicit attention has been paid to the buffer stock notion in an attempt to explain anomalies that have arisen in econometric estimates of the short-run demand for money (Judd and Scadding, 1982; Laidler, 1984; Knoester, 1984).

(e) The reconciliation of demand with supply

Multiply equation (11) by $N$ to convert it from a per capita to an aggregate demand function, and equate it to equation (10), omitting for simplicity the asterisks designating expected values, and letting $R$ stand for a vector of interest rates:

$$M^S = h(R, Y, \ldots) = P \cdot N \cdot f(y, w, R, gP, u).$$

The result is quantity equation (6) in an expanded form. In principle, a change in any of the underlying variables that produces a change in $M^S$ and disturbs a pre-existing equilibrium can produce offsetting changes in any of the other variables. In practice, as already noted earlier, the initial impact is likely to be on $y$ and $R$, the ultimate impact predominantly on $P$.

A frequent criticism of the quantity theory is that its proponents do not specify the transmission mechanism between a change in $M^S$ and the offsetting changes in other variables, that they rely on a black box connecting the input – the nominal quantity of money – and the output – effects on prices and quantities.

This criticism is not justified insofar as it implies that the transmission mechanism for the quantity equation is fundamentally different from that for a demand–supply analysis of a particular product – shoes, or copper, or haircuts. In both cases the demand function for the community as a whole is the sum of demand functions for individual consumer or producer units, and the separate demand functions are determined by the tastes and opportunities of the units. In both cases, the supply function depends on production possibilities, institutional arrangements for organizing production, and the conditions of supply of resources. In both cases a shift in supply or in demand introduces a discrepancy between the amounts demanded and supplied at the pre-existing price. In both cases any discrepancy can be eliminated only by either a price change or some alternative rationing mechanism, explicit or implicit.

Two features of the demand–supply adjustment for money have concealed this parallelism. One is that demand–supply analysis for particular products typically deals with flows – number of pairs of shoes or number of haircuts per year – whereas the quantity equations deal with the stock of money at a point in time. In this respect the correct analogy is with the demand for, say, land, which, like money, derives its value from the flow of services it renders but has a purchase price and not merely a rental value. The second is the widespread tendency to confuse ‘money’ and ‘credit’, which has produced misunderstanding about the relevant price variable. The ‘price’ of money is the quantity of goods and services that must be given up to acquire a unit of money – the inverse of the price level. This is the price that is analogous to the price of land or of copper or of haircuts. The ‘price’ of money is not the
interest rate, which is the ‘price’ of credit. The interest rate connects stocks with flows – the rental value of land with the price of land, the value of the service flow from a unit of money with the price of money. Of course, the interest rate may affect the quantity of money demanded – just as it may affect the quantity of land demanded – but so may a host of other variables.

The interest rate has received special attention in monetary analysis because, without quite realizing it, fractional reserve banks have created part of the stock of money in the course of serving as an intermediary between borrowers and lenders. Hence changes in the quantity of money have frequently occurred through the credit markets, in the process producing important transitory effects on interest rates.

On a more sophisticated level, the criticism about the transmission mechanism applies equally to money and to other goods and services. In all cases it is desirable to go beyond equality of demand and supply as defining a stationary equilibrium position and examine the variables that affect the quantities demanded and supplied and the dynamic temporal process whereby actual or potential discrepancies are eliminated. Examination of the variables affecting demand and supply has been carried farther for money than for most other goods or services. But for both, there is as yet no satisfactory and widely accepted description, in precise quantifiable terms, of the dynamic temporal process of adjustment. Much research has been devoted to this question in recent decades; yet it remains a challenging subject for research. (For surveys of some of the literature, see Laidler, 1985; Judd and Scadding, 1982.)

(f) First-round effects

Another frequent criticism of the quantity equations is that they neglect any effect on the outcome of the source of change in the quantity of money. In Tobin's words, the question is whether ‘the genesis of new money makes a difference’, in particular, whether ‘an increase in the quantity of money has the same effect whether it is issued to purchase goods or to purchase bonds’ (1974, p. 87).

Or, as John Stuart Mill put a very similar view in 1844, ‘The issues of a Government paper, even when not permanent, will raise prices; because Governments usually issue their paper in purchases for consumption. If issued to pay off a portion of the national debt, we believe they would have no effect’ (1844, p. 589).

Tobin and Mill are right that the way the quantity of money is increased affects the outcome in some measure or other. If one group of individuals receives the money on the first round, they will likely use it for different purposes than another group of individuals. If the newly printed money is spent on the first round for goods and services, it adds directly at that point to the demand for such goods and services, whereas if it is spent on purchasing debt, or simply held temporarily as a buffer stock, it has no immediate effect on the demand for goods and services. Such effects come later as the initial recipients of the ‘new’ money dispose of it. However, as the ‘new’ money spreads through the economy, any first-round effects tend to be dissipated. The ‘new’ money is merged with the old and is distributed in much the same way.

One way to characterize the Keynesian approach (see below) is that it gives almost exclusive importance to the first-round effect by putting primary emphasis on flows of spending rather than on stocks of assets. Similarly, one way to characterize the quantity-theory approach is to say that it gives almost no importance to first-round effects.

The empirical question is how important the first-round effects are compared with the ultimate effects.
Theory cannot answer that question. The answer depends on how different are the reactions of the recipients of cash via alternative routes, on how rapidly a larger money stock is distributed through the economy, on how long it stays at each point in the economy, on how much the demand for money depends on the structure of government liabilities, and so on. Casual empiricism yields no decisive answer. Maybe the first-round effect is so strong that it dominates later effects; maybe it is highly transitory.

Despite repeated assertions by various authors that the first-round effect is significant, none, so far as I know, has presented any systematic empirical evidence to support that assertion. The apparently similar response of spending to changes in the quantity of money at widely separated dates in different countries and under diverse monetary systems establishes something of a presumption that the first-round effect is not highly significant. This presumption is also supported by several empirical studies designed to test the importance of the first-round effect (Cagan, 1972).

(g) The international transmission mechanism

From its very earliest days, the quantity theory was intimately connected with the analysis of the adjustment mechanism in international trade. A commodity standard, in which money is specie or its equivalent, was taken as the norm. Under such a standard, the supply of money in any one country is determined by the links between that country and other countries that use the same commodity as money. Under such a standard, the same theory explains links among money, prices, and nominal income in various parts of a single country – money, prices, and nominal income in Illinois and money, prices, and nominal income in the rest of the United States – and the corresponding links among various countries. The differences between interregional adjustment and international adjustment are empirical: greater mobility of people, goods, and capital among regions than among countries, and hence more rapid adjustment.

According to the specie-flow mechanism developed by Hume and elaborated by Henry Thornton, David Ricardo and their successors, ‘too’ high a money stock in country A tends to make prices in A high relative to prices in the rest of the world, encouraging imports and discouraging exports. The resulting deficit in the balance of trade is financed by shipment of specie, which reduces the quantity of money in country A and increases it in the rest of the world. These changes in the quantity of money tend to lower prices in country A and raise them in the rest of the world, correcting the original disequilibrium. The process continues until price levels in all countries are at a level at which balances of payments are in equilibrium (which may be consistent with a continuing movement of specie, for example, from gold- or silver-producing countries to non-gold- or silver-producing countries, or between countries growing at different secular rates).

Another strand of the classical analysis has recently been revived under the title ‘the monetary theory of the balance of payments’. The specie-flow mechanism implicitly assumes that prices adjust only in response to changes in the quantity of money produced by specie flows. However, if markets are efficient and transportation costs are neglected, there can be only a single price expressed in a common currency for goods traded internationally. Speculation tends to assure this result. Internally, competition between traded and nontraded goods tends to keep their relative price in line with relative costs. If these adjustments are rapid, ‘the law of one price’ holds among countries. If the money stock is not distributed among countries in such a way as to be consistent with the equilibrium prices, excess demands and
Supplies of money will lead to specie flows. Domestic nominal demand in a country with ‘too’ high a quantity of money will exceed the value of domestic output and the excess will be met by imports, producing a balance of payments deficit financed by the export of specie; and conversely in a country with too ‘low’ a quantity of money. Specie flows are still the adjusting mechanism, but they are produced by differences between demand for output in nominal terms and the supply of output at world prices rather than by discrepancies in prices. Putative rather than actual price differences are the spur to adjustment. This description is highly oversimplified, primarily because it omits the important role assigned to short- and long-term capital flows by all theorists – those who stress the specie-flow mechanism and even more those who stress the single-price mechanism (Frenkel, 1976; Frenkel and Johnson, 1976).

In practice, few countries have had pure commodity standards. Most have had a mixture of commodity and fiduciary standards. Changes in the fiduciary component of the stock of money can replace specie flows as a means of adjusting the quantity of money.

The situation is still different for countries that do not share a unified currency, that is, a currency in which only the name assigned to a unit of currency differs among countries. Changes in the rates of exchange between national currencies then serve to keep prices in various countries in the appropriate relation when expressed in a common currency. Exchange rate adjustments replace specie flows or changes in the quantity of domestically created money. And exchange rate changes too may be produced by actual or putative price differences or by short- or long-term capital flows. Moreover, especially during the Bretton Woods period (1945–71), but more recently as well, governments have often tried to avoid changes in exchange rates by seeking adjustment through subsidies to exports, obstacles to imports, and direct controls over foreign exchange transactions. These measures involved either implicit or explicit multiple rate systems and were accompanied by government borrowing to finance balance-of-payments deficits, or governmental lending to offset surpluses. They sometimes led to severe financial crises and major exchange rate adjustments – one reason the Bretton Woods system finally broke down in 1971. Since then, exchange rates have supposedly been free to float and to be determined in private markets. In practice, however, governments still intervene in an attempt to affect the exchange rates of their currencies, either directly by buying or selling their currency on the market, or indirectly, by adopting monetary or fiscal or trade policies designed to alter the market exchange rate. However, most governments no longer announce fixed parities for their currencies.

2 Keynesian challenge to the quantity theory

The depression of the 1930s produced a wave of scepticism about the relevance and validity of the quantity theory of money. The central banks of the world – the Federal Reserve in the forefront – proclaimed that, despite the teachings of the quantity theory, ‘easy money’ was proving to be ineffective in stemming the depression. They pointed to the low level of short-term interest rates as evidence of how ‘easy’ monetary policy was. Their claims seemed credible not only because of the confusion between ‘lowness of interest’ and ‘plenty of money’ pointed out by Hume but also because of the absence of readily available evidence on what was happening to the quantity of money. Most observers at the time did not know, as we do now, that the Federal Reserve permitted the quantity of money in the United States to decline by one-third between 1929 and 1933, and hence that the accompanying contraction in economic activity and deflation of prices was entirely consistent with the quantity theory. Monetary
policy was incredibly ‘tight’ not ‘easy’.

The scepticism about the quantity theory was further heightened by the publication of John Maynard Keynes's *The General Theory of Employment, Interest and Money* (Keynes, 1936) which offered an alternative interpretation of economic fluctuations in general and the depression in particular. Keynes emphasized spending on investment and the stability of the consumption function rather than the stock of money and the stability of the demand function for money. He relegated the forces embodied in the quantity theory to a minor role, and treated fiscal rather than monetary policy as the chief instrument for influencing the course of events. Received wisdom both inside and outside the economics profession became ‘money does not matter’.

Keynes did not deny the validity of the quantity equation, in any of its forms – after all, he had been a major contributor to the quantity theory (Keynes, 1923). What he did was something very different. He argued that the demand for money, which he termed the liquidity-preference function, had a special form such that under conditions of underemployment the $V$ in equation (4) and the $k$ in equation (6) would be highly unstable and would passively adapt to whatever changes independently occurred in money income or the stock of money. Under such conditions, these equations, though entirely valid, were largely useless for policy or prediction. Moreover, he regarded such conditions as prevailing much, if not most of the time.

That possibility rested on two other key propositions. First, that, contrary to the teachings of classical and neoclassical economists, the *long-run equilibrium* position of an economy need not be characterized by ‘full employment’ of resources even if all prices are flexible. In his view, unemployment could be a deep-seated characteristic of an economy rather than simply a reflection of price and wage rigidity or transitory disturbances. This proposition has played an important role in promoting the acceptance of Keynesianism, especially by non-economists, even though, by now, it is widely accepted that, as a theoretical matter, the proposition is false. Keynes's error consisted in neglecting the role of wealth in the consumption function. There is no fundamental ‘flaw in the price system’ that makes persistent structural unemployment a possible or probable natural outcome of a fully operative market system (Haberler, 1941, pp. 242, 389, 403, 491–503; Pigou, 1947; Tobin, 1947; Patinkin, 1948; Johnson, 1961). The concept of ‘underemployment equilibrium’ has been replaced by the concept of a ‘natural rate of unemployment’ (see section 3 below).

Keynes's final key proposition was that, as an empirical matter, prices, especially wages, can be regarded as rigid – an institutional datum – for short-run economic fluctuations; in which case, the distinction between real and nominal magnitudes that is at the heart of the quantity theory is irrelevant for such fluctuations. This proposition, unlike the other two, did not conflict with the teachings of the quantity theory. Classical and neoclassical economists had long recognized that price and wage rigidity existed and contributed to unemployment during cyclical contractions, and to labour scarcity during cyclical booms. But to them, wage rigidity was a defect of the market; to Keynes, it was a rational response to the possibility of underemployment equilibrium (Keynes, 1936, pp. 269–71).

In his analysis of the demand for money (i.e., the form of equation (6) or (11)), Keynes treated the stock of money as if it were divided into two parts, one part, $M_1$, ‘held to satisfy the transactions- and precautionary-motives’, the other, $M_2$, ‘held to satisfy the speculative-motive’ (Keynes, 1936, p. 199). He regarded $M_1$ as a roughly constant fraction of income. He regarded the demand for $M_2$ as arising from ‘uncertainty as to the future course of the rate of interest’ (Keynes, 1936, p. 168) and the amount
quantity theory of money: The New Palgrave Dictionary of Economics

demanded as depending on the relation between current rates of interest and the rates of interest expected to prevail in the future. Keynes, of course, recognized the existence of a whole complex of interest rates. However, for simplicity, he spoke in terms of ‘the rate of interest’, usually meaning by that the rate on long-term securities that were fixed in nominal value and that involved minimal risks of default – for example, government bonds. In a ‘given state of expectations’, the higher the current rate of interest, the lower would be the (real) amount of money that people would want to hold for speculative motives for two reasons: first, the greater would be the cost in terms of current earnings sacrificed by holding money instead of securities, and, second, the more likely it would be that interest rates would fall, and hence bond prices rise, and so the greater would be the cost in terms of capital gains sacrificed by holding money instead of securities.

To formalize Keynes's analysis in terms of the symbols we have used so far, we can write his demand (liquidity-preference) function as

$$M / P = M_1 / P + M_2 / P = k_1 y' + f \left( R - R^*, R^* \right)$$

(13)

where $R$ is the current rate of interest, $R^*$ is the rate of interest expected to prevail, and $k_1$, the analogue to the inverse of the income velocity of circulation of money, is treated as determined by payment practices and hence as a constant at least in the short run. Later writers in this tradition have argued that $k_1$ too should be regarded as a function of interest rates (Baumol, 1952; Tobin, 1956).

Although expectations are given great prominence in developing the liquidity function expressing the demand for $M_2$, Keynes and his followers generally did not explicitly introduce an expected interest rate into that function as is done in equation (13). For the most part, in practice, they treated the amount of $M_2$ demanded as a function simply of the current interest rate, the emphasis on expectations serving only as a reason for attributing instability to the liquidity function. Moreover, for the most part, they omitted $P$ (and replaced $y'$ by $Y$) because of their assumption that prices were rigid.

Except for somewhat different language, the analysis up to this point differs from that of earlier quantity theorists, such as Fisher, only by its subtle analysis of the role of expectations about future interest rates, its greater emphasis on current interest rates, and its narrower restriction of the variables explicitly considered as affecting the amount of money demanded.

Keynes's special twist concerned the empirical form of the liquidity-preference function at the low interest rates that he believed would prevail under conditions of underemployment equilibrium. Let the interest rate fall sufficiently low, he argued, and money and bonds would become perfect substitutes for one another; liquidity preference, as he put it, would become absolute. The liquidity-preference function, expressing the quantity of $M_2$ demanded as a function of the rate of interest, would become horizontal at some low but finite rate of interest. Under such circumstances, an increase in the quantity of money by whatever means would lead holders of money to seek to convert their additional cash balances into bonds, which would tend to lower the rate of interest on bonds. Even the slightest lowering would lead
speculators with firm expectations to absorb the additional money balances by selling any bonds demanded by the initial holders of the additional money. The result would simply be that the community as a whole would hold the increased quantity of money without any change in the interest rate; \( k \) would be higher and \( V \) lower. Conversely, a decrease in the quantity of money would lead holders of bonds to seek to restore their money balances by selling bonds, but this would tend to raise the rate of interest, and even the slightest rise would induce the speculators to absorb the bonds offered.

Or, again, suppose nominal income increases or decreases for whatever reason. That will require an increase or decrease in \( M_1 \), which can come out of or be transferred to \( M_2 \) without any further effects.

The conclusion is that, under circumstances of absolute liquidity preference, income can change without a change in \( M \) and \( M \) can change without a change in income. The holders of money are in metastable equilibrium, like a tumbler on its side on a flat surface; they will be satisfied with whatever the quantity of money happens to be.

Keynes regarded absolute liquidity preference as a strictly ‘limiting case’ of which, though it ‘might become practically important in future’, he knew ‘of no example … hitherto’ (1936, p. 207). However, he treated velocity as if in practice its behaviour frequently approximated that which would prevail in this limiting case.

Keynes's disciples went much farther than Keynes himself. They were readier than he was to accept absolute liquidity preference as the actual state of affairs. More important, many argued that when liquidity preference was not absolute, changes in the quantity of money would affect only the interest rate on bonds and that changes in this interest rate in turn would have little further effect. They argued that both consumption expenditures and investment expenditures were nearly completely insensitive to changes in interest rates, so that a change in \( M \) would merely be offset by an opposite and compensatory change in \( V \) (or a change in the same direction in \( k \)), leaving \( P \) and \( y \) almost completely unaffected. In essence their argument consists in asserting that only paper securities are substitutes for money balances – that real assets never are (see Hansen, 1957, p. 50; Tobin, 1961).

The apparent success during the 1950s and 1960s of governments committed to a Keynesian full-employment policy in achieving rapid economic growth, a high degree of economic stability, and relatively stable prices and interest rates, for a time strongly reinforced belief in the initial Keynesian views about the unimportance of variations in the nominal quantity of money.

The 1970s administered a decisive blow to these views and fostered a revival of belief in the quantity theory. Rapid monetary growth was accompanied not only by accelerated inflation but also by rising, not falling, average levels of unemployment (Friedman, 1977), and by rising, not declining, interest rates. As Robert Lucas put it in 1981,

"Keynesian orthodoxy … appears to be giving seriously wrong answers to the most basic questions of macroeconomic policy. Proponents of a class of models which promised \( \frac{3}{2} \) to \( \frac{4}{2} \) percent unemployment to a society willing to tolerate annual inflation rates of 4 to 5 percent have some explaining to do after a decade [i.e., the 1970s] such as we have just come through. A forecast error of this magnitude and central importance to policy has consequences (pp. 559–60)."
This experience undermined the belief that the price level could be regarded as rigid – or at any rate as
determined by forces unrelated to the quantity of money; that the nominal quantity of money demanded
could be regarded as a function primarily of the nominal interest rate, and that absolute liquidity
preference was the normal state of affairs. No teacher of elementary economics since the late 1970s can,
as so many did in the 1940s, 1950s, and 1960s, draw on the blackboard a downward sloping liquidity-
preference diagram with the nominal quantity of money on the horizontal axis and a nominal interest
rate on the vertical axis and confidently proclaim that the only important effect of an increase in the
nominal quantity of money would be to lower the rate of interest. The distinction between the nominal
interest rate and the real interest rate introduced by Irving Fisher in 1896 has entered – or re-entered –
received wisdom (Fisher, 1896).

Despite its subsidence, the Keynesian attack on the quantity theory has left its mark. It has reinforced the
tendency, already present in the Cambridge approach, to stress the role of money as an asset and hence
to regard the analysis of the demand for money as part of capital or wealth theory, concerned with the
composition of the balance sheet or portfolio of assets. The Keynesian stress on autonomous spending
and hence on fiscal policy remains important in its own right but also has led to greater emphasis on the
effect of government fiscal policies on the demand for money. Keynes's stress on expectations has
contributed to the rapid growth in the analysis of the role and formation of expectations in a variety of
economic contexts. Conversely, the revival of the quantity theory has led Keynesian economists to treat
to changes in the quantity of money as an essential element in the analysis of short-term change.

Finally, the controversy between Keynesians and quantity theorists has led both groups to distinguish
more sharply between long-run and short-run effects of monetary changes; between ‘static’ or ‘long-run
equilibrium’ theory and the dynamics of economic change.

As Franco Modigliani put it in his 1976 presidential address to the American Economic Association,
there are currently ‘no serious analytical disagreements between leading monetarists [i.e., quantity
theorists] and leading nonmonetarists [i.e., Keynesians]’ (1977, p. 1).

However, there still remain important differences on an empirical level. These all centre on the
dynamics of short-run change – the process whereby a change in the quantity of money affects aggregate
spending and the role of fiscal variables in the process.

The Keynesians regard a change in the quantity of money as affecting in the first instance ‘the’ interest
rate, interpreted as a market rate on a fairly narrow class of financial liabilities. They regard spending as
affected only ‘indirectly’ as the changed interest rate alters the profitability and amount of investment
spending, again interpreted fairly narrowly, and as investment spending, through the multiplier, affects
total spending. Hence the emphasis they give in their analysis to the interest elasticities of the demand
for money and of investment spending.

The quantity theorists, on the other hand, stress a much broader and more ‘direct’ impact of spending,
saying, as in section 1a above, that individuals will seek ‘to dispose of what they regard as their excess
money balances by paying out a larger sum for the purchase of securities, goods, and services, for the
repayment of debts, and as gifts than they are receiving from the corresponding sources’.

The two approaches can be readily reconciled on a formal level. Quantity theorists can describe the
transmission mechanism as operating ‘through’ the balance sheet and ‘through’ changes in interest rates.
The attempt by holders of money to restore or attain a desired balance sheet after an unexpected increase
in the quantity of money tends initially to raise the prices of assets and reduce interest rates, which
encourages spending to produce new assets and also spending on current services rather than on
purchasing existing assets. This is how an initial effect on balance sheets gets translated into an effect on income and spending. The resulting increase in spending tends to raise prices of goods and services which, in turn, by lowering the real value of the quantity of money and of nominal assets, tends to eliminate the initial decline in interest rates, even overshooting in the process. The difference between the quantity theorists and the Keynesians is less in the nature of the process than in the range of assets considered. The Keynesians tend to concentrate on a narrow range of marketable assets and recorded interest rates. The quantity theorists insist that a far wider range of assets and interest rates must be taken into account – such assets as durable and semi-durable consumer goods, structures, and other real property. As a result, the quantity theorists regard the market rates stressed by the Keynesians as only a small part of the total spectrum of rates that are relevant. This difference in the assumed transmission mechanism is largely a by-product of the different assumptions about price. The rejection of absolute liquidity preference forced Keynes's followers to let the interest rate be flexible. This chink in the key assumption that prices are an institutional datum was minimized by interpreting the ‘interest rate’ narrowly, and market institutions made it easy to do so. After all, it is most unusual to quote the ‘interest rate’ implicit in the sales and rental prices of houses and automobiles, let alone furniture, household appliances, clothes, and so on. Hence the prices of these items continued to be regarded as an institutional datum, which forced the transmission process to go through an extremely narrow channel. On the side of the quantity theorists there was no such inhibition. Since they regard prices as flexible, though not ‘perfectly’ flexible, it was natural for them to interpret the transmission mechanism in terms of relative price adjustments over a broad area rather than in terms of narrowly defined interest rates. Less important differences are the tendency for Keynesians to stress the short-run as opposed to the long-run impact of changes to a far greater extent than the quantity theorists; and, a related difference, to give greater scope to the first-round effect of changes in the quantity of money.

3 The Phillips curve and the natural rate hypothesis

A major postwar development that contributed greatly to the revival of the quantity theory grew out of criticism by quantity theorists of the ‘Phillips curve’ – an allegedly stable inverse relation between unemployment and the rate of change of nominal wages such that a high level of unemployment was accompanied by declining wages, a low level by rising wages. Though not formally linked to the Keynesian theoretical system, the Phillips curve was widely welcomed by Keynesians as helping to fill a gap in the system created by the assumption of rigid wages. In addition, it appeared to offer an attractive trade-off possibility for economic policy: a permanent reduction in the level of unemployment at the cost of a moderate sustained increase in the rate of inflation. The Keynesian assumption that prices and wages could be regarded as institutionally determined made it easy for them to accept a relation between a nominal magnitude (the rate of change of wages) and a real magnitude (unemployment). By contrast, the quantity theory distinction between real and nominal magnitudes implies that the Phillips curve is theoretically flawed. The quantity of labour demanded is a function of real not nominal wages; and so is the quantity supplied. Under any given set of circumstances, there is an equilibrium level of unemployment corresponding to an equilibrium structure of real wage rates. A higher level of unemployment will put downward pressure on real wage rates; a lower level will put upward pressure on real wage rates. The level of unemployment consistent with the equilibrium structure of real wage rates
has been termed the ‘natural rate of unemployment’ and defined as

the level that would be ground out by the Walrasian system of general equilibrium
equations, provided there is imbedded in them the actual structural characteristics of the
labour and commodity markets, including market imperfections, stochastic variability in
demands and supplies, the cost of gathering information about job vacancies and labour
availabilities, the costs of mobility, and so on (Friedman, 1968, p. 8).

The nominal wage rate that corresponds to any given real wage rate depends on the level of prices.
Whether that nominal wage rate is rising or falling depends on whether prices are rising or falling. If
wages and prices change at the same rate, the real wage rate remains the same. Hence, in the long run,
there need be no relation between the rate of change of nominal wages and the rate of change of real
wages, and hence between the rate of change of nominal wages and the level of unemployment. In the
long run, therefore, the Phillips curve will tend to be vertical at the natural rate of unemployment – a
proposition that came to be termed the Natural Rate Hypothesis.

Over short periods, an unanticipated increase in inflation reduces real wages as viewed by employers,
inducing them to offer higher nominal wages, which workers erroneously view as higher real wages.
This discrepancy simultaneously encourages employers to offer more employment and workers to
accept more employment, thereby reducing unemployment, which produces the inverse relation
encapsulated in the Phillips curve. However, if the higher rate of inflation continues, the anticipations of
workers and employers will converge and the decline in unemployment will be reversed. A negatively
sloping Phillips curve is therefore a short-run phenomenon. Moreover, it will not be stable over time,
since what matters is not the nominal rates of change of wages and prices but the difference between the
actual and the anticipated rates of change. The emergence of stagflation in the 1970s quickly confirmed
this analysis, leading to the widespread replacement of the original Phillips curve by an expectations-
adjusted Phillips curve (Friedman, 1977).

Acceptance of the natural rate hypothesis has had far-reaching effects not only on received wisdom
among economists but also on economic policy. It became widely recognized that expansionary
monetary and fiscal policies at best gave only a temporary stimulus to output and employment and if
long continued would be reflected primarily in inflation.

4 The theory of rational expectations

A subsequent theoretical development was the belated flowering of a seed planted in 1961 by John F.
Muth, in a long-neglected article on ‘Rational expectations and the theory of price movements’ (Muth,
1961). The theory of rational expectations offers no special insight into stationary-state or long-run
equilibrium analysis. Its contribution is to dynamics – short-run change, and hence potentially to
stabilization policy.
It has long been recognized by writers of all persuasions that, as Abraham Lincoln put it over a century
ago, ‘you can't fool all of the people all of the time.’ The tendency for the public to learn from
experience and to adjust to it underlies David Hume's view that monetary expansion ‘is favourable to
industry’ only in its initial stages, but that if it continues, it will come to be anticipated and will affect
prices and nominal interest rates but not real magnitudes. It also underlies the companion view associated with the natural rate hypothesis that a ‘full employment’ policy in which monetary, or for that matter fiscal, measures are used to counteract any increase in unemployment will almost inevitably lead not simply to uneven inflation but to uneven inflation around a rising trend – a conclusion often illustrated by analogizing inflation to a drug of which the addict must take larger and larger doses to get the same kick.

Nonetheless, the importance of anticipations and how they are formed in determining the dynamic response to changes in money and other magnitudes remained largely implicit until Lucas and Sargent applied the Muth rational expectations idea explicitly to the reliability of econometric models of the economy and to stabilization policies (Fischer, 1980; Lucas, 1976; Lucas and Sargent, 1981).

The theory of rational expectations asserts that economic agents should be treated as if their anticipations fully incorporate both currently available information about the state of the world and a correct theory of the interrelationships among the variables. Anticipations formed in this way will on the average tend to be correct (a statement whose simplicity conceals fundamental problems of interpretation, Friedman and Schwartz, 1982, pp. 556–7).

The rational expectations hypothesis has far-reaching implications for the validity of econometric models. Suppose a statistician were able to construct a model that predicted highly accurately for a past period all relevant variables; also, that a monetary rule could be devised that if used during the past period with that model could have achieved a particular objective – say keeping unemployment between 4 and 5 per cent. Suppose now that that policy rule were adopted for the future. It would be nearly certain that the model for which the rule was developed would no longer work. The economic equivalent of the Heisenberg indeterminacy principle would take over. The model was for an economy without that monetary rule. Put the rule into effect and it will alter rational expectations and hence behaviour. Even without putting the rule into effect, the model would very likely continue to work only so long as its existence could be kept secret because if market participants learned about it they would use it in forming their rational expectations and thereby falsify it to a greater or lesser extent. Little wonder that every major econometric model is always being sent back to the drawing board as experience confounds it, or that their producers have reacted so strongly to the theory of rational expectations.

The implication of one variant of the theory that has received the most attention and generated the most controversy is the so-called neutrality hypothesis about stabilization policy – in particular, about discretionary monetary policy directed at promoting economic stability. Correct rational expectations of economic agents will include correct anticipation of any systematic monetary policy; hence such policy will be allowed for by economic agents in determining their behaviour. Given further the natural rate hypothesis, it follows that any systematic monetary policy will affect the behaviour only of nominal magnitudes and not of such real magnitudes as output and employment. The authorities can affect the course of events only by ‘fooling’ the participants, that is, by acting in an unpredictable, ad hoc way. But, in general, such strictly ad hoc intervention will destabilize the economy, not stabilize it, serving simply to introduce another series of random shocks into the economy to which participants must adapt and which reduce their ability to form precise and accurate expectations.

This is a highly oversimplified account of the rational expectations hypothesis and its implications. All otherwise valid models of the economy will not be falsified by being known. All real effects of systematic and announced governmental policies will not be rendered nugatory. Serious problems have arisen in formulating the hypothesis in a logically satisfactory way, and in giving it empirical content,
especially in incorporating multi-valued rather than single-valued expectations and allowing for non-
independence of events over time. Research in this area is exploding; rapid progress and many changes
in received opinion can confidently be anticipated before the rational expectations revolution is fully
domesticated.

5 Empirical evidence

There is perhaps no empirical regularity among economic phenomena that is based on so much evidence
for so wide a range of circumstances as the connection between substantial changes in the quantity of
money and in the level of prices. There are few if any instances in which a substantial change in the
quantity of money per unit of output has occurred without a substantial change in the level of prices in
the same direction. Conversely, there are few if any instances in which a substantial change in the level
of prices has occurred without a substantial change in the quantity of money per unit of output in the
same direction. And instances in which prices and the quantity of money have moved together are
recorded for many centuries of history, for countries in every part of the globe, and for a wide diversity
of monetary arrangements.

The statistical connection itself, however, tells nothing about direction of influence, and this is the
question about which there has been the most controversy. A rise or fall in prices, occurring for
whatever reason, could produce a corresponding rise or fall in the quantity of money, so that the
monetary changes are a passive consequence. Alternatively, changes in the quantity of money could
produce changes in prices in the same direction, so that control of the quantity of money implies control
of prices. The second interpretation – that substantial changes in the quantity of money are both a
necessary and a sufficient condition for substantial changes in the general level of prices – is strongly
supported by the variety of monetary arrangements for which a connection between monetary and price
movements has been observed. But of course this interpretation does not exclude a reflex influence of
changes in prices on the quantity of money. The reflex influence is often important, almost always
complex, and, depending on the monetary arrangements, may be in either direction.

Evidence from specie standards

Until modern times, money was mostly metallic – copper, brass, silver, gold. The most notable changes
in its nominal quantity were produced by sweating and clipping, by governmental edicts changing the
nominal values attached to specified physical quantities of the metal, or by discoveries of new sources of
specie. Economic history is replete with examples of the first two and their coincidence with
corresponding changes in nominal prices (Cipolla, 1956; Feavearyear, 1931). The specie discoveries in
the New World in the 16th century are the most important example of the third. The association between
the resulting increase in the quantity of money and the price revolution of the 16th and 17th centuries
has been well documented (Hamilton, 1934).

Despite the much greater development of deposit money and paper money, the gold discoveries in
Australia and the United States in the 1840s were followed by substantial price rises in the 1850s
(Cairnes, 1873; Jevons, 1863). When growth of the gold stock slowed, and especially when country after
country shifted from silver to gold (Germany in 1871–3, the Latin Monetary Union in 1873, the
quantity theory of money: The New Palgrave Dictionary of Economics

Netherlands in 1875–6) or returned to gold (the United States in 1879), world prices in terms of gold fell slowly but fairly steadily for about three decades. New gold discoveries in the 1880s and 1890s, powerfully reinforced by improved methods of mining and refining, particularly commercially feasible methods of using the cyanide process to extract gold from low-grade ore, led to much more rapid growth of the world gold stock. Further, no additional important countries shifted to gold. As a result, world prices in terms of gold rose by 25 to 50 per cent from the mid-1890s to 1914 (Bordo and Schwartz, 1984).

Evidence from great inflations

Periods of great monetary disturbances provide the most dramatic evidence on the role of the quantity of money. The most striking such periods are the hyperinflations after World War I in Germany, Austria, and Russia, and after World War II in Hungary and Greece, and the rapid price rises, if not hyperinflations, in many South American and some other countries both before and after World War II. These 20th-century episodes have been studied more systematically than earlier ones. The studies demonstrate almost conclusively the critical role of changes in the quantity of money (Cagan, 1965; Meiselman, 1970; Sargent, 1982).

Substantial inflations following a period of relatively stable prices have often had their start in wartime, though recently they have become common under other circumstances. What is important is that something, generally the financing of extraordinary governmental expenditures, produces a more rapid growth of the quantity of money. Prices start to rise, but at a slower pace than the quantity of money, so that for a time the real quantity of money increases. The reason is twofold: first, it takes time for people to readjust their money balances; second, initially there is a general expectation that the rise in prices is temporary and will be followed by a decline. Such expectations make money a desirable form in which to hold assets, and therefore lead to an increase in desired money balances in real terms.

As prices continue to rise, expectations are revised. Holders of money come to expect prices to continue to rise, and reduce desired balances. They also take more active measures to eliminate the discrepancy between actual and desired balances. The result is that prices start to rise faster than the stock of money, and real balances start to decline (that is, velocity starts to rise). How far this process continues depends on the rate of rise in the quantity of money. If it remains fairly stable, real balances settle down at a level that is lower than the initial level but roughly constant – a constant expected rate of inflation implies a roughly constant level of desired real balances; in this case, prices ultimately rise at the same rate as the quantity of money. If the rate of money growth declines, inflation will follow suit, which will in turn lead to an increase in actual and desired real balances as people readjust their expectations; and conversely. Once the process is in full swing, changes in real balances follow with a lag changes in the rate of change of the stock of money. The lag reflects the fact that people apparently base their expectations of future rates of price change partly on an average of experience over the preceding several years, the period of averaging being shorter the more rapid the inflation.

In the extreme cases, those that have degenerated into hyperinflation and a complete breakdown of the medium of exchange, rates of price change have been so high and real balances have been driven down so low as to lead to the widespread introduction of substitute moneys, usually foreign currencies. At that point completely new monetary systems have had to be introduced.
A similar phenomenon has occurred when inflation has been effectively suppressed by price controls, so that there is a substantial gap between the prices that would prevail in the absence of controls and the legally permitted prices. This gap prevents money from functioning as an effective medium of exchange and also leads to the introduction of substitute moneys, sometimes rather bizarre ones like the cigarettes and cognac used in post-World War II Germany.

Other evidence

The past two decades have witnessed a literal flood of literature dealing with monetary phenomena. Expressed in broad terms, the literature has been of two overlapping types – qualitative and econometric – and has dealt with two overlapping sets of issues – static or long-term effects of monetary change and dynamic or cyclical effects.

Some broad findings are:
(1). For both long and short periods there is a consistent though not precise relation between the rate of growth of the quantity of money and the rate of growth of nominal income. If the quantity of money grows rapidly, so will nominal income, and conversely. This relation is much closer for long than for short periods.

Two recent econometric studies have tested the long-run effects using comparisons among countries for the post-World War II period. Lothian concludes his study for 20 countries for the period 1956–80:

In this paper I have examined three sets of hypotheses associated with the quantity theory of money: the classical neutrality proposition [i.e., changes in the nominal quantity of money do not affect real magnitudes in the long run], the monetary approach to exchange rates [i.e., changes in exchange rates between countries reflect primarily changes in money per unit of output in the several countries], and the Fisher equation [i.e., differences in sustained rates of inflation produce corresponding differences in nominal interest rates]. The data are completely consistent with the first two and moderately supportive of the last (1985, p. 835).

Duck concludes his study for 33 countries and the period 1962 to 1982 – which uses overlapping data but substantially different methods:

Its [the study's] findings suggest that (i) the real demand for money is reasonably well explained by a small number of variables, principally real income and interest rates; (ii) nominal income is closely related to the quantity of money, but is also related to the behaviour of other variables, principally interest rates; (iii) most changes in nominal income or its determinants are absorbed by price increases; (iv) even over a 20-year period some nominal income growth is to a significant degree absorbed by real output growth; (v) the evidence that expectations are rational is weak (1985, p. 33).

(2). These findings for the long run reflect a long-run real demand function for money involving, as Duck notes, a small number of variables, that is highly stable and very similar for different countries.
The elasticity of this function with respect to real income is close to unity, occasionally lower, generally higher, especially for countries that are growing rapidly and in which the scope of the money economy is expanding. The elasticity with respect to interest rates is, as expected, negative but relatively low in absolute value. The real quantity demanded is not affected by the price level (i.e., there is no ‘monetary illusion’) (Friedman and Schwartz, 1982; Laidler, 1985).

(3). Over short periods, the relation between growth in money and in nominal income is often concealed from the naked eye partly because the relation is less close for short than long periods but mostly because it takes time for changes in monetary growth to affect income, and how long it takes is itself variable. Today's income growth is not closely related to today's monetary growth; it depends on what has been happening to money in the past. What happens to money today affects what is going to happen to income in the future.

(4). For most major Western countries, a change in the rate of monetary growth produces a change in the rate of growth of nominal income about six to nine months later. This is an average that does not hold in every individual case. Sometimes the delay is longer, sometimes shorter. In particular, it tends to be shorter under conditions of high and highly variable rates of monetary growth and of inflation.

(5). In cyclical episodes the response of nominal income, allowing for the time delay, is greater in amplitude than the change in monetary growth, so that velocity tends to rise during the expansion phase of a business cycle and to fall during the contraction phase. This reaction appears to be partly a response to the pro-cyclical pattern of interest rates; partly to the linkage of desired cash balances to permanent rather than measured income.

(6). The changed rate of growth of nominal income typically shows up first in output and hardly at all in prices. If the rate of monetary growth increases or decreases, the rate of growth of nominal income and also of physical output tends to increase or decrease about six to nine months later, but the rate of price rise is affected very little.

(7). The effect on prices, like that on income and output, is distributed over time, but comes some 12 to 18 months later, so that the total delay between a change in monetary growth and a change in the rate of inflation averages something like two years. That is why it is a long row to hoe to stop an inflation that has been allowed to start. It cannot be stopped overnight.

(8). Even after allowance for the delayed effect of monetary growth, the relation is far from perfect. There's many a slip over short periods ‘twixt the monetary change and the income change.

(9). In the short run, which may be as long as three to ten years, monetary changes affect primarily output. Over decades, on the other hand, as already noted, the rate of monetary growth affects primarily prices. What happens to output depends on real factors: the enterprise, ingenuity and industry of the people; the extent of thrift; the structure of industry and government; the relations among nations, and so on. (In re points 3 to 9, Friedman and Schwartz, 1963a, 1963b; Friedman, 1961, 1977, 1984; Judd and Scadding, 1982.)

(10). One major finding has to do with severe depressions. There is strong evidence that a monetary crisis, involving a substantial decline in the quantity of money, is a necessary and sufficient condition for a major depression. Fluctuations in monetary growth are also systematically related to minor ups and downs in the economy, but do not play as dominant a role compared to other forces. As Friedman and Schwartz put it,

Changes in the money stock are ... a consequence as well as an independent source of
change in money income and prices, though, once they occur, they produce in their turn still further effects on income and prices. Mutual interaction, but with money rather clearly the senior partner in longer-run movements and in major cyclical movements, and more nearly an equal partner with money income and prices in shorter-run and milder movements – this is the generalization suggested by our evidence (1963b, p. 695; Friedman and Schwartz, 1963a; Cagan, 1965, pp. 296–8).

(11). A major unsettled issue is the short-run division of a change in nominal income between output and price. The division has varied widely over space and time and there exists no satisfactory theory that isolates the factors responsible for the variability (Gordon, 1980, 1981, 1982; Friedman and Schwartz, 1982, pp. 59–62).

(12). It follows from these propositions that inflation is always and everywhere a monetary phenomenon in the sense that it is and can be produced only by a more rapid increase in the quantity of money than in output. Many phenomena can produce temporary fluctuations in the rate of inflation, but they can have lasting effects only insofar as they affect the rate of monetary growth. However, there are many different possible reasons for monetary growth, including gold discoveries, financing of government spending, and financing of private spending. Hence, these propositions are only the beginning of an answer to the causes and cures for inflation. The deeper question is why excessive monetary growth occurs.

(13). Government spending may or may not be inflationary. It clearly will be inflationary if it is financed by creating money, that is, by printing currency or creating bank deposits. If it is financed by taxes or by borrowing from the public, the main effect is that the government spends the funds instead of the taxpayer or instead of the lender or instead of the person who would otherwise have borrowed the funds. Fiscal policy is extremely important in determining what fraction of total national income is spent by government and who bears the burden of that expenditure. It is also extremely important in determining monetary policy and, via that route, inflation. Essentially all major inflations, especially hyperinflations, have resulted from resort by governments to the printing press to finance their expenditures under conditions of great stress such as defeat in war or internal revolution, circumstances that have limited the ability of governments to acquire resources through explicit taxation.

(14). A change in monetary growth affects interest rates in one direction at first but in the opposite direction later on. More rapid monetary growth at first tends to lower interest rates. But later on, the resulting acceleration in spending and still later in inflation produces a rise in the demand for loans which tends to raise interest rates. In addition, higher inflation widens the difference between real and nominal interest rates. As both lenders and borrowers come to anticipate inflation, lenders demand, and borrowers are willing to offer, higher nominal rates to offset the anticipated inflation. That is why interest rates are highest in countries that have had the most rapid growth in the quantity of money and also in prices – countries like Brazil, Chile, Israel, South Korea. In the opposite direction, a slower rate of monetary growth at first raises interest rates but later on, as it decelerates spending and inflation, lowers interest rates. That is why interest rates are lowest in countries that have had the slowest rate of growth in the quantity of money – countries like Switzerland, Germany, and Japan.

(15). In the major Western countries, the link to gold and the resultant long-term predictability of the price level meant that until some time after World War II, interest rates behaved as if prices were expected to be stable and both inflation and deflation were unanticipated; the so-called Fisher effect was almost completely absent. Nominal returns on nominal assets were relatively stable; real returns
unstable, absorbing almost fully inflation and deflation.
(16). Beginning in the 1960s, and especially after the end of Bretton Woods in 1971, interest rates started to parallel rates of inflation. Nominal returns on nominal assets became more variable; real returns on nominal assets, less variable (Friedman and Schwartz, 1982, pp. 10–11).

6 Policy implications

On a very general level the implications of the quantity theory for economic policy are straightforward and clear. On a more precise and detailed level they are not. Acceptance of the quantity theory means that the quantity of money is a key variable in policies directed at controlling the level of prices or of nominal income. Inflation can be prevented if and only if the quantity of money per unit of output can be kept from increasing appreciably. Deflation can be prevented if and only if the quantity of money per unit of output can be kept from decreasing appreciably. This implication is by no means trivial. Monetary authorities have more frequently than not taken conditions in the credit market – rates of interest, availability of loans, and so on – as criteria of policy and have paid little or no attention to the quantity of money per se. The emphasis on credit as opposed to the quantity of money accounts both for the great contraction in the United States from 1929 to 1933, when the Federal Reserve System allowed the stock of money to decline by one-third, and for many of the post-World War II inflations. The quantity theory has no such clear implication, even on this general level, about policies concerned with the growth of real income. Both inflation and deflation have proved consistent with growth, stagnation, or decline.

Passing from these general and vague statements to specific prescriptions for policy is difficult. It is tempting to conclude from the close average relation between changes in the quantity of money and in money income that control over the quantity of money can be used as a precision instrument for offsetting other forces making for instability in money income. Unfortunately the loose relation between money and income over short periods, the long and variable lag between changes in the quantity of money and other variables, and the often conflicting objectives of policy-makers precludes precise offsetting control.

An international specie standard leaves only limited scope for an independent monetary policy. Over any substantial period, the quantity of money is determined by the balance of payments. Capital movements plus time delays in the transmission of monetary and other impulses leave some leeway, which may be more or less extensive, depending on the importance of foreign transactions for a country and the sluggishness of response. As a result, monetary policy under an effective international specie standard has consisted primarily of banking policy, directed towards avoiding or relieving banking and liquidity crises (Bagehot, 1873).

Until 1971, departures from an international specie standard, at least by major countries, took place infrequently and only at times of crisis. Surveying such episodes, Fisher concluded in 1911 that ‘irredeemable paper money has almost invariably proved a curse to the country employing it’ (1911, p. 131), a generalization that has applied equally to most of the period since, certainly up to 1971, and that explains why such episodes were generally transitory.

The declining importance of the international specie standard and its final termination in 1971 have changed the situation drastically. ‘Irredeemable paper money’ is no longer an expedient grasped at in
times of crisis; it is the normal state of affairs in countries at peace, facing no domestic crises, political or economic, and with governments fully capable of obtaining massive resources through explicit taxes. This is an unprecedented situation. We are in unexplored terrain.

As Keynes pointed out in 1923, monetary authorities cannot serve two masters: as he put it, ‘we cannot keep both our own price level and our exchanges stable. And we are compelled to choose’ (p. 126).

Experience since has converted his dilemma into a trilemma. In principle, monetary authorities can achieve any two of the following three objectives: control of exchange rates, control of the price level, freedom from exchange controls. In practice, it has in fact proved impossible to achieve the first two by accepting exchange controls. Such controls have proved extremely costly and ultimately ineffective. The Bretton Woods system was ultimately wrecked on this trilemma. The attempts by many countries to pursue an independent monetary policy came into conflict with the attempt to maintain pegged exchange rates, leading to the imposition of exchange controls, repeated monetary crises, accompanied by large, discontinuous changes in exchange rates, and ultimately to the abandonment of the system in 1971.

Since then, most countries have had no formal commitment about exchange rates, which have been free to fluctuate and have fluctuated widely. Nonetheless, Keynes's dilemma is still alive and well. Monetary authorities have tried to influence the exchange rates of their currency and, at the same time, achieve internal objectives. The result has been what has been described as a system of managed floating.

One recent strand of policy discussions has consisted of attempts to devise a substitute for the Bretton Woods arrangements that would somehow combine the virtues of exchange rate stability with internal monetary stability. For example, one proposal, by McKinnon (1984), is for the USA, Germany, and Japan to fix exchange rates among their currencies and set a joint target for the rate of increase of the total quantity of money (or high-powered money) issued by the three countries together. So far, no such proposal has gained wide support among either economists or a wider public.

A different strand of policy discussions has been concerned with the instruments, targets, and objectives of monetary authorities. One element of the quantity theory approach that has had considerable influence is emphasis on the quantity of money as the appropriate intermediate target for monetary policy. Most major countries now (1985) follow the practice of announcing in advance their targets for monetary growth. That is so for the USA, Great Britain, Germany, Japan, Switzerland, and many others. The record of achievement of the announced targets varies greatly – from excellent to terrible. Recently, a considerable number of economists have favoured the use of nominal income (usually nominal gross national product) as the intermediate target. The common feature is the quantity theory emphasis on nominal magnitudes.

A more abstract strand of policy discussions has been concerned with the optimum quantity of money: what rate or pattern of monetary growth would in principle promote most effectively the long-run efficiency of the economic system – meaning by that a Pareto welfare optimum. This issue turns out to be closely related to a number of others, in particular the optimum behaviour of the price level; the optimum rate of interest; the optimum stock of capital, and the optimum structure of capital (Friedman, 1969, pp. 1–50).

One widely accepted answer is based on the observation that no real resource cost need be incurred in increasing the real quantity of money since that can be done by reducing the price level. The implication is that the optimum quantity of money is that at which the marginal benefit from increasing the real quantity is also zero. Various arrangements are possible that will achieve such an objective, of which perhaps the simplest, if money pays no interest, is a pattern of monetary growth involving a decline in
the price level at a rate equal to the real interest rate (Mussa, 1977; Ihori, 1985).
This answer, despite its great theoretical interest, has had little practical consequence. Short-run
considerations have understandably been given precedence to such a highly abstract long-run
proposition.
Finally, there has been a literal explosion of discussion of the basic structure of the monetary system.
One component derives from the belief that Fisher's generalization about irredeemable paper money will
continue to hold for the present world fiat money system and that we are headed for a world monetary
collapse ending in hyperinflation unless a specie (gold) standard is promptly restored. In the United
States, this monetary belief was powerful enough to lead Congress to establish a Commission on the
Role of Gold. In its final report, ‘the Commission concludes that, under present circumstances, restoring
a gold standard does not appear to be a fruitful method for dealing with the continuing problem of
inflation. … We favour no change in the flexible exchange rate system’ (Commission, 1982, vol. 1, pp.
17, 20). The testimony before the Commission revealed that agreement on a ‘gold standard’ concealed
wide differences in the precise meaning of the phrase, varying from a system in which money consisted
of full-bodied gold or warehouse receipts for gold to one in which the monetary authorities were
instructed to regard the price of gold as one factor affecting their policy.
A very different component of the discussion has to do with possible alternatives to gold as a long-term
anchor to the price level. This include proposals for subjecting monetary authorities to more specific
legislative or constitutional guidelines, varying from guidelines dealing with their objectives (price
stability, rate of growth of nominal income, real interest rate, etc.) to guidelines specifying a specific rate
of growth in money or high-powered money. Perhaps the most widely discussed proposal along this line
is the proposal for imposing on the authorities the obligation to achieve a constant rate of growth in a
specified monetary aggregate (Friedman, 1960, pp. 92–5; Commission, 1982, vol. 1, p. 17). Other
proposals include freezing the stock of base money and eliminating discretionary monetary policy, and
denationalizing money entirely, leaving it to the private market and a free banking system (Friedman,
Finally, a still more radical series of proposals is that the unit of account be separated from the medium
of exchange function, in the belief that financial innovation will establish an efficient payment system
dispensing entirely with the use of cash. The specific proposals are highly sophisticated and complex,
and have been sharply criticized. So far, their value has been primarily as a stimulus to a deeper analysis
of the meaning and role of money. (For the proposals, see Black, 1970; Fama, 1980; Hall, 1982a, 1982b;
Greenfield and Yeager, 1983; for the criticisms, see White, 1984b; McCallum, 1985).
One thing is certain: the quantity theory of money will continue to generate agreement, controversy,
repudiation, and scientific analysis, and will continue to play a role in government policy during the next
century as it has for the past three.

**How to cite this article**

A real function $f$ defined on a convex subset $C$ of a linear space $E$ is said to be quasi-concave if

$$x, y \in C, t \in [0, 1] \Rightarrow f(tx + (1-t)y) \geq \min [f(x), f(y)].$$

(1)

A function $g$ is said to be quasi-convex if $-g$ is quasi-concave. Concave functions are quasi-concave, convex functions are quasi-convex.

For all $\lambda \in \mathbb{R}$, let $S(\lambda) = \{x : x \in C, f(x) \geq \lambda\}$. These sets are termed as the upper level sets of $f$. Upper level sets play an essential role in quasi-concavity. In particular, an alternative and useful way of characterizing quasi-concavity is to say that a function $f$ is quasi-concave if all its upper level sets are convex.

Like concave functions, quasi-concave functions enjoy nice properties: the set of maximizing points is convex, the infimum of a family of quasi-concave functions is quasi-concave, if $f$ is quasi-concave and $k$ is a real non-decreasing function on $\mathbb{R}$ then $k \circ f$ is quasi-concave. But, in contrast, a quasi-concave function is not necessarily continuous on the interior of its domain and the sum of quasi-concave functions is not quasi-concave in general.

Quasi-concavity was pioneered by De Finetti (1949), Fenchel (1953), Arrow and Enthoven (1961), Mangasarian (1965). It occurs in consumer theory where, under reasonable assumptions, a consumer's preferences can be represented by a quasi-concave utility function. In producer theory, production functions can also be reasonably assumed to be quasi-concave.

Characterizations of quasi-concave differentiable functions
For the sake of simplicity, we assume hereafter that $E$ is the $n$-dimensional space $\mathbb{R}^n$ and $C$ is an open convex set of $\mathbb{R}^n$. Assume that $f$ is differentiable on $C$, then $f$ is quasi-concave on $C$ iff

$$x, y \in C, f(x) \leq f(y) \Rightarrow (y - x)^\top \nabla f(x) \geq 0.$$  \hspace{1cm} (2)

Because quasi-concavity is often concerned with maximization problems, it would be suitable for $f$ to achieve its maximum at each $x$ so that $\nabla f(x) = 0$, but this is not so. A slight change of (2) leads to the following definition: a differentiable function $f$ defined on the open convex set $C$ is said to be pseudoconcave if

$$x, y \in C, f(x) < f(y) \Rightarrow (y - x)^\top \nabla f(x) > 0.$$  \hspace{1cm} (3)

Pseudoconcave functions are quasi-concave and concave functions are pseudoconcave. Actually, pseudoconcave functions are those quasi-concave functions which achieve their maximum at each point so that $\nabla f(x) = 0$.

Now, assume that $f$ is twice differentiable on $C$. Then $f$ is pseudoconcave iff

(a) $x \in C, v^\top \nabla f(x) = 0 \Rightarrow v^\top \nabla^2 f(x)v \leq 0$,

and

(b) if $x \in C, \nabla f(x) = 0$. 

then $f$ achieves its maximum at $x$. Similarly, $f$ is quasi-concave iff (a) holds and (b′) if $\nabla f(x) = 0$ then for all $h \in \mathbb{R}^n$ the function $t \mapsto f(x + th)$ is quasi-concave. 

Condition (a) can be formulated alternatively in terms of the bordered hessian of the function.

**Duality**
Assume that $f$ is continuous and quasi-concave on the closed convex subset $C$ of $\mathbb{R}^n$, define

$$F(p, \lambda) = \inf \{ px : x \in C, \; f(x) \geq \lambda \},$$

and

$$G(p, r) = \sup \{ f(x) : x \in C, \; px \leq r \}.$$ 

Then

$$f(x) = \inf_{\lambda} \{ G(p, \lambda) : x \in C \} = \inf_{\lambda} \sup_{p} \{ \lambda : F(p, \lambda) \leq px \}.$$ 

Thus, $f$ can be generated from either $F$ or $G$. The functions $F$ and $G$ each have a useful economic interpretation. Assume that $C$ is the set of available commodities, $p$ is the vector of commodity prices and the consumer's preferences are given by the utility functions $f$. Then $F(p, \lambda)$ is the minimal cost to be paid by the consumer to get a value of utility greater than or equal to $\lambda$ and $G(p, r)$ is the maximal value of utility that he can get for expenditure $r$. The function $p \rightarrow G(p, 1)$ is sometimes called the indirect utility function (Diewert, 1981, Crouzeix, 1983).

### Concavifiability

If a consumer's preferences are represented by a continuous utility function $u$, then $f = k \circ u$ when $k$ is a real continuous increasing function on $\mathbb{R}$ is also a continuous utility function that represents these preferences; and all utility functions are of this kind. In many economic problems, it is extremely useful to know if there exists a concave utility function, but this is not true in general. The problem was initiated by De Finetti (1949) and Fenchel (1953), a recent reference is Kannai (1981). Dual functions are extremely useful here, thanks to the following characterization to concave functions: a continuous quasi-concave function $f$ is concave iff for all $p$ the function $\lambda \rightarrow F(p, \lambda)$ is convex or alternatively iff for all $p$ the function $r \rightarrow G(p, r)$ is concave.

If preferences can be represented by a concave utility function, then they admit a concave utility function $u$ such that for any other concave utility function $v$ there exists a real increasing concave function $k$ such that $v = k \circ u$. This function is called (Debreu, 1976) a least concave utility. Least concave utility functions are useful in the context of decision making under uncertainty.
Additivity

The sum of quasi-concave functions is not quasi-concave, even when each are separable. Assume that the set $C$ of commodities and a consumer's utility function have the following form

$$C = C_1 \times C_2 \times \ldots \times C_p, u(x_1, x_2, \ldots, x_p) = u_1(x_1) + u_2(x_2) + \ldots + u_p(x_p)x_i C_i.$$

Assume that $u$ is quasi-concave on $C$ and that the functions $u_i$ are not, constant. Then all functions $u_i$ are concave except perhaps one which is concavifiable (Debreu and Koopmans, 1982; Crouzeix and Lindberg, 1986). Quasi-concavity and additivity cannot be brought together without problems.

Bibliography

An important and up to date discussion of quasiconcavity and related topics with their applications for economics as well as for mathematical programming can be found in Generalized Concavity in Optimization and Economics, a collection of papers by several authors edited by S. Schaible and W.T. Ziemba (New York: Academic Press, 1981).

How to cite this article

Quesnay was born at Mère, Seine-et-Oise. He came from a family of humble origin, the eighth of 13 children. His father Nicholas was a small merchant, and the family also had a piece of land; thanks to these two activities they were comfortably off. François Quesnay had no systematic education; at ten he could not even read, but early on he developed an interest in medicine. In 1711 he went to Paris for formal training in medicine and surgery. There he read Descartes and Malebranche, and the latter's *Recherche de la vérité* had a profound impact on the young Quesnay. In 1717 he married Jeanne-Cathérine Dauphin, who gave him four children, two of whom survived. He began his career at Mantes, a small town not far from Paris, and in the 1720s and 1730s he made his reputation as a surgeon, particularly with respect to bleeding techniques. In 1736 he published *l'Essai physique sur l'oeconomie animale*, his first major work. Quesnay was deeply involved in the polemic between surgeons and physicians which took place in the 1740s. At that time he was also physician to the Duke of Villeroy and through him and the Comtesse d'Estrades he met Madame de Pompadour, Louis XV's favourite. Quesnay became her private physician and established himself at Versailles. In 1752 he saved the Dauphin from smallpox, and in gratitude the King granted Quesnay a noble title and a sum of money which he used to buy an estate at Beauvoir in the Minervois for his son Blaise-Guillaume. In 1750 and 1751 Quesnay published the last of his medical works and became a member of the French Académie des Sciences and of the Royal Society in London.

In the early 1750s Quesnay became interested in economics and in particular in agricultural matters. He was in contact with many important thinkers including D'Alembert and Diderot, Buffon, Helveticus and Condillac. He was induced to contribute to the *Encyclopédie*, for which he wrote two articles: *Evidence*, which appeared in Volume VI in January 1756, and *Fonction de l’âme* which was never published there since the *Encyclopédie* had been condemned by the government. Quesnay preferred to publish his articles anonymously. In 1756 he also published his article *Fermiers*, while in 1757 he wrote *Grains* for the seventh volume of the *Encyclopédie*. These two articles are Quesnay's first economic writings. He wrote three more pieces for the *Encyclopédie: Hommes, Impôts* and *Intérêt de l’argent*. But after the attack on the King's life at Damiens, the enemies of the *encyclopédistes* managed to obtain the repeal of its royal privilege and Quesnay, like Turgot, withdrew his three articles from publication. The third appeared 1766 in the *Journal de l'agriculture; Hommes* was published in 1908 by Etienne Bauer and *Impôts* appeared in 1902 thanks to Gustave Schelle.

In 1757 Quesnay met Victor Riquetti, Marquis de Mirabeau (see Hecht, 1958, p. 256). Mirabeau came from an old noble family and supported the view that the main cause of national wealth was the number of people. Quesnay convinced him that agriculture was much more important than population, because it produced the commodities which were necessary for men's subsistence, Mirabeau became the most faithful propagator of Quesnay's ideas, and this episode marks the beginning of the Physiocratic school.

In 1758 Quesnay published the *Questions intéressantes sur la population, l'agriculture et le commerce* and at the end of the same year he wrote the first edition of the *Tableau économique*. In the first half of 1759 this was followed by two other editions. The *Tableau*, printed in a limited edition at Versailles, was presented to Louis XV, who was apparently greatly impressed by Quesnay's strange schemes. Quesnay was also engaged in supervising Mirabeau's writings, which were designed to illustrate the rather obscure *Tableau*, and, more generally, to spread Physiocratic doctrine. Mirabeau's *Thèorie de l'impôt*, the result of this close collaboration, appeared at the end of 1760. The reactions to this work and Mirabeau's consequent imprisonment convinced the two that it was better to work silently. Almost three years elapsed before Mirabeau published the *Philosophie rurale* in three volumes, in November 1763. There can be no doubt that Quesnay revised the entire work and wrote some chapters (Meek, 1962, p. 38).

The year 1763 marked the beginning of a period of active intervention by the Physiocrats in economic debates. Quesnay found new followers: Du Pont de Nemours, Mercier de La Rivière, Baudeau and Turgot, a good friend of the Physiocrats. Quesnay contributed to the development of Physiocratic ideas with articles which appeared in the *Journal de l'agriculture* and after 1767 in the *Ephémérides du citoyen*. In these latter works he discusses the sterility of industry and trade and the productivity of agriculture. The most famous of Quesnay's articles appeared in the *Journal de l'agriculture* of 1766 with the title *Analyse de la formule arithmétique du Tableau économique*, in which he presented a simplified version of the *Tableau*. This new *Tableau* was also used by Quesnay in the *Premier problèmes économique*, which appeared in the same periodical. Between 1767 and 1768 Quesnay published several articles in the *Ephémérides*: *Despotisme de la Chine, Analyse du gouvernement des Incas du Pérou*. In 1767 he also wrote the *Second problème économique* for the *Physiocratie*, a collection of his main writings prepared by Du Pont de Nemours. Between 1764 and 1767 Quesnay was the true master of the Physiocrats; new disciples joined the group and his ideas found some application in French economic policy. By 1768 the cultural and political impact of Physiocracy began to decline and Quesnay's theory was bitterly criticized. He spent his last years studying geometry, notwithstanding the advice of his friends and the fact that he was ridiculed by some of his enemies (Hecht, 1958, pp. 278–9). Quesnay died in December 1774 at Grand-Commun, a place not far away from Versailles, a few months after the death of Louis XV.

Quesnay was directly responsible for all the main aspects of Physiocratic thought and, in particular, for its economic analysis. Some Physiocrats contributed to the development and the explanation of particular aspects of the doctrine, but Quesnay was the one who put forward the most innovative concepts and the general framework in which they were inserted. The analysis of Quesnay's economic writings presents a peculiar problem; he did not write a single major text as a summary of his entire thought, but instead wrote small pieces,
articles for the *Encyclopédie* and for the periodicals which were controlled by the Physiocrats (Vaggi, 1987, ch. 2, part 2). Thus usually he discussed only one economic issue at the time. This methodology is quite clear in his first works, where he presents the major features of Physiocratic economics, such as the role of farmers and capital in agriculture; the importance of commercial policies and free trade, the question of the fiscal system. But the same method of analysis characterizes the writings of the period 1766–8, where Quesnay had to defend his theory from the criticisms of many important thinkers of the time.

Correct interpretation of Quesnay's economics must take all his writings into account and cannot be limited to the analysis of the most famous. There are clear logical links between Quesnay's different works. On several occasions he himself indicates where these connections are to be found. Indeed, despite his method of writing on one specific issue at a time, the analytical structure of Quesnay's economics is clearly characterized by systematic cause-and-effect relationships. It is an important feature of Quesnay's thought that he explained economic facts and individual actions on the basis of a view of society as a general interrelated system. Therefore, he believed that all aspects of social life were linked together and that it was possible to find the underlying causal relationships, which were nothing else than the outcome of natural laws.

The role and significance of the *Tableau économique* within Quesnay's economics needs further clarification since this is the most important and famous work of Physiocracy and has often been regarded as a summary of the entire corpus of Physiocratic economics (Herlitz, 1961, p. 134; Fox-Genovese, 1976, p. 258). The *Tableau* has also been regarded as the analytical synthesis of the logical structure of Quesnay's economics, or at least as its most relevant aspect. In any case, all too often knowledge of Physiocracy is limited to the *Tableau économique*. However, the various types of *Tableau* elaborated by Quesnay between 1758 and 1766 cannot be analysed in isolation; by themselves they do not provide an exhaustive presentation of Physiocratic economics. An accurate understanding of Quesnay's theory and of the *Tableau* itself requires the study of his other writings. Some of these are particularly significant because they supplement the *Tableau*. For instance, Quesnay's first economic articles, *Hommes, Fermiers et Grains*, were written just before the *Tableau* and can be regarded as the basis on which the analysis of the *Tableau* is carried out. Quesnay's economics must be regarded as a mosaic, where all the inlays are necessary, though the *Tableau* is the central part of the picture.

The *Tableau économique* is one of those works in the history of economics which have often been regarded as an anticipation of modern theories. The *Tableau* has been considered a first rough presentation of Keynes's multiplier and as a sort of general equilibrium system of a Walrasian type (Schumpeter, 1954, p. 242). For others, the *Tableau* is an input–output table (Phillips, 1955, pp. 137–8). Because of the *Tableau*, Quesnay has been regarded as an early econometrician. The *Tableau* has also been interpreted as the first classical system of price determination, thus anticipating Marx's reproduction schemes and Sraffa's price system (Cartelier, 1976, p. 57).

There are two main reasons why the *Tableau* impressed Quesnay's contemporaries and later interpreters so much. The first is the 'obscurity' of the schemes, the second is the fact that there is not just one *Tableau* but many. The history of the *Tableau économique* begins at the end of 1758 with the first manuscript edition of the work, which included a table and a few pages of comments entitled *Remarques sur les variations de la distribution des revenus annuels d'une nation* comprising 22 remarks. The second edition, the first to be printed, followed a few months later (Kuczynski and Meek, 1972, pp. xvi–xviii). This *Tableau* is similar to the earlier one, but is now followed by 23 remarks which are very similar to the *Maximes générales* at the end of the 1757 article *Grains* and are entitled *Extrait des oeconomies royales de M. de Sully*. The third edition appeared in 1759, but then it disappeared for more than two centuries. It was rediscovered and published in 1965 by Marguerite Kuczynski (Kuczynski and Meek, 1972, pp. xxv ff.). The third edition of the *Tableau* is made up of the table itself plus an enlarged version of the *Extrait* with 24 remarks and long footnotes and a new text called *Explications du Tableau économique*. Clearly, Quesnay must have felt that more explanations of the scheme were required. All three editions present the original type of *Tableau*, which is characterized by three columns whose figures are related to each other by means of descending lines crossing the table. This is the so called zig-zag version of the *Tableau*.

A similar *Tableau* can also be found in the sixth part of Mirabeau's, *L'ami des hommes*, published in 1760 (Mirabeau, 1758–60, vol. 2, pp. 118 ff.). The two side-columns give the annual advances of the productive sector – agriculture – and of the sterile sector – industry. The central column presents the revenue of the landlords and the way in which it is spent. In the first row of each column Quesnay writes the value of each of the three magnitudes at the beginning of the process of circulation of commodities and revenue. These figures are characterized by some peculiar ratios; the revenue and the annual advances of the productive class have the same value; these annual advances are twice as large as those of the sterile class. All the zig-zag *Tableaux* and most of the following ones have these ratios. Among the figures in the first row, particularly important is the value assumed by revenue, which is usually called the ‘basis’ of the *Tableau* because it determines all the other figures. The first zig-zag started with a revenue of 400 *livres*, while the next two editions had a revenue of 600 *livres*. The *Tableau* shows the effects of the expenditure of revenue on the other two classes. Quesnay generally assumes that landlords spend half of their revenue in the purchase of agricultural products and half in the purchase of manufactures (Elitis, 1984, pp. 20 ff.). According to Quesnay, all classes comply their pattern of consumption to this 50–50 division. From the second row onwards, the *Tableau* describes the exchanges which take place between the two sectors of the economy, agriculture and industry. The workers of each of the two sectors spends half of the money received by the landlords in purchasing goods of the other class, while the other half is spent inside the same class. The *Tableau* registers the exchanges of money and commodities which take place between the classes, but it abstracts from the circulation of commodities between people of the same class.

According to Quesnay there is a major difference between the productive and the sterile class, only the former giving rise to a net product over costs. In the *Tableau* this is expressed as horizontal lines which connect the first column to the revenue column. Therefore the *Tableau* is a synthetic way of describing the circulation of money and commodities in relation to both the expenditure of revenue and the technical and social relationships between the two main sectors of the economy. In the *Tableau* there is a concise description of the way in which the process of circulation of revenue must guarantee the reproduction of the annual advances which have been consumed during the previous year by the two sectors. The *Tableau*'s iterative process is completed when the peasants and the artisans have no money left to spend, in particular when the value of their receipts is equal to that of the annual
advances which have been used up. In fact, as a result of the sequence of exchanges, all three classes receive 600 livres, which is the sum of the figures from the second row to the bottom of each column. The productive and sterile classes have recovered their annual advances, and the landlords have got back their revenue. Hence the process of circulation of commodities depends upon the technical requirements of production, which are described by the reconstruction of the means of production in each sector, and by a particular rule in the distribution of income, which states that the revenue accrues entirely to the owners of land. At the end of the process of circulation there are all the conditions needed to start a new productive cycle.

The Tableau also serves as a representation, and perhaps to Quesnay's mind also as a proof, that a surplus exists only in agriculture. The first two columns from the right show that agriculture reproduces its means of production plus a revenue for the landlords, and, for this reason, is regarded as a productive sector. Some problems arise with respect to the third column. The overall production of the sterile class is 600 livres and its annual advances are only 300 livres. However, Quesnay says that industrial activities are unproductive because they do not contribute to the landlord's revenue. But it is clear from the figures of the Tableau that at the end of the process of circulation the sterile class has 300 livres in excess of its advances. This derives from the assumption that each class spends half of its revenue in the purchase of the products of the other sector. In order to reconcile this result with the opinion that only agriculture yields a surplus, it is necessary to resort to some further considerations. Some commentators have pointed out that the Tableau does not include one particular act of exchange: the purchase by the sterile class of an amount of agricultural products whose value is 300 livres (Meek, 1962, pp. 275–7).

If this act of exchange is included in the picture the sterile class has no surplus left. Alternatively it has been said that in the Tableau the sterile class sells part of its output abroad in exchange for agricultural goods (Meek, 1962, p. 283; Gilibert, 1977, pp. 42–5). In any case industry does not seem to be as sterile as the Physiocrats maintain.

A few years after the first version, Quesnay slightly modified the Tableau économique. In the 1764 Philosophie rurale there are several tableaux, some of them are still of the zig-zag type but others have evolved into a new scheme which is called Précis des résultats de la distribution représentée dans le Tableau, that is to say a summary of the Tableau itself (Mirabeau, 1764, vol. 1, p. 327). In the Précis Quesnay changed the ‘basis’ of the Tableau: the revenue and the annual advances of the productive class are now 2,000 livres, the advances of the sterile class are still half this value. Above all there is no iterative process with the descending lines. Instead, Quesnay gives the final results of the circulation of commodities and of revenue. Only a few exchanges are indicated in the scheme and the first and last row are almost exactly alike; they show that the process of reproduction of revenue and both sectors' advances has been completed. The only difference between the first and last row is the annual output of industry, 2,000 livres, and its annual advances, 1,000 livres. Thus at first sight it would seem that the value of industrial output still exceeds that of its inputs. But there is an important difference between the zig-zag and the Précis; in this latter type of Tableau the advances of industry are entirely made up of agricultural commodities and do not include manufactures. Moreover, even though this does not appear in the diagram Quesnay now quite clearly states in the accompanying text that the artisans purchase 1,000 livres of raw materials to transform them into manufactured goods. Therefore industry now uses 2,000 livres of primary products to produce an output of equal value. There is no net product left.

Because of this new act of exchange between industry and agriculture, the output of the primary sector must rise in order to account for these 1,000 livres of raw materials which go to industry. At the same time, farmers must buy 1,000 livres of manufactured goods as a repayment for the raw materials which they sell to the artisans. In the Précis the farmers receive this 1,000 livres of industrial products as ‘interests’ on their original advances (Meek, 1962, pp. 278–9). The third edition of the zig-zag already included these interests, but it was not at all clear whether these products came from industry, or, more probably from agriculture itself (Eltis, 1984, p. 26). The existence of these 1,000 livres of industrial products which are purchased by the farmers is another reason why the Tableau économique cannot be regarded as a proof of the sterility of industry. The cultivation of land requires industrial goods, and this prevents agriculture from being considered as a self-sufficient sector. Industry produces part of the means of production of the primary sector, and therefore contributes, albeit indirectly, to the production of the net product.

The Précis is an intermediate step in the evolution of the Tableau économique, whose final version is the so called Analyse de la formule arithmétique du Tableau économique of 1766. This is also the most well-known version of the Tableau and it has been often confused with the original 1758 zig-zag. There are many similarities between the Précis and the Analyse. Both schemes give a concise representation of all transactions; and the advances of the sterile class are entirely made up of agricultural goods. But in the Analyse Quesnay explicitly includes the purchase of manufactured goods by farmers, as their ‘interests’. Moreover, the Analyse is a very well-written article, which condenses both the scheme and the texts needed to explain it in a few pages, while in the Philosophie rurale, the Précis and its explanations run into many pages. In the Analyse, Quesnay gives the final explanation of the technicalities of the Tableau. The formula has become the true Tableau économique; this is the version which has been converted into an input–output table (Phillips, 1955), and which has been extensively analysed by modern economists (Tsuru, 1942).

The Tableau of the formula type works in the following way. Landlords receive two ‘milliards’ of livres from the farmers as their annual rent and spend this revenue half in the purchase of foodstuffs and half in that of manufactured goods. Artisans buy raw materials and necessaries of life from agriculture. Now the cultivators have the two milliards, one of which is used to buy the manufactured products which are necessary to maintain the initial value of the fixed capital of cultivation. The artisans need the necessities of life and one milliard goes back to the productive class. In the end one sees that industry has produced two milliards of products using two milliards of primary commodities as input. The total reproduction of agriculture is five milliards because the cultivators sell three milliards, one to the landlords and two to the artisans, but they also keep two milliards of output for themselves, to be used as raw materials and necessaries for future production. For Quesnay five ‘milliards’ is also the level of output in the whole economy, because the two milliards of manufactured goods are nothing more than reshaping of the same primary commodities which have been used as inputs. Of course this is a flaw in Quesnay’s analysis; following his criterion, agricultural output should only be two milliards, because the overall means of production employed in agriculture amount to three milliards. Alternatively, the gross national product should include industrial output too, and its value would be seven milliards. This inconsistency in Quesnay’s economics derives from his belief that industry cannot produce a surplus, a view by no means backed up by the figures of the formula-type Tableau, where it is quite clear that industrial products are used as inputs in agriculture (Meek, 1962, p. 154).

The Analyse has one further merit; from the very beginning Quesnay explicitly states all the hypotheses which characterize the economic system depicted in the Tableau (Meek, 1962, p. 298). The same assumptions can be found in Quesnay’s comments and explanations in the other Tableaux, but in the Analyse they are grouped together in a few pages (Meek, 1962, pp. 151–3).

The main features of the economy described in the Tableau are as follows. First, in agriculture there are the best methods of cultivation, with large capital stock and high productivity, so that the annual advances can produce a surplus of the same size. A second assumption relates to the fiscal system; all duties and excises which exist in France ought to be substituted by a single tax on agricultural surplus. Third, free competition rules both in domestic and foreign trade in agricultural products, thus there is a bon prix for primary commodities and cultivation is a profitable activity. A fourth hypothesis relates to the landlords, who have made all the necessary ground advances, such as drainage, transport facilities etc. We could, of course, add other assumptions which clearly appear in the articles which precede the 1758 zig-zag. The State guarantees the ownership rights for all citizens and not only for landlords. In particular, the State protects the capital invested by cultivators as original advances (Kuczynski and Meek, 1972, pp. 7–8). Another assumption states that the landlords spend their revenue half in the purchase of foodstuffs and half in manufactures (p. 12). This hypothesis implies that in the Tableau the revenue is entirely consumed and is neither hoarded nor used to make financial investments, which are considered a sterile form of activity (pp. 4, 13).

It goes without saying that the society examined in the Tableau has little in common with the France of Louis XV. It is an ideal country where all reforms and economic measures advocated by the Physiocrats have already been implemented. This economic system is quite similar to the natural order of society. According to Quesnay, England is the country which most resembles this ideal society, and this explains why England is so prosperous and wealthy (see INED, 1958, vol. 2, pp. 474, 533). The Tableau is a normative benchmark for the government; it describes the circulation and distribution of the social product and surplus, and it shows the final effects of these exchanges on future production. The first zig-zag version of the Tableau (Table 1 above) and the Analyse are the most coherent descriptions of this ideal situation. In these works Quesnay highlights the normal and regular working conditions of an economic system which is a mirror of the natural order of society. From this point of view one could describe these Tableaux as types of equilibrium conditions, but no further similarity can be found with general equilibrium analysis (Meek, 1962, p. 292). But Quesnay is not interested in the conditions of logical consistency between all economic variables. He pinpoints some specific causal relationships which are regarded as particularly important for the development of the economy. Thus, even though the Tableau presents the mutual relationships between several aspects of the economy, Quesnay stresses the relationships of cause and effect affecting the increase in national wealth. In several of his writings Quesnay uses the Tableau to study what happens when government regulations or the behaviour of landlords does not conform to this natural order. For instance, in the 1767 article Second problème économique he analyses the consequences of several forms of indirect taxation, and shows that these taxes are ultimately damaging (Meek, 1962, pp. 186 ff.). In an earlier article, a formula Tableau had been used to illustrate the beneficial effects of an increase in the prices of agricultural products (Meek, 1962, p. 168). The Tableau is also used to examine what happens when the landlords modify their pattern of consumption. The proprietors can modify the level of surplus through their decisions to spend more or less revenue on the purchase of agricultural products (Mirabeau, 1764, vol. 3, pp. 33–53). Quesnay uses the zig-zag version and the Précis to show that the higher the proportion of revenue which is spent in the consumption of primary goods the higher will be the surplus. From these articles, it emerges that Quesnay was always primarily concerned with the effects of different economic measures on gross and net output. Far from regarding the Tableau as a static scheme, Quesnay uses it to show the government ways of speeding up economic growth.

Quesnay, François (1694–1774): The New Palgrave Dictionary of Economics

The social product is surplus; its distribution is not linked to technological factors, but customs and laws ascribe it to the landowners, including the Sovereign and the Church. This destination of output depends on the technical conditions which must be fulfilled to guarantee the self-sustaining character of the economic system. The other share of the social product replenishes the means of production which have been consumed. As the Net Product clearly states the three milliards of returns to the cultivators depend on the methods of production.

For Quesnay, productivity increases are strictly dependent on the amount of means of production available and hence on the original advances of the cultivators. The main way of increasing national wealth was by securing the existence of a large agricultural sector with wealthy farmers. While the notion of surplus can be detected in the economic analysis of some authors who preceded Physiocracy – for instance, Petty’s *A Treatise of Taxes and Contributions* (1662, pp. 30–31). But it is only with Quesnay that net product is defined precisely as the difference between the social product and its means of production. Here too the 1766 *Analyse* provides the most satisfactory description of the relationships between these magnitudes.

Quesnay believes that only agriculture can generate a net product; this view is taken for granted in the various *Tableaux* but is widely discussed in the *Dialogue sur les travaux des artisans*. This is highly significant; it testifies that Quesnay was not satisfied simply with the accounting definition of surplus, but also attempted to explain its origin and then the factors which might lead to its increase. The net product is the new wealth produced in each productive cycle. The main problem in Quesnay’s analysis is of the nature of wealth and the ways in which it can be created. From this point of view Quesnay clearly set out the main economic issues which were subsequently examined by Adam Smith in the *Wealth of Nations*.

The concept of net product characterizes Quesnay’s entire economic analysis and not just the *Tableau*. For instance in the 1757 article *Grains* he analyses the distribution of surplus between social classes; the Physiocratic theory of taxation is also built on the distinction between surplus and means of production. The notion of net product was the main analytical tool used by Quesnay to examine all the other important economic features in society. The idea of a single tax on rent is closely related to the determination of surplus. Rent is landlords’ revenue, the landlords receiving the highest share of the net product of cultivation.

Agriculture is the only productive sector, and taxation of surplus is the only way of avoiding damage to future production. The stock of productive capital must not be reduced by taxes, otherwise it would be impossible to maintain the same level of activity as the previous year. Hence rent is the only taxable magnitude. Quesnay’s theory of circulation and distribution of income is also founded on the distinction between gross and net product. Part of the social product must circulate in such a way to replenish the means of production which have been consumed. As the *Tableau* clearly states the three milliards of returns to the cultivators depend on the methods of production. Hence the destination of output depends on the technical conditions which must be fulfilled to guarantee the self-sustaining character of the economic system. The other share of the social product is surplus; its distribution is not linked to technological factors, but customs and laws ascribe it to the landowners, including the Sovereign and the Church.
The merchants dominate the process of circulation of commodities because they are wealthy enough to stock the products of agriculture and wait for the best moments for their sale. Their gains must be measured by current prices, when a product leaves the first producer there is no further increase in wealth, hence the merchants' gains are a burden for the whole economy. As a result, prices is the merchant's gain, whose activity damages both the consumers and the producers, because it depresses the 'current price' and raises the retail one (p. 947). National wealth, which is the price paid by the merchant to the farmer. Besides this wholesale price, there is also the vendeur prix de l'acheteur, which governs the exchange between the merchant and the consumer. This distinction is important because it allows Quesnay to analyze the characteristics of the domestic and foreign trade of agricultural products. There is the prix du product, which makes it suitable for the satisfaction of specific needs and desires. This is a sort of prerequisite which a good must have in order to be exchanged; there must be somebody willing to buy it. But the price of a commodity is independent of the utility derived from its consumption; use and exchange values are regulated by different laws (INED, 1958, vol. 2, p. 865).

Quesnay took the exchange ratios between the products of industry and those of agriculture as given, and fixed. Other authors maintain that prices exist in Physiocratic economics and that the agricultural output and its means of production are heterogeneous goods. However, they believe that the exchange ratios between the products of industry and those of agriculture are fixed, and that prices exist only in the sense of the current price of a particular commodity. Quesnay's concept of profit is the notion which relates the three concepts of surplus, investments and capital accumulation. Moreover, Quesnay considers profits as the necessary stimulus to induce the cultivators to increase their advances; they act in consideration of profitability (INED, 1958, vol. 2, p. 807).

A careful reading of Quesnay's writings shows that he was very concerned about prices and changes in prices. This problem is not dealt with in the Tableau, but price theory is a necessary element in Quesnay's theory of the growth of national wealth. Grains and Hommes are the articles where Quesnay gave the clearest exposition of his price theory. Like many other economists before him, Quesnay separates the use value of commodities from their exchange value. In Grains he refers to a precise physical characteristic of a good which makes it suitable for the satisfaction of specific needs and desires. This is a sort of prerequisite which a good must have in order to be exchanged; there must be somebody willing to buy it. But the price of a commodity is independent of the utility derived from its consumption; use and exchange values are regulated by different laws (INED, 1958, vol. 2, p. 526). Quesnay singles out many concepts of price, which he uses to analyse the characteristics of the domestic and foreign trade of agricultural products. There is the prix du vendeur, which is the price paid by the merchant to the farmer. Besides this wholesale price, there is also the prix de l'acheteur, which governs the exchange between the merchant and the consumer. The retail price is always higher than the prix du vendeur which can also be called the 'current price' (INED, 1958, vol. 2, p. 752). The difference between the two prices is the merchant's gain, whose activity damages both the consumers and the producers, because it depresses the 'current price' and raises the retail one (p. 947). National wealth must be measured by current prices, when a product leaves the first producer there is no further increase in wealth, hence the merchants' gains are a burden for the whole economy. The merchants dominate the process of circulation of commodities because they are wealthy enough to stock the products of agriculture and wait for the best moments for their sale.
purchases and their sales. On the contrary the farmers must always sell the entire output, because they are too poor to wait (INED, 1958, vol. 2, p. 985). Moreover, merchants usually enjoy exclusive rights, granted by the government, which give them a monopolistic position on certain markets. Free competition in domestic and foreign trade reduces merchants' profits and the difference between the retail and current price greatly diminishes; as was happening in England, where laissez-faire had already been implemented. The main purpose of free trade is that of raising the profitability of cultivation, without damaging the standard of living of consumers. This can be achieved thanks to the squeeze on merchants' profits. The merchants do not appear in the Tableau, even though they are mentioned in the accompanying texts. But here too one must remember that the Tableau describes an economy working according to natural laws, and free competition is one of the main features of natural order.

Quesnay was particularly interested in securing the free exportation of French corn. He believed that one of the main reasons for the backwardness of agriculture was the low level of the prices of its products. This fact made cultivation unprofitable, but domestic demand was not sufficient to raise these prices, because, on the whole, French consumers were too poor. In France there was lack of effective consumption (INED, 1958, vol. 2, p. 824), and Quesnay clearly separates the concept of effective demand, which is the demand of those who actually pay for a product, from the generic desire to consume more. A similar distinction was later to be found in Adam Smith's economics. Because of the lack of purchasing power at home it is necessary to allow the exportation of corn, so that the 'current price' can rise. Quesnay's arguments in favour of free trade are that it will strictly sustain the effective demand and the price of primary commodities, in order to achieve a higher profitability for cultivation. The 'current price' of corn was a bon prix in England, where the farmers were stimulated to reinvest their profits. It is the existence of a bon prix which guarantees profits to farmers and new investments in agriculture. Therefore the main aim of commercial policy is to restrict the gains made by merchants and increase the profits made by farmers. Landlords will also benefit from these measures, because they will receive higher rents when their leases are renewed and, above all, rent will rise because capital accumulation increases the productivity of agriculture and its surplus (Mirabeau, 1764, vol. 2, pp. 366 ff.).

Another important concept of price in Physiocratic economics is that of prix fondamental. This price is the sum of the overall expenses incurred by the farmer in the production of one unit of corn, it includes wages, raw materials and the repayment of wear and tear on fixed capital. These three items make up the technical cost of cultivation but they do not exhaust the expenses of production. To go on farming, the farmer must also fulfill his obligations towards the landlords by paying them the rent. This payment was a necessary social condition of production in 18th-century France, and was the way in which the king and the aristocracy received part of the fruits of their land. The fundamental price is the price level below which the farmer makes a loss and stops farming the soil (INED, 1958, vol. 2, p. 529; Du Pont de Nemours, 1764, p. 18). This notion defines the lower limit of the current price, whose variations must be above the unit cost of production. If free competition rules in the process of circulation of commodities there is a positive difference between the current price and the fundamental one, which is the profit of the cultivator. In Quesnay's economics, theories of distribution and of value are closely related. Profits depend upon the technical conditions of cultivation, which influence the fundamental price, but are also affected by changes in the current price, which depend upon the state of the market for agricultural products and, in particular, on their effective demand.

Price theory is the final piece required to complete the picture of Quesnay's economic analysis of the ways of achieving growth and development. There are several steps to reach the well-ordered economy described in the Tableau. The implementation of free trade stimulates the effective demand for primary commodities and raises their current prices. This leads to higher profits for the farmers. If the fiscal system is based on the single tax on rent profits can be entirely reinvested in agriculture, thus raising the advances of cultivation. Capital accumulation in the productive sector of the economy leads to productivity increases. The surplus rises both in absolute terms and as a share of the social product; more and more resources can be reinvested in production, and national wealth grows. Quesnay develops a theory of growth which is based on the notion of surplus, but he used other concepts to complete it. In this mosaic the Tableau was also designed to single out the ultimate effects of this process of growth, to show the nobles that they would receive the benefits of Physiocratic economic policy.

Quesnay's main contributions to economic science are certainly the concept of surplus and the Tableau économique. But one must also stress that for the first time there is a complete and relatively coherent theory designed to answer the most important problems of economic systems on the basis of a general analysis of all their main features. All economic issues are examined with the help of precise concepts and on the basis of a theoretical approach. Economic policy proposals derive from theoretical speculation, and are part of a single general model of the growth of national wealth. Finally all the aspects of Quesnay's economics are linked, in one way or the other, to his notion of surplus, which provides a sort of unifying thread to his thought. Quesnay can quite appropriately be regarded as the founder of that approach to the analysis of economic events which is called theory of surplus.

R&D races

Jennifer F. Reinganum
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article summarizes recent theoretical and empirical research on R&D races. Two canonical models of an R&D race are described, and their implications for the investment behaviour of incumbent leaders and potential entrants are discussed. Empirical studies that attempt to verify or refute the implied patterns of investment are also discussed.

Keywords

R&D races; innovation; invention; patents

Article

Models of R&D races, in which the winning firm receives all (or most) of the reward, rely on two basic paradigms. In a deterministic race (Barzel, 1968), invention requires a known investment; the value of the patent grows over time and a potential inventor decides when to invest. Equivalently, the investment required to invent by time \( T \) is an increasing function \( C(T) \). Let \( \Pi e^{-rT} \) denote the present value of a patent on an invention completed at \( T \) (assume that \( \Pi \) is also the social value). Among non-cooperative firms, the potential for pre-emption causes the date of invention to advance until \( \Pi e^{-rT_0} - C(T_0) = 0 \). Since \( T_0 \) precedes the socially optimal invention time, racing results in over-investment in R&D. This model assumes that only the winning firm actually invests its ‘bid’.

The first fully game-theoretic model of a stochastic race is presented by Loury (1979); for a decision-theoretic antecedent, see Kamien and Schwartz (1974). Firm \( i \)'s lump-sum investment \( x_i \) yields a random invention date \( \tau_i \) with \( \Pr\{\tau_i \leq t\} = 1 - \exp\{-h(x_i)t\} \); thus, firm \( i \)'s hazard rate is \( h(x_i) \). The firm is also uncertain about the success date of its rival, which invests simultaneously. If firm \( i \) succeeds at \( t \), the chance that it is the first inventor is \( 1 - \exp\{-h(x_j)t\} \). Firm \( i \)'s expected profit is \( \Pi h(x_i) / [r + h(x_j) + h(x_i)] - x_i \). Lee and Wilde (1980) re-specified investment as a rate per unit of...
time. The resulting payoff for firm $i$ is $\frac{[\Pi h(x_i) - x_i]}{[r + h(x_i) + h(x_j)]}$. In both versions, racing leads to over-investment. Malueg and Tsutsui (1997) incorporate uncertainty about the hazard rate; as time passes without success, firms become increasingly pessimistic and reduce their rates of investment. Weeds (2002) combines aspects of the Barzel and the Loury models with the theory of real options. Two firms monitor the stochastic growth of the patent value and decide when to invest. The required investment is exogenous and lump-sum, and in exchange the firm receives an exponentially distributed time until success. Firms do not invest until certain threshold values of the patent are reached. In one type of equilibrium, a firm invests only because it fears pre-emption by its rival; the rival invests strictly later, and firms' profits are equal (and low). In the other type, firms engage in mutual forbearance, and invest only at the optimal joint-investment time. Profits are equal (and high); this equilibrium involves strategic delay in investment relative to the social optimum.

**Action-reaction or increasing dominance within a race**

Although the exponential specification is gratifyingly simple, conditional on no success to date, the race looks exactly as it did at the beginning. If a firm could accumulate a ‘lead’, would a firm that is ‘ahead’ invest more than its rival? If so, then the race exhibits ‘increasing dominance’; if not, then the lagging firm tends to catch up and the race exhibits ‘action-reaction’ (Vickers, 1986). Of course, a lagging firm can invest more than the leader and still be less likely to win the race. Harris and Vickers (1985) provide a deterministic racing model in which two firms alternate in making investments until one reaches the finish line. If one firm is sufficiently close to winning (in a region called its ‘safety zone’), the other drops out and the leader proceeds unchallenged. In the limit (as the rate of alternation goes to infinity), the winning firm invests just enough to reach its safety zone, whereupon its rival drops out and the firm continues, at a more leisurely pace, to the finish line. If the firms are otherwise symmetric, the firm that begins the race closer to the finish line will win. Doraszelski (2003) provides a stochastic model wherein a firm's hazard rate depends on its accumulated stock of knowledge; its investment rate can vary with its own progress and that of its rival. Firm $i$'s hazard rate is $h_i' = \lambda x_i + \gamma z_i \psi$, where $\lambda$, $\gamma$, $\psi$ are positive constants, $x_i$ is firm $i$'s rate of investment and $z_i$ is firm $i$'s accumulated stock of knowledge. Since $x_i$ and $z_i$ are substitutes in the hazard rate, a firm's equilibrium investment rate is decreasing in its knowledge stock, and the leading firm invests less than its rival; in this sense, the model exhibits action-reaction. Nevertheless, if one of the firms begins with a larger stock of knowledge, it remains ex ante more likely to win the race. Progress can also be modelled by assuming that multiple stages must be completed in order to invent. Grossman and Shapiro (1987) provide a two-firm two-stage model; each stage involves a race of the Lee and Wilde form (see also Harris and Vickers, 1987, for a somewhat different model). They find that the leader invests more than the follower, but both increase their investments should the follower catch up. Thus, this literature suggests that a firm that is ‘ahead’ in the race is more likely to win.

**Action-reaction or increasing dominance across multiple races**

With a sequence of innovations, we ask whether a firm that is ‘ahead’ in the market (the one with a
larger market share) would invest more in the next race than its rival. That is, will the industry's evolution exhibit increasing dominance (persistence of the market leader) or action-reaction (turnover of the market leader)? Consider an incumbent monopolist, with current flow profits of $R$, racing with a potential entrant for a cost-reducing invention. If the incumbent wins, it receives the present value of monopoly profits with the new technology, $\Pi$. If the entrant wins, the two firms compete in Cournot–Nash fashion, receiving the present value of profits $\pi_I$ and $\pi_E$ for the incumbent and entrant, respectively. A drastic invention is one for which $\pi_I = 0$ and $\pi_E = \Pi$ (that is, the incumbent can no longer compete when the entrant invents); if the innovation is non-drastic, then $\Pi > \pi_I + \pi_E$.

Gilbert and Newbery (1982) show that an incumbent monopolist would bid strictly more than a potential entrant for a non-drastic invention (and an equal amount for a drastic one); this is referred to as the 'efficiency effect'. Suppose an entrant would invent at time $TE$, where $\Pi > \pi_I + \pi_E$; that is, if the invention is non-drastic. Vickers (1986) analyses a sequence of such races and finds that a sufficient condition for increasing dominance (action-reaction) is that each invention is sufficiently drastic (incremental).

Reinganum (1983) adapts the Lee and Wilde model to this scenario; the firms' payoffs are now $[\Pi h(x_I) + \pi_I h(x_E) + R - x_I] / [r + h(x_E) + h(x_I)]$ for the incumbent and $[\pi_E h(x_E) - x_E] / [r + h(x_E) + h(x_I)]$ for the entrant. In equilibrium, the incumbent invests at a higher rate than the entrant, at least for innovations that are sufficiently drastic. This is a consequence of Arrow's (1962) 'replacement effect' (originally identified for a single inventor): the incumbent has a lower incentive to advance the invention date (and replace himself) than does the entrant. Reinganum (1985) extends this result to a sequence of drastic inventions. Thus, the stochastic model suggests action-reaction, at least for sufficiently drastic inventions; however, increasing dominance can occur for sufficiently incremental inventions.

**Empirical studies**

Apparently, both models admit both investment patterns, but for opposite types (drastic versus incremental) of inventions. Since the nature of the inventive process (deterministic or stochastic) and that of the invention itself (drastic or incremental) are likely to vary across inventions and industries, the empirical pattern is also likely to vary. For a single race, the deterministic model has stark empirical implications: no real racing occurs beyond a possible initial burst. While the stochastic model implies investment by multiple firms, it is difficult to determine whether strategic effects play a significant role. The key indicator of strategic behaviour – the best response function – is an out-of-equilibrium phenomenon. Including rival investment in a regression explaining own investment should add no further information beyond that provided by the other explanatory variables. Using program-level data on pharmaceuticals R&D, Cockburn and Henderson (1994) detect no evidence of racing, but do find significant spillovers in output, calling into question the 'winner-take-all' assumption. They conclude that investment is driven by heterogeneous firm ability, adjustment costs, and technological opportunity.
In a laboratory experiment based on Harris and Vickers's (1987) multi-stage model, Zizzo (2002) finds that (contrary to predictions) the investments of leaders and followers are not significantly different. Lerner (1997) considers a sequence of races in the disk drive industry, with each invention serving to increase storage capacity. Firms that follow the technological leaders are most likely to introduce improved drives and to make the greatest technological progress. His data also show that leaders in a given year had about a 40 per cent chance of remaining leaders the next year. Czarnitzki and Kraft (2004) employ data from a survey of German manufacturing firms, which also asks firms to state their motives in conducting R&D; thus they distinguish between (self-designated) potential entrants and incumbents. R&D expenditures per dollar of sales are significantly higher for potential entrants (but the sales normalization confounds effects). The results of the latter two studies seem consistent with the stochastic model for relatively drastic inventions, but also with the deterministic model for relatively incremental inventions.

Abstract

This article reviews the recent theoretical and empirical literature in economics that aims to establish empirically whether police engage in racially biased law enforcement practices. It considers different objective functions that might be posited for police officers and the tests that can be derived under these objectives. Assuming a hit rate objective function leads to a simple, empirically implementable outcomes-based test that can potentially explain an observed empirical regularity in many police datasets whereby disparities in hit rates tend to be very small despite large disparities in search rates.

Keywords

deterrence; omitted-variable bias; optimal auditing; racial profiling; rational expectations; statistical discrimination

Article

In recent years, numerous lawsuits have been brought against US city police departments alleging racially biased law enforcement practices. (Many of these lawsuits were initiated by the American Civil Liberties Union or the US Department of Justice.) As a result of closer scrutiny, many police departments now routinely collect administrative data on the characteristics of the individuals that they subject to stops and searches and on the outcomes of these encounters. It is a common finding in these data that African–Americans and Hispanic drivers are searched at a higher rate than white drivers. For example, African Americans represented 63 per cent of motorists searched by Maryland state police on the I-95 highway between 1995 and 1999, but only 18 per cent of motorists on the road. A refined version of this benchmark test for discrimination estimates the probability of being searched as a function of race and other observable characteristics thought to be related to criminal propensity. If race has explanatory power in the regression, then this is taken as evidence of discrimination (see, for example, Donohue, 1999).
One drawback of benchmark tests is that they require data on the full set of characteristics that a police officer uses in deciding whether to search a motorist. (A training manual issued by the Illinois State Police highlights some indicators of criminal activity, such as tinted windows and leased vehicles.) If some characteristics are missing, then race could have explanatory power due to omitted-variable bias. Alternatively, if race is found to be insignificant, it is still possible that police target individuals with certain characteristics, because of their correlation with race and not because of their use in predicting criminality. Additionally, benchmark tests can reveal only whether a disparity exists and not the motivation for the disparity. In many racial profiling investigations, it is clear that a disparity exists and the key concern is whether the higher rates of stop and search among certain groups can be justified as an optimal monitoring response to higher rates of criminality. The judicial standpoint on racial profiling is not clear-cut. The dominant view is that race or ethnicity can be used as a factor in determining the likelihood that a person has committed a crime, so long as its use relates to law enforcement and is not a pretext for racial harassment. However, a significant dissenting view argues that race should not be used as a criterion, except in very limited cases, as when the race of a perpetrator of a particular crime is known; see Kennedy, 1997. For detailed discussions of the legality of racial profiling practices, see, for example, Kennedy, 1997; Harcourt, 2004; Gross and Barnes, 2002; Persico and Castleman, 2005.

This article reviews the recent theoretical and empirical literature in economics that aims to empirically establish from data on stops and searches of motor vehicles whether police behaviour is indicative of racial bias. The early literature on crime (for example, Becker, 1968; Stigler, 1970) examined citizens' incentives to misbehave under an exogenous probability of being monitored. The more recent literature assumes that police and citizens behave strategically, with police deciding on optimal search strategies and citizens deciding whether to break the law, given police search strategies. Unlike the criminology literature, where it is sometimes assumed that police can make citizens believe that the monitoring probabilities are higher than in reality (for example, Sherman, 1990), the economics literature typically assumes rational expectations. (The recent economic literature is also related to the literature on optimal auditing, which mainly deals with income reporting and tax evasion; see Reinganum and Wilde, 1986; Border and Sobel, 1987; Scotchmer, 1987.) An advance in the literature is a better understanding of the assumptions on police and motorist behaviour required to justify alternative tests for discrimination.

We next describe the frameworks that have been developed in the recent economic literature and the tests that have been derived from using these frameworks. Subsequently, we present a brief summary of some of the empirical evidence from police stop/search data-sets.

**Theoretical models of police–motorist behaviour**

Two leading paradigms are put forward in the economic literature. One assumes that police officers operate in a decentralized way, allocating their search activities so as to catch as many criminals as possible. In the context of motor vehicle searches, the goal is to maximize the number of successful searches given a cost of search, where a successful search is defined as one that uncovers some contraband. As noted in Persico (2002), an objective function that maximizes successful searches, or so-called hit rates, will in general not minimize the aggregate crime rate, because it does not give enough weight to the deterrent effects of policing; that is, it does not reward preventing a crime from being committed.
Nevertheless, in light of principal–agent problems in policing, a hit rate objective may still be a reasonable approximation to police behaviour. It is likely difficult for a police chief to verify that individual officers engage in search activities that deter crime, because the amount of crime deterred is usually not observed. How many criminals an officer apprehends is observed, providing a rationale for rewarding officers on that basis. A model where police act as independent agents trying to catch criminals can be viewed as a second-best objective that a police chief might reasonably adopt.

The other modelling framework examined in the literature is one in which a centralized police chief allocates resources so as to minimize the overall crime rate. We describe the theoretical and empirical results derived using these two different modelling frameworks, with particular emphasis on devising tests for racial bias.

Models of hit rate maximization

The model of KPT (2001)

Knowles, Persico and Todd (2001) (KPT) develop a model of police–motorist behaviour that they use to study the implications of racial bias for equilibrium search outcomes. In the model, police officers decide which vehicles to subject to searches, and motorists decide whether to break the law by carrying contraband, such as drugs or illegal weapons, taking into account the probability of being searched. In the absence of racial bias, each officer pursues a monitoring strategy that maximizes the number of successful search outcomes. Racial bias is introduced as a preference parameter that reduces the perceived cost of searching vehicles of black or Hispanic drivers relative to white drivers, which can lead to over-searching of these groups. An equilibrium implication of racially biased monitoring, shown in KPT and discussed further below, is that the hit rate (the rate at which contraband is seized) should be lower for the groups subject to bias. (The general idea that tastes for discrimination lead to lower profits for discriminators originated with Becker, 1957. For further discussion of such tests in policing contexts, see Ayres, 2002.)

Let $r \in \{A, W\}$ denote the race of the motorist (African-American or white), assumed to be observable by the police officer. (We assume two groups here, but the analysis extends straightforwardly to more groups.) Let $c$ denote all characteristics other than race that are potentially used by the officer in the decision to search cars, which may be unobserved or only partially observed by the econometrician. For expositional ease, treat $c$ as a one-dimensional variable (results extend to the multidimensional case), and denote the distribution of $c$ in the white and African-American populations by $F(c|W)$ and $F(c|A)$. It is assumed that an individual police officer allocates search efforts so as to maximize the number of convictions minus a cost of searching cars. Each officer can choose to search motorists of any type $(c, r)$ at a marginal cost of $t_r$. Normalize the benefit of each arrest to equal 1, so that the cost is scaled as a fraction of the benefit (assume $t_A, t_W \in (0, 1)$). In deciding whether to carry contraband, motorists consider the probability of being searched and the penalty if they were to be caught. If they do not carry, their payoff is zero whether or not the car is searched. If they carry, their payoff is $v(c, r) + x$ if not searched and $-j(c, r)$ if searched, where both $j(c, r)$ and $v(c, r)$ are positive. $x$ represents private information of the motorists about their own benefit from carrying contraband. $j(c, r)$ can be interpreted as the cost of being convicted. (If there were discrimination in the court system leading to higher...
penalties for minority drivers, this could be thought of as operating through \( j(c,r) \). KPT do not test for this type of discrimination.

Denote by \( \gamma(c,r) \) the probability that the police officer searches a motorist of type \( c,r \). The expected payoff to a motorist from carrying contraband is

\[
\gamma(c, r) \left[ - j(c, r) \right] + \left[ 1 - \gamma(c, r) \right] \left[ v(c, r) + x \right].
\]

(1)

Given \( \gamma(c, r) \), the motorist chooses to carry contraband if this expression is greater than zero. Motorists with a high realized value of \( x \) strictly prefer to carry drugs and those with small values strictly prefer not to carry. However, police search strategies can be conditioned only on \( c \) and \( r \), because \( x \) is not directly observed by the police. Let \( G \) denote the event that the motorist searched is found guilty of carrying contraband, and denote the probability that a motorist of type \( c,r \) carries contraband by \( P(G|c, r) \). (We do not allow for the possibility of false accusation by police or planting of evidence, as considered in Donohue and Levitt, 2001.)

Assume that the police officer decides on the search probability \( \gamma(c,r) \) (the probability of searching each motorist of type \( c,r \)) to maximize the number of successful searches, net of costs. He or she solves

\[
\max_{\gamma(c, r), \gamma(c, A)} \sum_{r = W, A} \int [P(G|c, r) - t_r] \gamma(c, r) f(c|r) dc,
\]

taking as given \( P(G|c, r) \). The term \( P(G|c, r) - t_r \) represents the expected profit from searching a motorist of type \( c,r \). If \( P(G|c, r) - t_r > 0 \) then optimizing behaviour implies \( \gamma(c, r) = 1 \), that is, always search motorists of type \( c \) and \( r \). If \( P(G|c, r) = t_r \) then the police officer is willing to randomize over whether or not to search type \( c,r \).

KPT introduce racial bias into this framework as a difference in the perceived cost of searching motorists of different races. That is, a police officer is said to be biased against race \( A \) (or to have a taste for discrimination) if \( t_A < t_W \). If a police officer has no taste for discrimination and yet chooses search probabilities that differ by race, then the equilibrium is said to exhibit statistical discrimination. Statistical discrimination is motivated out of efficiency considerations and not out of racial bias. (Statistical discrimination is used here in the same sense as in Arrow, 1973.)

KPT (2001) study the equilibrium implications of this model for the case where officers are homogeneous in their costs of search and motorists are heterogeneous in the benefits they derive from carrying contraband. The model implies the following equilibrium conditions, for all \( c \)
\[ P^*(G|c, A) = t_A, P^*(G|c, W) = t_W \]

...where * denotes equilibrium values.

Suppose that \( t_A = t_W = t \) (that is, police officers are not biased). Then, for all \( c \), guilt probabilities at equilibrium must be equal across races:

\[ P^*(G|c, A) = t = P^*(G|c, W). \]

If guilt probabilities were not equalized, a police officer could do better by reallocating searches towards the group with the higher hit rate.

An important observation is that equalization of hit rates does not imply equalization of search rates. The equilibrium search intensity may be higher for African-Americans even in the absence of racial bias. This happens if \( \frac{\mathcal{V}(c, W)}{[\mathcal{V}(c, W) + \gamma(c, A)]} < \frac{\mathcal{V}(c, A)}{[\mathcal{V}(c, A) + \gamma(c, A)]} \). That is, if the expected value of carrying drugs is higher or the cost of being convicted lower for black motorists, then the search rate on that group would have to be higher in order to equalize the guilt probability to that of whites.

Equation (3) is the basis for the outcomes-based test proposed in KPT as a test for racial bias (a test for \( t_W \neq t_A \)). An advantage of the test is that it is implementable even in the absence of complete data on \( c \) and on \( \gamma \). It suffices to have data on the frequency of guilt by race conditional on being searched,

\[ D(r) = \int P^*(G|c, r) \frac{\gamma^*(c, r) f(c|r)}{\int \gamma^*(s, r) f(s|r) ds} dc. \]

Using (3) to substitute for \( P(G|c,r) \) we get the implication

\[ D(W) = t = D(A), \]

which KPT empirically test. In the model, there is nothing special about the characteristic ‘race’. The analogue of (4) should hold for any observed characteristic on which police can condition their search.
decision. Thus, the model has the strong implication that the guilty rates should be equal for any set of observed conditioning variables, such as age, gender, or type of car.

The assumption that motorists respond to the probability of being searched is key to obtaining a test for bias that is applicable even without data on all the characteristics that police use in the search decision. If motorists did not react to the probability of being searched, testing for prejudice would require data on \( c \).

To see why, consider a model where the probability that a motorist with characteristic \( c \) and race \( r \) carries drugs does not depend on the actions of police, and the only optimizing agents are the police. Let \( \pi(c, r) \) denote the probability that a type \( c, r \) carries drugs and suppose that \( \pi(c, r) \) is increasing in \( c \).

Then, it is optimal for police officers to choose two cut-offs \( k_W \) and \( k_A \) and to search any motorist of race \( r \) with a \( c \) greater than \( k_r \). In the absence of prejudice, police will choose \( k_W \) and \( k_A \) so that the probability that types \( k_W, W \) and \( k_A, A \) are guilty equals the marginal cost \( t \) of searching motorists.

Without data on \( c \), one cannot empirically identify the marginal motorists and so cannot test the equilibrium implications of this model, in the absence of strong assumptions on the shape of \( \pi(c, r) \) and on the distribution of the unobservables. When \( \pi(c, r) \) is determined endogenously, the only equilibrium is for \( \pi(c, r) \) to equal \( t \) for all \( c \). Thus, allowing for endogenous response of motorists to the probability of being searched eliminates the problem of having to identify the marginal motorists.

A number of papers have explored extensions or variations of the KPT model. For example, Antonovics and Knight (2004) raise the concern that police heterogeneity is a potential threat to the validity of the outcomes-based tests, and they present evidence that police are more likely to search the vehicles of drivers of a different race. Persico and Todd (2006) generalize the KPT model to allow for police heterogeneity in costs of search and for the possibility that drivers can adapt some of their characteristics to reduce the probability of being monitored. (For example, if drivers with sports cars are subject to high monitoring rates, an individual might choose to drive a different type of car.) They show that the hit rate test is still valid under these extensions. Persico and Todd (2005) further extend the model to allow for imperfections in the monitoring technology, namely, that searches do not always uncover contraband. Even with varying detectability rates across groups, the hit rate test can still be justified as a test for racial bias. (The extensions are developed in an application of the model to monitoring of passengers at airports.)

Hernandez-Murillo and Knowles (2004) consider how to test for racial bias with aggregated data that is contaminated by observations on non-discretionary stops. The KPT model assumes that police searches are discretionary, whereas Hernandez-Murillo and Knowles analyse a data-set from Missouri that mixes discretionary and non-discretionary stops. They derive tests for racial bias (inspired by the nonparametric bounding approach of Horowitz and Manski, 1995) that are robust to the contamination.

Dharmapala and Ross (2004) extend the KPT model by relaxing the assumption that police can search any motorist. They impose a technological limitation on the search capacities of police, whereby police observe motorists with probability less than 1. In this case, there can be some motorists for whom the constraint leads them to carry contraband all the time. Police would like to search this group harder to equalize guilty rates, but cannot. In equilibrium, such motorists will be searched whenever police observe them. Dharmapala and Ross (2004) demonstrate that, if this type of motorist is distributed differently among racial/ethnic groups, then the hit rate test breaks down. They also consider the set of equilibria in a modified version of the KPT model in which there are offences of varying levels severity.
and motorists sort over the level of severity.

The model of Anwar and Fang (2006)

A limitation of the KPT model is that it assumes that police officers first see some motorist characteristics and then decide whether to search them. A more realistic assumption is that police see some information prior to the stop decision and then acquire more information from interacting with the motorist. Anwar and Fang (2006) develop a framework in which the officers' search decisions can depend on the additional information they acquire after the initial stop. They also allow for the possibility that police behaviour varies with the race of the police officer. For example, white police may be biased against minority drivers and minority police biased against white drivers. (Persico and Todd, 2004, also allow for police heterogeneity in the bias, but do not allow for the sign of the bias to differ for individual officers. That is, they do not allow for the possibility that some police may be biased while others may exhibit favouritism, which is the case considered in Anwar and Fang, 2006.)

The model of Anwar and Fang (2006) is in the spirit of statistical discrimination models (see, for example, Coate and Loury, 1993). It assumes that during the stop and prior to the search decision the police officer observes a noisy but informative signal about whether the driver carries contraband. The signal is informative in the sense that guilty drivers (those carrying illegal contraband) are more likely than innocent drivers to generate suspicious signals, such as nervousness in answering the police officer's questions. (It is assumed that the drivers themselves do not know at the time of deciding whether to carry contraband whether they will generate a signal, only the probability that they will generate one.) As in the KPT model, police officers are considered racially biased if their cost of search depends on the race of the motorist and the objective of officers is to maximize the number of successful searches.

Anwar and Fang (2006) develop two tests. The first is a test for whether police officers of different races use different search criteria when dealing with motorists of the same race, which would indicate police heterogeneity. The test is based on the observation that, if officers do not differ in search costs, then the search rates and success rates of different groups of officers should on average be the same. The second test they develop is a test for racial prejudice that can uncover whether at least one of the groups of officers (for example, white or minority officers) is searching in a racially biased manner, although it cannot distinguish which group is biased.

Models of crime minimization

The previous class of models assumed that individual officers adopt search strategies that maximize successful search rates, or so-called hit rates. As noted above, a hit rate objective function would be a reasonable approximation to police behaviour if officers are rewarded on the basis of criminals apprehended, something that is easily observed. As demonstrated in Persico (2002), however, the hit rate objective function does not minimize the aggregate crime rate.

An alternative modelling framework assumes that there is a centralized authority, a police chief, say, who can direct officers to focus their searches on particular subgroups. In such a model, the hit rate test fails as a test of the unbiasedness of the police chief, because, in the equilibrium of such a model, an
racial profiling: The New Palgrave Dictionary of Economics

unbiased police chief will allocate searches to equate the deterrence effect and not the hit rates across groups. Crime deterred is unobserved, making it difficult to test for whether the deterrence effect is being equalized across groups. While one could conceivably introduce racial bias in a crime minimization model in the same way as in the hit rate maximization models – as a difference in the costs of searching different types of motorists – there is currently no empirically implementable test for racial bias in such a model. (Eeckhout, Persico and Todd, 2003, study optimal monitoring strategies for police assuming that the objective is to minimize crime. They show that in some cases it can be optimal to randomly subject even identical motorists to different levels of monitoring. This could be considered random profiling, in that motorists are randomly divided into different groups and are subjected to different levels of monitoring.)

**Imposing a race-blind constraint on police behaviour**

Persico (2002) studies the effects of constraints on police behaviours, within a model where police maximize hit rates, but the assumed socially efficient objective is to minimize the aggregate crime rate. He shows that imposing a ‘race-blind’ constraint on police search behaviour does not necessarily entail any loss in efficiency and can sometimes increase efficiency. That is, not allowing police to condition their search probabilities on race can sometimes lead to a lower-cost way of achieving a given crime rate. This somewhat surprising result follows because search strategies that aim to maximize arrests do not take into account the deterrence value that arrests have on different groups. The incentive scheme that minimizes the crime rate would place a higher value on arresting motorists of the race that is more likely to be deterred by the prospect of being arrested.

To see how a fairness constraint can increase efficiency, suppose, for example, that whites were more numerous in the population and were also less likely than blacks to carry drugs at a given search rate. In the absence of any constraints on search behaviour, police would search blacks at a higher rate so as to equalize the hit rates across groups. Under a fairness constraint, however, the two groups are pooled and experience the same probability of being searched. In equilibrium, the overall carrying rate will remain the same as in the unconstrained equilibrium and will equal the cost of search. However, equalizing search rates by race leads to an increase in the black carrying rate, and an offsetting decrease in the white rate. If whites are deterred by a relatively small increase in the probability of search and they are more numerous in the population, then it is possible to achieve the same overall carrying rate at a lower search cost in the constrained equilibrium than in the unconstrained equilibrium. Persico (2002) finds that whether imposing a fairness constraint leads to an increase in efficiency (defined as a decrease in the crime rate for the same cost) crucially depends on the proportion of blacks in the population relative to the cost of search.

For further consideration of how to incorporate efficiency and equity considerations into an assessment of racial profiling as a public policy, see Durlauf (2005) and Risse and Zeckhauser (2004). Also, see Dominitz (2003) for discussion of the statistical relationship between various outcomes that could be considered when formulating public policy, such as search rates, find rates, thoroughness of search, rates of detention of the innocent, and rates of apprehension of the guilty.

**Empirical evidence**
As noted above, models that assume that police maximize hit rates and that motorists take into account the probability of being caught when deciding whether to break the law lead to simple procedures to test for racial bias. The KPT test compares hit rates across different groups of motorists, which can be performed using the type of data that is conventionally available.

Table 1 (reproduced from Persico and Todd, 2006) summarizes findings from 16 different city-level and state-level racial profiling studies/reports, in which the hit rates by race/ethnicity are reported. The table displays what appears to be an empirical regularity: there is not a large disparity in hit rates for black and white drivers, especially when compared with the disparity in search/stop rates. This regularity is puzzling in the context of a crime-minimizing police chief, but not in light of a simple hit rate maximization model, which offers a rationale for the equalization of hit rates across races, namely, (a) that police are allocating searches in a way that maximizes efficiency in catching criminals and (b) that police departments, on average, are not afflicted by widespread bias against African Americans. In Table 1, the hit rates for Hispanics are in many cases notably lower than that of whites or blacks, which is suggestive of bias against Hispanics. Whether in fact this is really the case can be ascertained only with more work on the police data-sets that are becoming available.

*A single hit rate is reported for all minorities.
Anwar and Fang (2006) apply their alternative test (not described here, for the sake of brevity) to a dataset on highway stops and searches collected by the Florida Highway Patrol. The data reveal search patterns that differ significantly by race of the officer. Despite the differences in search behaviour, however, the test does not reject the null hypothesis of no relative racial prejudice between black and white officers. (The authors advise caution in interpreting the results, as the test is informative only about relative racial bias and cannot rule out the possibility that all police – of both races – might be biased.)

Summary and conclusions

Recent advances in the economic literature have led to a better appreciation of the assumptions that underlie different approaches to testing for racial/ethnic bias in policing. Simple benchmark tests for discrimination only uncover whether a disparity exists; they do not reveal the motivation for the disparity, which plays a key role in racial profiling investigations. Assuming a hit rate objective function and strategic behaviour on the part of both police officers and motorists leads to a simple, empirically implementable outcomes-based test for racial bias. Such a model can potentially explain an observed empirical regularity in many police data-sets to the effect that there is little disparity in hit rates for black and white drivers, despite large disparities in search/stop rates. An alternative modelling framework is one in which a police chief allocates resources so as to minimize the aggregate crime rate. An implication of unbiased policing in this type of model is that the deterrence effect be equated across different groups of motorists, which is difficult to test empirically.

Even if an outcomes-based test concludes that racial disparities in search rates do not reflect racial bias, there is still the question of whether statistical discrimination is justified. Statistical discrimination may be considered unfair, because drivers experience different probabilities of being searched, depending on their race. An intriguing aspect of Persico's (2002) findings is that, when police are maximizing a second-best objective (hit rates), imposing a race-blind constraint can bring them closer to a first-best objective (minimizing overall crime). In practice, though, it may be difficult to ask police officers to simply ignore race in their decision-making. More race-neutral policing might instead be achieved by giving police differential rewards for hit rates on white and minority drivers. Designing optimal incentive schemes for achieving a particular objective is a current area of research.

Finally, the economic literature on racial profiling is relatively nascent, and there are many ways of extending existing models. For example, none of the existing models specifies how a police chief allocates police officers to patrol particular areas. For this reason, existing tests are usually applied to data on highway searches where selective allocation of officers to monitor certain populations is less of an issue. Also, existing theory has mainly been developed for discretionary stops, but a major proportion of police stops and searches are triggered by events that make a search of the vehicle mandatory.

Contemporary radical economics comprises a broad set of methodological approaches, including Marxian political economy, institutionalism, Post Keynesianism, analytical political economy, radical feminism and postmodernism. Unlike radical economics in the mid-1980s, radical thought today emphasizes conflict other than class conflict, policy-relevant analysis and incorporation of more mainstream methods into radical research. Nonetheless, despite substantial evolution, radical economics remains faithful to its original vision. Uniting the various approaches is a set of unchanged core principles, the three most salient of which are the importance of history, embeddedness of individual choice in an institutional environment, and the centrality of conflict to understanding capitalism.

Article
Contemporary radical economics comprises a broad set of methodological approaches, including Marxian political economy, institutionalism, Post Keynesianism, analytical political economy, radical feminism and postmodernism (see for example Pietrykowski, 2000; Colander, Holt and Rossiter, 2004; Dutt, 2005). This inclusive definition of radical economics differs in many respects from the radical
economics of the mid-1980s. Today radical thought emphasizes conflict outside of class conflict, policy-relevant analysis and incorporation of more mainstream methods into radical research. Nonetheless, despite substantial evolution, radical economics (or, as it is often called now, heterodox economics) remains at the core faithful to its original vision. All approaches are grounded in a stable set of uniting principles, the three most salient of which are the importance of history, embeddedness of individual choice in an institutional environment and the centrality of conflict to understanding capitalism.

Roots of radical economics

Radical economics has always identified its fundamental project as the construction of realistic representations of the capitalist system, the better to identify and redress exploitation, alienation and inequality. Specifically, the shared goal from the beginning has been to incorporate a degree of reality not available in neoclassical models based on assumptions of atomistic individuals optimizing under conditions of complete information and perfect foresight.

The first unifying proposition of radical thought is the importance of history. The past shapes the present through inherited initial conditions: all choices in the current period are made within constraints imposed by history. Moreover, projections into the future must eschew assumptions of perfect foreknowledge or even, in some strands of radical thought, a known risk embodied in a fixed distribution of outcome probabilities. Path dependence renders the future unpredictable and unknowable.

Social construction of norms and endogeneity of preferences to institutional constraints constitute a second set of shared radical concepts. Individuals make choices on the basis of ‘background’ criteria derived from social norms, which in turn arise from stable institutions and rules of the game (Searle, 1995).

The radical critique of exogenous preferences does not simply replace individual agency with structure. Rather, most strands of radical thought assume interaction between individual and social structure. The dominant view posits that intentional human agency exerts its most powerful effect on institutions in contentious historical conjunctures (Setterfield, 2005; Searle, 1995). Conflictual historical periods give rise to re-examination, rejection and perhaps supersession of existing institutions because individuals challenge established norms.

Conflict in turn is seen by radicals as endemic to capitalism and a cause of chronic inefficiency. Conflict at the workplace makes capitalism operate at less than maximum achievable output (Bowles and Jayadev, 2005). At the macroeconomic level, conflict over distribution is implicated in lack of stability or consistent growth (Bhaduri, 2006; Pollin, 1997). Chronic conflict periodically and unavoidably rises to an acute level, crises emerge and institutions once supportive of growth fail to resolve the crisis.

Impetus to the evolution of radical thought

While most current practitioners of radical economics are, as noted above, still working broadly within the original radical vision, since the mid-1980s internal criticisms of radical research have precipitated significant change within the field. Citing lack of coherence or realism, critics urge theoretical overhaul to achieve a truly integrated analysis of history, institutions and conflict.
Immanent criticism argues that radical theory must explain collective action, both to establish the centrality of class and to sustain a critique of the neoclassical behavioural model predicated on atomistic, self-interested individuals. Radical theory, in its original incarnation, provided little analysis of how individuals decide to engage in collective action. Thus, radical analysis fell short in explaining how or when the working class decides to act in its own interest. Most radical economics rejected early on any explanation derived from an overly simplified materialist assertion that individuals are simply bearers of their class roles. Nonetheless, lacking a clear alternative, radical explanations still tended to fall back into an unexamined and unacknowledged use of functionalist arguments, in which behaviours derive from the structure and requirements of capitalism.

Exploitation, also a central proposition of radical theory, similarly required further elaboration. The labour theory of value as the theoretical foundation of the role of labour as the sole source of surplus and profit sustained damaging attack from analytical Marxists, losing pride of place as the radical theory of profit and prices. Without a labour theory of value, much of crisis theory inherited from Marx in turn became unsustainable.

Finally, despite theoretical commitment to a path-dependent theory of historical change, radical economics tended to fall back into an overly deterministic theory of history, in which capitalism moves according to knowable and immutable laws. The inconsistency of a deterministic theory of history with the notion of path dependence weakened claims to realism and superior understanding of capitalist development.

In addition to identifying such theoretical vulnerabilities of radical theory, critics argued for recognition of new empirical realities in capitalism. Most important has been the growing belief that class is simply too crude a tool with which to analyse conflict. Inequality along many dimensions, particularly race and gender, has emerged as a topic of radical investigation, further undercutting a classical Marxian analysis of capitalism. Radical feminists, for example, question the relevance of exploitation of labour to understanding inequality within the household. Resilience of capitalism in the face of crisis, in contrast to fragility of socialist countries, confronted radicals with another dilemma, since radical theory based on historical materialism had predicted opposite results.

Absence of radical analysis from policy debates fuelled the criticism that radicals neglected empirical work. Complaints have been widespread, coming even from the more Marxist of the radicals. Howard Sherman, for example, has argued that radicals are obliged ‘to always start from actual problems, not from ideal models, universal laws or any rigid rules of research’ (Sherman, 1995, p. 262). Empirical Marxists bemoaned radicals’ insistence on the purity of Marxian categories, which led radicals to avoid empirical analysis, resulting in exclusion from policy discussions (Dunne, 1991). Prominent non-Marxist radicals too have argued that radicals must confront reality through policy-relevant research if they are to claim superior reality of their analysis (Reich, 1995).

**Contours of change**

Three shifts in the body of radical research most clearly embody these critiques of early radical theory. First, characterization of the core injustice of capitalism has moved from a narrowly defined concept of exploitation at the point of production to broader inequality beyond both production and class. Second, the role of individual choice relative to structure has become more prominent in explanations of the nature and development of capitalism. The third shift marks movement away from a still ‘virtual’ radical
representation of capitalism to ever more realism.

The prominence given now to inequality signals a further loosening of bonds to Marxian theory. Inequality encompasses race and gender relations as sites of conflict independent of class. As a result, class is now one of several fault lines along which capitalism is both unequal and fragile, and cannot be said to be determinate of relations in other spheres of conflict. Attention to agency reflects that radicals now take seriously the need to demonstrate the inapplicability of *homo economicus* either at the point of production or at other sites such as the household. Thus, the new radical economics unpacks the ‘black boxes’ of the Marxian theory from which it originated. Gone are the stylized facts of homogenous workers confronting homogeneous capitalists or of a unitary household providing a sanctuary from, as well as valueless inputs to, capitalist production. On the agenda now are, for example, the effects of altruism on intra-household allocation decisions and the role of race in worker decisions to participate in strikes.

Similarly, a key point of the shift to the ‘real’ is to examine actually existing capitalist countries rather than construct an ideal capitalist type in relation to which actual economies are to be interpreted. The implication for policy is clear. Capitalist countries differ; some provide considerable room for redress of inequality and reduction of conflict, hence improved efficiency. Rather than condemning capitalism as an abstract, necessarily exploitative system, radicals increasingly focus on specific sites within capitalism where potential for improvement may be found. Again, even radicals more firmly within a Marxian tradition call for and applaud a new determination to ‘come to grips with … the realities of contemporary capitalism as opposed to the creation of a “virtual world”’ (Fine, 2002, p. 2062).

Contested evolution

These three evolutionary shifts, while evident throughout radical research, are nonetheless both contested and incomplete. Movement towards fulfilling the promise of more realistic representations of capitalism has raised thorny issues of subject and method. Radicals now contend over the appropriate definition of reality and the ability of competing theories and methods to represent reality.

Radical analysis of globalization provides one example of competing visions of what is real and of methods appropriate to represent reality. On this topic there is still general agreement on the core principles of a radical theory and on the inadequacies of mainstream theory. Radicals reject the so-called Washington consensus, a set of liberalizing policies derived from the claim that opening of markets will lead to improved efficiency and economic growth. Radicals counter both efficiency and growth propositions of the liberalizing story, while focusing instead on distributional consequences of globalization. (Arestis and Sawyer, 2002, and Baker, Epstein and Pollin 1998, provide overviews of critiques of liberalization.)

Beyond unity in opposition to the free market position, however, radicals disagree profoundly on critical features of globalization. The appropriate definition and indicators of globalization are in dispute, meaning that radicals cannot agree on such basic issues as the degree of globalization of the world economy and role of nation states versus transnational corporations (Glynn and Sutcliffe, 1999). Differences also are apparent in competing theoretical understandings of how globalization affects distribution and growth.

The Asian Tigers' perspective on globalization focuses on aggregate demand as the engine of growth and
maintains that aggregate demand must be sustained domestically, requiring both controls on capital flows and avoidance of excessive competition (Crotty, 2001; Baker, Epstein and Pollin, 1998). In contrast to the Washington consensus perspective, unemployment in this view is caused by insufficient aggregate demand rather than inflexible labour markets. The role of the state in a globalized economy, often modelled on recent Korean experience, is not only to manage domestic demand but also to develop non-traditional export industries through central control of credit. Class conflict plays at most a peripheral role. Instead, the main locus of conflict is between developed capitalist and developing countries.

This nation-state version of the Keynesian approach calls for controls on capital flows in part to sanitize domestic economics from the effects of ‘hot’ money. Within the same general aggregate demand framework, however, others deny that nation states have the capacity to control capital flows. A ‘one-world’ position, for example, calls instead for an international financial authority to regulate financial flows. This authority further must intervene even into the shaping of firm-level decisions to achieve consistency between firm incentives and international financial stability (Eatwell and Taylor, 2002).

An alternative radical vision disputes the relevance of a Keynesian model in the current historical conjuncture because history is not reversible. If history is indeed path-dependent, a theory grounded in history and institutions must conclude that it is not possible to revive the golden age of capitalism through a return to Keynesian policy. The current leaden age cannot be regilded to reproduce the growth of the post-war period exactly because the institutions that once supported growth through demand management policy are not sustainable in the globalized economy. In the new economic environment, it is not possible to reconstruct the institutions that once fuelled growth, namely, concentrated industrial sectors, strong trade unions (at least in manufacturing sectors), growing export markets and a world trade system denominated in dollars.

The golden age is also questioned for lack of attention to intra-country conflict of class, gender or race. The nation state is not a homogeneous unit in which aggregate growth benefits all. Moreover, this position contends that a new world order has emerged in which transnational corporations have the character and goals of a supra-national capitalist class. If capitalism has moved to a fundamentally new structure in which nation states have lost the power to determine policy for good, the restorative power attributed to Keynesian macro policy is a delusion.

A third radical vision takes a more positive view of globalization by examining intra-country class relations. This approach sees globalization as offering new space to national policies that can simultaneously increase growth and improve distribution. Focusing on capitalist inefficiency due to conflict, Bardhan, Bowles and Wallerstein (2006) conclude that pressures of globalization can force national governments to implement policies that both improve efficiency and reduce inequality. While the Bardhan et al. story rests on microeconomic behaviour, at the macro level, too, national policy and internal class dynamics are linked. The main contention is that poor countries too often merely use protection from the world economy to redistribute income and assets from the poor to the rich (see for example Griffin, 1998). Globalization can undercut the entrenched power of exploitative elites and hence enhance equality as well as growth.

The last divide among radicals to note here is disagreement about the role of foreign investment. The dominant position for some time has been that foreign investment is detrimental to developing countries because of concentration in low-wage industries and competition with existing domestic production. The stylized facts of this view are that foreign investment is footloose and relentlessly pursues ever-lower
wages. Therefore, on balance, foreign investment creates negative rather than positive spillover effects. Recently, however, several radical research projects have challenged the accuracy of this picture, pointing to a different set of realities. Nations are seen to have leverage over the terms and flow of foreign investment. Leverage in turn comes from political stability and skilled workers, which, rather than low wages, are the major determinants of investment patterns. Moreover, open countries have succeeded and closed countries have failed, depending upon the role of the domestic government in exploiting opportunities of openness (Chang, 1998).

Nihilism or high theory?

The globalization debate highlights the point that as radical theory has attempted to move towards less ‘virtual’ representations of capitalism, hitherto concealed splits have surfaced. Much of the purported greater realism comes from analytical methods based in mathematical or formal models, forcing radicals to confront underlying divisions about the proper role of mathematics and analytical models. Competing radical positions now contend over fundamental issues of method, particularly over whether radical core principles are sustained or abandoned by use of formal analytical techniques.

Debate over use of game theory and experimental economics is one illuminating example of current controversy. If the radical project includes understanding endogeneity of preferences and providing a more realistic concept of individual rationality than neoclassical economics, game theory would seem to provide a powerful tool. Feminist economics in particular seeks to move beyond a *homo economicus* model of behaviour to demonstrate that ‘many alternatives exist to the traditional self-interested model, with motivations responding, for instance, to notions of altruism, fairness, and reciprocity’ (Beneria, 1999, p. 71; see also, Folbre and Goodin, 2004). Further, policy relevance is the explicit goal of much radical experimental economics. Cross-country experiments are seen to yield insights to improve ‘the design of institutions and contracts, the allocation of property rights, the conditions for successful collective action …’, all considerations dear to radical economists (Henrich et al., 2001, p. 76).

Game theory from this perspective achieves greater realism by identifying parameter values or relationships from which a range of outcomes, here varying preferences or levels of collective action, may arise. To its proponents game theory offers a mechanism for demonstrating that there are no immutable laws or behaviours applicable to all times and all places. Norms and preferences are endogenous to and, therefore, vary with institutional arrangements, whether across countries or households.

Critics vehemently oppose game-theoretic models of preferences or norms exactly on grounds of insufficient realism. In this view, any reduction of complex reality to a model privileging at most a few variables and relationships is antithetical to the radical claim to realism. Models which use any form of optimization are considered to be ahistorical and lacking in institutional specificity, including work by new institutionalists like Bowles and Gintis (1998). Ben Fine, among many others, asserts that such work ‘relies on utility, production, inputs and informational asymmetries, timeless and rootless optimizing of individuals …’ (Fine, 2002, p. 2060).

Equilibrium, too, is a matter of much dispute. The strongest repudiation of equilibrium comes from the recent temporal single system interpretation of Marx, which maintains that incorporating history into theory requires neither equilibrium nor disequilibrium models, but non-equilibrium (Kliman and
McGlone, 1999). To many radicals the complexity of history and the necessity of non-equilibrium render inadmissible use of techniques such as optimization or simultaneous equation models (Lawson, 2006).

Defenders of the use of analytical models and mathematics respond that all analysis, mathematical or not, requires the same process of model construction in simplifying reality to a small set of main variables and relationships. The narrow neoclassical concept of equilibrium, with implausible assumptions about foresight and information, not equilibrium itself, must be abandoned. Without some notion of equilibrium, theory is simply nihilistic: ‘the social world is complex and determinate but it is impossible to say anything systematic about it’ (Foley, 2003, p. 3). An alternative equilibrium concept, compatible with heterodox theory and goals, can be defined ‘in the general sense of the balancing of forces within a particular model…’ without any market clearing or settlement to ‘tranquil states’ (Dutt, 1994, p. 3).

Adding fuel to the debate over the requirements of radical theory is the proposition that theories are converging and radicals are all post-Walrasi ans now. Convergence contends that mainstream economics is no longer bound to what Colander, Holt and Rossiter (2004) and Colander (2005) call the Walrasian unholy trinity of rationality, equilibrium and greed. Method and message are no longer linked because new methods explicitly are not ahistorical and asocial and hence are appropriate for radical inquiry (Gibson, 2005). Michael Reich has argued further that the liberal wing of neoclassical economics now can accommodate analyses of ‘disequilibrium economics, non-market-clearing equilibria, multiple equilibria and the new institutional economics, which have brought radical economics ‘out of the ghetto’ and into the liberal mainstream’ (Reich, 1995, p. 50). Duncan Foley expands this point, asserting that complexity and chaos theory finally can liberate radicals from dependence on the concept of ‘determination in the last instance’ or functionalist arguments to close the system (Foley, 2003).

The convergence contention poses a sharp choice for radicals. If new methods like complexity and chaos theory are not just consistent with but necessary for preservation of core radical principles, radicals who repudiate new methods are abandoning history, institutions and conflict as central concerns. The other pole of the dilemma emerges starkly from Colander's otherwise sympathetic assessment of post-Walrasian theory. While supporting Foley's call for more sophistication in radical analysis, Colander's contrasting conclusion is that, in the face of increasing complexity, recent theoretical innovations cannot provide a guide to policy but only an ‘aid to one's intuition’ (Colander, 2005, p. 23). With more realistic representations of capitalism the very complexity of the analytical tools means that no precise policy can be devised and we can only, as Colander says, muddle through.

Conclusion

Radical economics remains, as it was in the mid 1980s, a body of thought defined by common core principles while divided on method. What has changed is the depth of division across the several strands of radical economics. Attempts to develop more realistic and nuanced analyses of capitalism, together with the emergence of new methods of analysis, have generated sharp conflict over both method and object of radical inquiry. To the extent that the choice facing radicals is indeed nihilism or high theory, the centre of the paradigm is eroding and common ground is being lost. Nonetheless, the shifts in radical thought since the mid-1980s have yielded significant positive results. Radicals are indeed more involved
in policy discussions and more engaged with data, achieving successful policy interventions as exemplified by living wage legislation (Pollin, 2002). Self-criticism also has opened space for re-examination of basic tenets of radical theory and energized debate, which bodes well for continued dynamism and evolution of the broad radical paradigm.

Rae, John (1796–1872)

John Rae was born in Aberdeen on 1 June 1796 into a merchant and shipping family. He graduated from the University of Aberdeen in 1815 and read medicine in the University of Edinburgh, but had to abandon his studies when his father's business failed in 1817. He emigrated to Canada in 1822 and turned to medical practice (whence 'Dr' Rae) and school teaching. He also participated in public affairs, but his career was shattered in 1848 when he was dismissed on spurious grounds after becoming embroiled in controversies about church control of education. Rae set out to start a new life first in California, and then the Hawaiian island of Maui. After another 20 years of farming, teaching, providing medical services to the natives, and serving as district judge and notary public, Rae went to live with a former pupil in New York, where he died on 12 July 1872.

None of Rae's many misfortunes and distractions could quell his scientific curiosity. He reported scientific experiments and inventions, lectured on scientific subjects, and wrote on public affairs, geology, and Polynesian language and customs (James, 1965). The only book he ever managed to get published, his *Statement of Some New Principles on the Subject of Political Economy* (1834), originally intended as an appendix to a larger work on the natural history and statistics of Canada, is one of the highlights of classical economic theory.

Rae's economics is rooted in a natural history of man which he had conceived in the tradition of Montesquieu, Turgot and the Scottish Enlightenment, but never came to execute. Political power and economic progress are seen to result not from the pursuit of self-interest, but to require ‘social instincts’ which create ‘an intelligent and moral community’ that furthers both the ‘effective desire of accumulation’ and the ‘rational spirit of invention’. Charging Adam Smith with building his system...
exclusively on the pursuit of self-interest, and neglecting the role of inventions, Rae contended that economic activity is based primarily on an unselfish regard for the future. In consequence Rae emphasized the temporal aspect of economic activity, and developed a theory of capital accumulation and technical progress which goes far beyond what can be found in Adam Smith or other classical writers. In language which Fisher was to take up, Rae argued that ‘provident forethought’ leads man to create ‘instruments’, that is, capital goods, in order to change the course of events. The sum total of such instruments constitutes the wealth of a society. All instruments are formed, directly or indirectly, by labour; all have the capacity to provide, directly or indirectly, for future wants; and they need time before they are finally exhausted (land being a special case). Rae assumes that the cost of production, and capacity, of any instrument can be measured, in a given society, in exogenously given wage units. All instruments whose capacity exceeds their cost of production can ‘be arranged in … a series, of which the orders are determined, by the proportions existing between the labour expended in the formation of instruments, the capacity given to them, and the time elapsing from the period of formation to that of exhaustion’ (1834, p. 100). Rae expresses this ‘order’ by the time which elapses before the instrument has yielded twice its cost of production, that is, by in the expression where is the internal rate of return of the quasi-rents associated with the instrument. Rae rejected working with the latter because it leads, in his view, to the assumption that the stock of all instruments is ‘an homogeneous quantity’ which he ‘found to be the foundation of much of the contradictions, in which the reasonings on these subjects are involved’ (1834, p. 197). His calculation rests on the assumption that every instrument can be associated with a unique rate of return. This need not be the case, but the possible multiplicity of internal rates of return does not affect his argument. Rae argued that with knowledge stationary, both capital widening and capital deepening (that is, increasing the durability of instruments) necessarily lower the internal rate of return. Nevertheless, capital goods will be created as long as their internal rate of return is higher than the ‘effective desire of accumulation’, or rate of time preference, which Rae also expresses in time periods, that is, by in the expression where is the rate of time preference. Such time preference exists because life is finite and its end uncertain, and because ‘passion’ is often stronger than ‘reason’. But it is counteracted by the concern for future generations, or what Rae called ‘social and benevolent affections’ (1834, p. 122), which depend on a healthy climate that increases life expectancy, or on social circumstances such as internal and external security, good government, and so on. Hence the strength of the ‘effective desire of accumulation’, which Rae considers as much a social habit as an individual inclination, varies from one society to another. Variations from one person to another, Rae shows in an almost neoclassical manner, will be equalized by the exchange of instruments among them, so that a social rate of time preference can be juxtaposed to an internal rate of return which is equalized across different ‘employments’ by profit-seeking ‘merchants’. Rae defines the equality of the social rate of return with the social rate of time preference as a stationary state in which accumulation ceases. ‘Gravitation’ towards it is slow. In a comparative static analysis Rae shows that the division of labour – which he views as a consequence of the accumulation of capital rather than its cause, as Adam Smith did – reduces the time for which instruments lie idle, and consequently increases their quasi-rents; hence more instruments can be created before the stationary state is reached, and wealth is increased. Similarly, foreign trade is said to increase the productivity of instruments, while conspicuous consumption (his term) will lower the effective desire of accumulation.
Rae also argues that as accumulation proceeds, more and more wealth will be tied up in instruments of increasing durability; hence the value of cash balances, and thus liquidity preferences, will increase. But far and away the most important factor making for changes in the progress of accumulation was in Rae's view the progress of inventions. Apart from raising quasi-rents, and hence the internal rate of return, and thus providing scope for more accumulation, inventions also raise the value of existing capital goods. Obviously assuming that these Wicksell effects were positive, Rae placed such capital 'augmentation' alongside capital accumulation as a factor in creating wealth. Indeed, Rae ascribes to inventions a more important role for economic progress (and thus the creation of political power) than capital accumulation, and criticizes Adam Smith for emphasizing savings too much, and neglecting technical progress.

The policy conclusions Rae draws from his analysis are also used to controvert Adam Smith. Instead of pursuing a policy of non-intervention, the 'legislator' should stimulate foreign trade and technical progress, encourage the transfer of knowledge, tax luxuries, and use tariffs to protect infant industries. It was in this sense that Rae tried to expose 'the fallacies of the system of free trade, and of some other doctrines maintained in the Wealth of Nations', as he announced on his title page. But, issued in the midst of a protectionist campaign, Rae's book was mistaken as a heavy-going anti-free-trade tract, and ignored. It did find a champion in Nassau Senior (Bowley, 1937, ch. 4) and through him in J.S. Mill, who quoted from it copiously in his Principles (1848), comparing Rae on accumulation to Malthus on population. But there the matter rested, except that it seems to have had a strong influence on Hearn's Plutology (1863). Rae was re-discovered by Mixter (1897) as a forerunner of Böhm-Bawerk, who acknowledged him as such (1900, ch. XI) despite some criticism. Together with a (botched, because re-arranged) reprint of Rae's book by Mixter (Rae, 1905), this brought Rae's work to the attention of capital theorists such as Irving Fisher (1907; 1930) who dedicated one of his main works to Rae, as well as Wicksell and Åkerman. It also influenced Schumpeter's (1911) concept of economic development, and Veblen's (1899) notion of conspicuous consumption.

In his criticism of Adam Smith, Rae did not go beyond Bentham (1787) and Lauderdale (1804). But he added poignancy because he derived it from a theory of economic development which was altogether novel. Based on a materialist conception of capital and a vintage-type approach complete with the distinction between capital goods and their value, Rae clearly separated the supply of from the demand for capital goods, and investigated their determinants. He saw but dimly the equality between discounted marginal returns and marginal costs, but he was clear about the equality of opportunities to invest to the 'inclination … to yield up a present good'. He was quite clear, too, about the equality between the rate of return on capital and on money, and about what brought about such equalities: and also about the effects technical progress and the growth of knowledge have upon both demand and supply of capital. All this adds up to a remarkably original and creative performance which was, like that of Gossen, Cournot or Thünen, ahead of its time.

Rae, John (1845–1915)

Andrew Skinner

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Keywords

Rae, J. (1845–1915); eight-hour movement

Article

John Rae was born in Wick, Caithness, Scotland on 26 May 1845, the eldest son of William Rae who was for some years Provost of the town. Rae received his early education at Edinburgh Academy, before proceeding to university in the city. He graduated in 1866 with first class honours in philosophy. Rae was awarded an honorary doctorate in 1897 by his alma mater. He died on 19 April 1915, having spent the last 15 years of his life in London, and was buried in Wick.

John Rae has been variously described as ‘author and journalist’ (1953, p. 582) and as ‘economist, writer on socialism’ (1966, p. 1057). He was certainly all of these, publishing numerous articles, notably in the Fortnightly Review (1885), the Temple Bar (1882, 1883, 1897), MacMillan’s Magazine (1893) and the National Review (1889). The great bulk of his considerable output is to be found in the Contemporary Review (from 1880) of which he was assistant editor.

Rae's contributions to the Contemporary Review disclose an interest in at least five major areas. These include a review of contemporary literature on social philosophy (in seven parts), and a number of articles on the Socialism of Karl Marx and the Hegelians, Christian Socialism in Germany, and State Socialism and Social Reform. Rae also contributed articles on the crofting problem in the Highlands, supplementing these with pieces on the Highland Shealing (Temple Bar, 1883) and on the Scotch Village Community (Fortnightly Review, 1885). Rae wrote a number of articles on taxation and a review of recent economic literature. Finally, he addressed questions of industrial relations, in considering the implications of the eight-hour day in the context of unemployment and of foreign competition.

Rae's journalistic interests resulted in three major books. The first of these was entitled Contemporary Socialism (1884). This was followed by Eight Hours for Work (1894), a book which consisted largely of his articles on labour questions, supplemented by chapters on the connection between hours and wages,
the eight-hour movement of 1833, and current legislative proposals.
John Rae is now best known for his admirable Life of Adam Smith (1895) which was favourably reviewed in The Times for 8 March 1895 as presenting a ‘vivid picture’ of his subject. The review also drew attention to the point that the book’s real merit lay ‘not in the originality of the matter, but in the patient industry, with which Mr Rae has collected his materials, old and new, and in the skill and judgement with which he has presented them to the reader’.
While more critical of Rae’s scholarship (1965, p. 12), Jacob Viner has noted that Rae was a trained writer who made his Life ‘an interesting and highly readable book’ (p. 13). Viner also drew attention to the remarkable fact that ‘As a comprehensive biography, it had no substantial predecessor. Seventy years after its publication, it still has no substantial successor’ (1965, p. 5). These judgements are still valid.

Frank Plumpton Ramsey died at the age of 26 after making brilliant contributions to philosophy, mathematical logic, and, of course, economics. His two contributions to economics both appeared in the *Economic Journal*, then edited by J.M. Keynes. The first, ‘A Contribution to the Theory of Taxation’, published in March, 1927, laid the foundation for the modern theory of commodity taxation. The second, the subject of this entry, was ‘A Mathematical Theory of Saving’, published in December, 1928. Keynes, in his obituary notice published two months after Ramsey’s death, in the *Economic Journal* of March, 1930, described the latter as ‘one of the most remarkable contributions to mathematical economics ever made, both in respect of the intrinsic importance and difficulty of its subject, the power and elegance of the technical methods employed, and the clear purity of illumination with which the writer’s mind is felt by the reader to play about its subject’.

Ramsey asked how much of its income should a nation save and derived a remarkably simple rule, usually known as the Keynes–Ramsey rule, as Keynes provided a non-technical argument for the result. The rule states that the rate of saving, multiplied by the marginal utility of consumption, should always be equal to the amount by which the total net rate of enjoyment of utility falls short of the maximum possible rate.

Ramsey’s formulation of the problem served as a model for almost all subsequent studies of optimal
economic growth, and, with the critical addition of a growing population, might have created neoclassical growth theory about 30 years before Solow's (1956) contribution. He assumed a one-good world, in which labour with a stock of capital would produce a flow of output, part of which was consumed, and the balance was saved and thereby added to the stock of capital. The objective, or criterion, was to achieve the maximum level of enjoyment, summing over all time, where enjoyment was the utility of consumption, \( U(C) \), less the disutility of working, \( V(L) \). Ramsey made three crucial assumptions which together allowed him to solve explicitly an otherwise intractable problem. He assumed that there was no population growth, no technical progress, and no discounting of utility, ‘a practice which is ethically indefensible and arises merely from the weakness of the imagination’ (Ramsey, 1928, p. 543). He further supposed that there was a ‘maximum obtainable rate of enjoyment’ called Bliss, \( B \), either because of capital or consumption saturation. As neither population grows nor future utilities are discounted, Ramsey then argues, rather informally, that it must be desirable to save enough to eventually reach bliss, or approximate to it indefinitely. To stop short means forgoing a finite amount of utility, which, summed over an infinite time horizon, is infinitely costly. Formally, Ramsey deals with this problem of a potentially unbounded integral of utility (summed without discounting over infinite time) by minimizing the amount by which enjoyment falls short of bliss integrated throughout time:

\[
\min \int_0^\infty \left[ B - U(C) + V(L) \right] dt
\]

subject to

\[
\frac{dK}{dt} + C = F(K, L).
\]

Ramsey attacks the problem from two directions: economic and mathematical. His economic argument first solves for the relationship between consumption and the effort by equating the marginal disutility of labour to the product of the marginal product of labour and the marginal disutility of consumption. He then solves the basic arbitrage relationship equating the marginal utility of consuming a unit now with the marginal utility of consuming the product of investing the unit until the next instant of time. This key relationship implies that the marginal utility of consumption, \( U'(C) \), must fall at the rate of interest, equal to the marginal product of capital, \( \frac{\partial F}{\partial K} \). These two conditions, together with (2), the initial stock of capital, and a terminal condition as \( t \to \infty \), produce a differential equation which can be integrated to give the result.
The mathematical approach observes that the calculus of variations gives the first two conditions directly, but also observes that the variable of integration in (1) can be changed from $t$ to $K$ by using (2) to give

$$\min_{K_0} \int_0^\infty \frac{B - U(C) + V(L)}{F(K, L) - C} \, dK$$

(3)

and since $C$ and $L$ are arbitrary functions of $K$ all that is needed to minimize the integrand is to set its partial derivations to zero. Differentiating with respect to $C$ gives

$$F(K, L) - C = \frac{B - [U(C) - V(L)]}{U'(C)}.$$  

(4)

The left-hand side of (4) is the rate of investment or saving, while the right-hand side is equal to bliss minus the additional rate of enjoyment, divided by the marginal utility of consumption, and the whole is the Keynes–Ramsey rule.

Ramsey concluded from this rule that the optimal rate of saving should be ‘greatly in excess of that which anyone would normally suggest’ and gave an illustration in which the savings rate should be 60 per cent of income. One of the main themes explored by later writers was whether this was a robust conclusion, or whether the optimal rate of saving was very sensitive to the simplifying assumptions – a theme which is discussed below. Ramsey recognized that discounting utility would destroy the simple reasoning which led to (4), and was thus anxious to have an ethical reason for rejecting it. He believed that population growth would argue for higher rates of saving whilst technical progress would have ambiguous effects – as proved to be the case in later formal models.

Ramsey drew attention to two remarkable features of the rule. The first is that the level of saving does not depend on the production function. The second is that it does not depend on the rate of interest, unless this is actually zero. In fact, the first feature is only apparently the case, for in (4), $C$ will depend on the level of output, $F$, and since savings, given by the right-hand side, also depends on $C$, it will depend on $F$. In his Section III, Ramsey clearly pointed out that the level of saving was motivated by the demand for future consumption, while the rate of interest was determined by the current stock of capital (in this one-sector model). In a concluding remark to this section he notes that ‘in the accounting of a Socialist State the function of the rate of interest would be to ensure the wisest use of existing capital, not to serve in any direct way as a guide to the proportion of income which should be saved’. The second result does not survive in more general models which allow for utility discounting. Nevertheless, the arbitrage relationship does suggest a way in which the rate of interest can guide the rate of saving. If
the rate of decline of the marginal utility of consumption is less than the rate of interest, taken to be the rate of return on investment, then the rate of saving is too low, and vice versa.

The main contribution of the paper was to pose a fruitful question – what should the rate of savings be – and propose a method of analysis – that of intertemporal welfare maximization using the techniques of dynamic optimization, in this case the calculus of variations. The main result was striking – the rate of saving should apparently be rather high. In addition to this contribution, the paper also contained various remarkable extensions. It considers the choice of savings rate for an individual facing constant factor prices, who wishes to optimize his lifetime consumption pattern, and as such provides a positive theory of life-cycle savings. It shows that if utility is to be discounted, then it must be discounted at a constant rate if one is to escape the contradiction ‘that successive generations are motivated by the same system of preferences’. Later, Strotz (1956) would return to this issue and the related problem of dynamic consistency. Finally, Ramsey shows that if a society consists of individuals who differ in their rate of discount, and if it is in steady state, then the equilibrium would be attained by a division of society into two classes, the thrifty enjoying bliss and the improvident at the subsistence level. In short, he characterizes the long-run general equilibrium of a society of heterogeneous individuals.

Ramsey thus laid the foundations for the study of optimal accumulation and optimal growth, as well as the positive theory of savings and the rate of interest. Space precludes a full assessment of the subsequent work his paper stimulated, though Burmeister and Dobell’s (1970) textbook lists 107 references in their chapter on optimal economic growth, and much has happened since that date. Instead we shall briefly mention some of the themes of this subsequent work.

Ramsey’s model represented a significant advance on the classical analysis of stationary states, since it made possible the analysis of non-stationary time paths of capital accumulation, but ultimately his model would tend towards a stationary state. With the development of growth theory the profession acquired a more appealing concept of long-run equilibrium – that of steady growth. In due course this suggested the obvious extension to Ramsey’s model of incorporating these dynamic features – population growth at the steady rate $n$ and Harrod-neutral technical progress at a steady rate $g$. The instantaneous level of national welfare was variously taken as $U(C_t)$, $U(C_t/L_t)$, or, most satisfactorily, $L_t u(C_t/L_t)$, where $L_t$ was the total population or workforce, and $C_t$ was total consumption. Since welfare now depended on time, it made no drastic difference to include a utility discount rate, $\delta$, and to propose a more general objective such as

$$ W = \int_0^\infty U(C_t, t) dt = \int_0^\infty L_t u(C_t / L_t) e^{-\delta t} dt. \tag{5} $$

Steady growth now raised the question of the existence of an optimal savings policy in an acute form, for the integral in (5) might diverge unless $\delta$ was sufficiently large. Ramsey had faced a similar problem and avoided it by minimizing the shortfall from a reference path (or bliss). Similar devices were invoked to deal with divergent integrals, and much effort was expended on devising criteria of optimality and categorizing conditions under which an optimal savings plan existed, though many apparently
reasonable problems nevertheless failed to possess an optimal savings plan, as Hammond and Mirrlees (1973) demonstrated. (They also give references to earlier discussions of the problem of non-existence.) They observe that no restrictions on the class of utility function will ensure existence, nor will any realistic restrictions on the production assumptions by themselves be enough to avoid the problem. They then argue that if we could specify date after which events are of no significance, then the problem reduces to a finite horizon model, for which the utility integral would converge. Different people might disagree on the horizon date, but if the initial $T_0$ years of the plan were relatively insensitive to any horizon date later than some date $T_1$, then everyone would agree with the $T$ year plan, and, in their language, the plan would be agreeable. Hammond and Mirrlees show that in the one good model with a general instantaneous utility function $U(C_t, t)$ the agreeable path is unique and locally optimal, and that if an optimal path exists it is agreeable. Establishing the existence of agreeable paths is, however, considerably easier than establishing the existence of optimal paths.

While existence problems are important and raise intriguing philosophical problems (what if optimal growth paths do not exist?), they are not central to the economics of the problem. One of the key issues that has engaged the attention of subsequent researchers is whether the optimal savings rate is indeed as high as Ramsey argued (though, as Samuelson, 1969, pointed out, Ramsey's conclusion depended on a particular choice of utility function). Certainly, Tinbergen (1956) was inclined to agree, but Mirrlees (1967) argued that Ramsey's model was seriously misleading, and that once population growth, technical progress and utility discounting were admitted, the initial value of the optimal rate of saving was typically very different from that implied by the Keynes–Ramsey rule. Once time enters the production function, it is no longer possible to obtain explicit solutions and an alternative solution strategy is required. Mirrlees argued that it was preferable to find the asymptotic form of the optimally developing economy in which output, consumption and consumption per head all grow at steady rates along a ‘modified Golden Rule’, and in which the savings rate is constant. The initial value of the savings rate could then be estimated by expanding around this asymptotic solution.

Mirrlees, in common with a large number of other optimal growth theorists, used a particular utility function – the iso-elastic form

$$u(c) = -c^{1-\nu}, \ \nu > 1, = \log c, \ \nu = 1$$

(6)

for which Ramsey's rule gives a savings rate of $1/\nu$ (providing an optimum exists). Mirrlees was impressed that for plausible values of the parameters of his model, the optimum savings rate was very different from the Ramsey value, and might be quite low. He also pointed out that the asymptotic solution, or the ‘modified Golden Rule’, would differ from the Golden Rule (according to which the rate of savings should equal the share of profit), if utilities were discounted – for the obvious reason that one would expect optimum policies to reflect the values regarding the distribution between generations. Ramsey's model made skilful use of the classical calculus of variations, and in that vein Samuelson and Solow (1956) extended the model to deal with heterogeneous capital goods. In so doing they made
possible two notable contributions to capital theory. The first was to argue that on the optimum path it was not too misleading to think in terms of an abstract quantity of capital – heterogeneity did not significantly alter the Ramsey theory. Second, the Hahn–Samuelson problem of the indeterminacy of equilibrium with capital heterogeneity disappeared on the optimal path, though the significance of this did not emerge until the paper by Hahn (1966).

As Samuelson and Solow pointed out, the classical calculus of variations could be replaced by Hamiltonian methods which would be able to deal with inequality constraints. The powerful techniques of the Pontryagin Maximum Principle and Bellman's Dynamic Programming were in due course applied to various extensions of the Ramsey problem to good effect, and their advantages and interrelationships are well discussed in the textbook of Intriligator (1971). In both approaches shadow prices or co-state variables play an important role both in characterizing the solution and in demonstrating the relationships between optimality, intertemporal efficiency, and a set of intertemporal (shadow) prices (prices on futures markets) which might be used to decentralize the optimum. These shadow prices have a natural interpretation, for they value the capital stock in terms of the objective function, that is social welfare or the utility of consumption. The price guides the instantaneous allocation of output between consumption and investment, for consumption should be increased, if possible, until its value (the marginal utility of consumption) falls to the value of investment, that is, of the capital stock. The evolution of the price over time then satisfies the fundamental arbitrage relationship, so that asset holders obtain a return (including capital gains) on the asset equal to the return on other assets and to the return from delaying consumption.

The strengths of these alternative approaches are best appreciated in multisector models when there are constraints on reallocating resources. If investment goods are physically different from consumption goods, and capital is immobile between sectors, then savings will be constrained by the feasible output of the investment goods sector, and the planners' problem is primarily one of choosing the allocation of investment between the two sectors. In such a model the rate of return on capital will depend on the level of investment, and Ramsey's observation that in his model the two are independent is shown to be a feature of the one-good assumption. With two sectors corner solutions are quite likely (in the early stages) and the inequality constraints require the extra power of the new approaches.

The shadow prices are arguably most useful for cost–benefit analysis, rather than the more ambitious planning problems which so engaged the attentions of optimal growth theorists in the 1960s. Little and Mirrlees (1969; 1974) and Newbery (1972) and Stern (1972) were concerned to develop methods for calculating shadow or accounting prices in dual economy models of developing countries in which the level of aggregate savings was constrained. The two key accounting prices on which optimal growth models can shed light are the wage rate and the rate of discount to use in investment projects. The former emerges from the constraints on the allocation of labour and on the level of wages which must be paid, while the latter is again given by an arbitrage relation, or the rate of change of the shadow price of capital itself. The arbitrage equation gives a differential equation for the shadow price which, together with the equation for saving and the accumulation of capital, can be numerically integrated backwards from the asymptotic solution. Modern computers allow this to be done quickly, as illustrated in Newbery (1972).

The arbitrage equation comes into its own in exhaustible resource models where the return to the exhaustible resource must, while it remains in the ground, take the form of a capital gain equal to the
Ramsey model: The New Palgrave Dictionary of Economics

return on other assets. This rule, due originally to Hotelling (1931), and nicely exposited by Solow (1974), has achieved prominence since the dramatic rise in the oil price of 1973–4. Although the revival of interest in the Ramsey model in the 1960s was initially motivated by the post-war popularity of national economic planning, a popularity which waned rapidly in the 1970s, the model and its successors remain useful for the more modest aims of characterizing intertemporal competitive equilibrium in asset markets, especially for exhaustible resources like oil and gas, and for providing a more satisfactory neoclassical theory of equilibrium growth with individually rational savers. The common feature of Ramsey's two contributions to economics was that they were normative, and postulated an additive (utilitarian) social welfare function as the objective to be maximized. Several writers have taken the natural step of combining both of Ramsey's two interests and enquiring what optimal tax (and monetary) policy should be in an intertemporal model in which savings and investment are affected by these policies. Arrow and Kurz (1969) were the first to explore these issues and the closely related issues of the problem of public investment criteria systematically in a growth model in which full optimality is not achieved. Diamond (1973) extended their work to a model with many goods, and demonstrated the desirability (under constant returns) of equal efficiency, on average, between public and private production, even though aggregate efficiency was not desired. In particular the public and private sectors should use the same discount rates. Later work (surveyed, for example, by Kotlikoff, 1984) has explored the efficiency losses involved in an economy of intertemporal optimizing individuals in the presence of distortionary taxes on capital, and have used these estimates to rank alternative capital tax reform programmes – a compromise between the optimal tax approach of Diamond and the need to incorporate more of the complex features of particular economies.

In short, if the central question which Ramsey addressed of the right level of saving and investment has fallen from favour recently, nevertheless the spirit of the Ramsey model with its emphasis on intertemporal optimization lives on strongly, whether it be in the study of the oil market, the derivation of public investment rules, or the reform of the corporate tax system.

Ramsey pricing are prices that are Pareto optimal subject to a constraint on the total profits of a single supplier or group of suppliers. In particular, because a firm whose activities are characterized by scale economies will lose money if it sets the prices of its products equal to their marginal costs, Ramsey prices become for that firm the prices that are optimal (economically efficient) given the financial feasibility requirement that the firm's profits be non-negative. The same Ramsey prices can also be shown to be those necessary for maximization of the sum of consumers' and producers' surpluses. The concept is named after Frank Ramsey, its discover, whose 1927 paper on the subject was one of several revolutionary contributions to economics, mathematics and philosophy this extraordinary man made before he died at the age of 26. Since then and until the 1970s, the principle was largely forgotten even though it was rediscovered and expanded upon by Pigou, Boiteux and Samuelson. In 1970 it was publicized and its history explored in an article by Baumol and Bradford, and the principle has since been widely recognized and accepted by economists and practitioners. As an illustration, in 1983 the Interstate Commerce Commission adopted Ramsey pricing as the underlying principle it would follow in the regulation of railroad rates. Ramsey prices are an outstanding example of the use of pure economic theory to derive an operational solution to a difficult set of practical problems. It may also be as definitive as any available second-best theorem. The extraordinary achievement of the theorem lies in the very explicit formulae it is able to derive from so weak a premise – the Pareto optimality requirement that the prices be those which elicit such a set of outputs and purchase quantities that it is impossible to increase the welfare of any one individual without harming anyone else. Aside from the apparent weakness of this assumption, the definitive character of the Ramsey theorem is surprising in light of the conclusion suggested by much of the second-best literature, that where additional constraints are superimposed on the usual requirements
The Ramsey theorem and its interpretation

The Ramsey theorem is expressed in a variety of formulae all of which are essentially equivalent. Perhaps its simplest form asserts that when a producer supplies \( n \) commodities then Pareto optimality subject to a profit constraint requires the prices, \( p_j \) of these goods to satisfy

\[
\frac{p_j - mc_j}{p_n - mc_n} = \frac{mr_j - mc_j}{mr_n - mc_n}, \quad (j = 1, \ldots, n - 1),
\]

where \( mc_j \) and \( mr_j \) are, respectively, the marginal cost and marginal revenue of output \( j \), \( c(\cdot) \) is the supplier's total cost function and \( k \) is any constant.

In the special case in which none of the seller's goods is either a complement or a substitute in demand, the preceding relationship is easily shown to take the special form which is widely known as 'the inverse elasticity formula':

\[
\frac{(p_j - mc_j) / p_j}{(p_n - mc_n) / p_n} = E_n / E_j, \quad (j = 1, \ldots, n - 1),
\]

\[
\sum p_j y_j = c(\cdot) + k,
\]
where $E_j$ is the price elasticity of demand for product $j$.

In the particular case where an optimum satisfies locally the requirements of constant returns to scale, so that marginal cost pricing yields zero economic profits exactly, then (for $k=0$) conditions (1) and (2) are automatically transformed into the marginal cost pricing conditions

$$p_j = mc_j, \ (j = 1, \ldots, n).$$

(3)

It is easy to show that no prices can be Pareto optimal subject to the profit constraint indicated unless they satisfy (1). Moreover, as long as the proper concavity–convexity conditions hold, any prices which satisfy (1) will be consistent with Pareto optimality so constrained.

One can suggest in rough intuitive terms why constrained Pareto optimality requires prices which satisfy (1), or (2) – in the case of demand independence. The latter is perhaps the most illuminating case, and so it is useful to summarize the argument briefly.

As a starting point, one should recall that the reason marginal cost pricing is necessary for a ‘first best’ (unconstrained) optimum is that such prices equate the pecuniary cost to the consumer of purchasing an additional unit of the item and the economic cost of producing it, that is, its marginal cost. Thus, when the consumer selects his purchases so as to maximize the utility he derives from a given outlay of money, he thereby automatically maximizes the utility derivable from a bundle of economic resources.

However, where returns to scale are not constant at the vector of purchases elicited by the prices $p_i = mc_i$ then the requirement $\sum p_i y_i = \epsilon(\cdot)$ will be violated by those marginal cost prices. Consequently, prices will have to deviate from marginal costs in some pattern that satisfies the profit constraint. Of course, every such deviation will affect consumer purchases, and so the quantities produced, making them depart in different degrees from the optimal quantities that would have been selected under marginal cost pricing. The objective is to cause the $p_i$ to deviate from the $mc_i$ in a manner that satisfies the profit constraint and yet distorts consumer purchases from their optimal levels as little as possible.

For this purpose, consider two of the pertinent commodities, $i$ and $j$, with $i$'s demand highly elastic and $j$'s very inelastic. Start with $p_i = mc_i$ and $p_j = mc_j$ and assume that at those prices profits are negative.

Because of the high demand elasticity of $i$ a small rise in $p_i$ above $mc_i$ will cause a relatively large ‘distortion’ in consumer demand from its Pareto optimal quantity. Moreover, also because of the high elasticity, the rise in $p_i$ will yield a relatively small increase in revenue to help eliminate losses. In contrast, a similar percentage increase in $p_j$ will cause a smaller percentage change in quantity of $j$ demanded and a larger gain in revenue. Clearly less damage will be done to welfare if a larger share of the task of meeting the shortfall of total revenue relative to total cost is carried out via a rise in $p_j$, the price of the commodity with the more inelastic demand. This is, in essence, the logic of the inverse elasticity formula.
Informal derivation of the theorem

A simplified and rather informal derivation of the formulae is straightforward. For brevity only a single consumer and a single input, labour, is used in the following, but the proofs in the \( k \) consumer – \( m \) input cases are virtually identical. Let

- \( y_i \): the supplier's output of \( i \) (\( i=1, \ldots, n \))
- \( x \): the vector of outputs of all other goods
- \( R \): the available quantity of resource
- \( r \): unused resource (leisure)
- \( p_i \): the price of \( i \)
- \( w \): wage (price of leisure)
- \( U(y_1, \ldots, y_n, x, r) \): the consumer's utility function
- \( C(y_1, \ldots, y_n) \): the firm's input requirement function
- \( K(x) \): the input requirement for production of \( x \).

Then, optimality requires maximization of

\[
U(y_1, \ldots, y_n, x, r)
\]

subject to the resource constraint

\[
C(y_1, \ldots, y_n) + K(x) + r = R
\]

and the budget constraint

\[
\sum p_i y_i = wC(y_1, \ldots, y_n).
\]

This yields the Lagrangian

\[
L = U(\cdot) + \alpha [R - C(\cdot) - K(\cdot) - r] + \beta [\sum p_i y_i - wC(\cdot)]
\]
Using the notation $U_i$ for $\frac{\partial U}{\partial y_i}$, $U_r = \frac{\partial U}{\partial r}$, and so on, we have the first order conditions

$$U_i - \alpha C_i + \beta (mr_i - wC_i) = 0,$$

where $mr_i = \frac{\partial \sum p_jy_j}{\partial y_i}$ is the marginal revenue of $i$, and

$$U_r - \alpha = 0.$$

Since consumer equilibrium requires equality between price ratios and marginal rates of substitution (the ratios of marginal utilities) we have

$$\frac{U_i}{\rho_i} = \frac{U_r}{w} = k, \ (i = 1, \ldots, n)$$

so that (5) yields $U_i = kw = \alpha$, and therefore (4) becomes

$$p_i - wC_i + (\beta / k) (mr_i - wC_i) = 0,$$

which, writing $mc_i = wC_i$, yields the general Ramsey formula (1). To obtain the inverse elasticity formula (2) we simply use a standard relationship for the case of independent demands,

$$mr_i = p_i (1 - 1 / E_i),$$

substituting this into (6) we have
\[ p_i - mc_i = (\beta / k)(p_i - mc_i - p_i / E_i), \]

or

\[ (1 - \beta / k)(p_i - mc_i) = - (\beta / k) p_i / E_i \]

which immediately yields (2).

Applications

Aside from its obvious connection with pricing by the firm, the theorem also has applications to the principles of taxation and to the general equilibrium analysis of the economy. Indeed, Frank Ramsey presented his result as a theorem on taxation rather than pricing. The point is that, the theoretical concept of lump-sum taxes aside, any tax must be a levy on some sort of economic activity. Even if the price of that activity's product is equal to its marginal cost, the tax will in general drive a wedge between the two, particularly if the total tax revenue is required to meet some particular target. Thus the problem of determining the vector of tax rates on the economy's activities that will meet the overall revenue target with minimum social welfare loss is equivalent to determining the optimal vector of deviations between prices and marginal costs that will satisfy that revenue (budget) constraint. In sum, the search for the optimal (budget constrained) prices and the optimal (revenue constrained) tax rates are formally equivalent.

The analysis also has direct implications for general equilibrium theory, for it tells us that if lump-sum taxes are impossible, then a vector of (first-best) marginal cost prices may also be ruled out for the economy as a whole. Indeed, such a first-best parametric price solution is possible only if, at the corresponding vector of activity levels (outputs), the production frontier happens to be locally linear and homogeneous (meaning, in the differentiable case, that it must be tangent to a hyperplane through the origin in input–output space).

For suppose this is not so – say, that there are increasing returns to scale at any such point. Then marginal cost pricing will yield negative profits for the economy, and suppliers as a class will be able to survive financially with such prices only if they receive subsidies. But subsidies must be paid for by taxes, and any such taxes on activities whose pre-tax prices equal their marginal costs must yield after-tax prices which do not. In sum, one cannot escape the problem of finding the deviations of prices from their ‘first best’ magnitudes which meet the budget requirement that every subsidy must be covered by tax revenues. This, then, is the inescapable Ramsey problem for the entire economy if prices are parametric and no optimal output vector is a point of (at least local) linear homogeneity.

The case of diminishing returns poses corresponding problems, even though it is often thought to be compatible with competitive equilibrium and marginal cost pricing. As long as input quantities (including the input of entrepreneurship) can be expanded, marginal cost pricing will be incompatible
with equilibrium at an optimal point because marginal cost pricing will then yield positive economic
profits and the number of firms will therefore increase. There can be no finite number of firms at which
this manifestation of disequilibrium ceases unless marginal cost pricing is abandoned. But then the best
equilibrium prices in terms of Pareto optimality must again be the Ramsey prices.

In sum, Ramsey pricing is no mere artifact of regulation of industry or tax policy. It is deeply embedded
in the logic of the general equilibrium mechanism.

History of Ramsey analysis

The basic theorem apparently first appeared in Frank Ramsey's classic article (1927). While the article
has sometimes attracted the attention it deserved, it did not effectively convey to the profession the
wider implications of its second-best pricing analysis. In 1928 A.C. Pigou, who had apparently posed the
original issue to Ramsey, published a restatement of the theorem. Here, too, it was presented as a result
on the principles of taxation and not related to pricing. Ursula Hicks (1947) independently provided a
similar discussion.

Perhaps the first work on Ramsey theory that was expressed in terms of pricing issues occurred in the
aftermath of Hotelling's (1938) classic paper on marginal cost pricing. There the author had advocated a
system of subsidies to firms subject to scale economies, but he himself came to recognize the tax
implications and the consequences for the overall optimality of the solution. He and J.R. Hicks discussed
the problem, and Hicks emerged with an independently discovered Ramsey theorem, which was never
published.

Early after the Second World War, two major contributions were made to the literature. Paul Samuelson
(1951) prepared a memorandum for the US Treasury pointing out the logic of the Ramsey approach to
taxation. As is to be expected, Samuelson's contribution was highly sophisticated and offered substantial
original insights, but, although widely circulated in public finance circles, it was never published. After
having published a less sophisticated version of the theorem in 1951, Marcel Boiteux, Directeur-Général
of Électricité de France 1967–87, published a major article on the subject in 1956. It explicitly dealt with
the topic as an issue in pricing policy for nationalized or regulated firms and derived its results directly
from a Pareto optimality model. Moreover, it provided a result more general than the inverse elasticity
form of the theorem on which Ramsey and Pigou had focused.

An even deeper exploration of the subject was provided by Diamond and Mirrlees (1971) as part of their
continuing work on the theory of optimal taxation. Their papers are important not only because of their
careful analysis but also because they played a major role in bringing the subject to the profession's
attention. Within a year or two of the appearance of their articles and that of Baumol and Bradford
(1970), ‘everyone’ in the profession was fully aware of the notion of Ramsey pricing and its logic. Since
then there has been an explosion of writings on the subject and it occurs centrally or peripherally in a
wide variety of fields.

An illustrative and perhaps surprising application which suggests the unexpected places in which the
construct can turn up, is the ‘weak invisible hand theorem’, that occurs in the contestable markets
literature (see Baumol, Bailey and Willig, 1977). That theorem states that if a monopolist who is
constrained by a regulatory (or other) profit ceiling chooses to adopt the Ramsey price vector rather than
some other set of prices that enable him to earn his allowed return, then under a fairly attractive set of
assumptions the monopolist will be rewarded for his virtuous decision by being protected from entry by those prices. In other words, self-interest may impel a monopolist to adopt Ramsey prices because those prices are *sustainable* against entry, meaning that at those prices the monopolist will earn the profits that the constraint allows to him, but any rival firm that undertakes to enter the field will be predestined to lose money even if the incumbent undertakes no strategic (retaliatory) response. Today Ramsey pricing is accepted as a basic proposition of microanalysis and appears with great frequency in new writings on the theory of the firm, industrial organization and public finance; it recurs regularly in the pricing discussions of American regulatory agencies.

How to cite this article

There are interesting parallels in the careers of Frank Ramsey and John von Neumann. Each was born in 1903, one the product of the ‘High Intelligentsia of England’ (Keynes, 1933, p. vii) and the other the son of a wealthy banker in Budapest (Ulam, 1976, p. 79). Each was a creative mathematician of high order but each also made major contributions to at least two other disciplines. Each wrote just three papers in economic theory, all six of which were of fundamental importance. Moreover, with one exception every one of these seminal papers had to wait many years for its proper recognition; even the exception – the utility theory set out in the Appendix to von Neumann and Morgenstern (1947) – at first encountered serious misunderstanding within the profession. Indeed, considering them purely as economists, one wonders how these two geniuses would fare today, when promotion and tenure so often depend on a good immediate showing in citation indexes and the like.

The three papers of Ramsey are in subjective probability and utility (1926), optimal taxation (1927), and optimal one-sector growth (1928), while those of von Neumann are in game theory (1928), optimal multi-sector growth (1937; 1945–6), and objective probability and utility (1947). It is quite striking that their work both on growth theory and on choice under uncertainty should be so complementary, especially since there is no evidence that von Neumann knew of Ramsey's work in either field.

Another and grievous similarity was that both men died early, Ramsey on 19 January 1930 of complications associated with jaundice, and von Neumann (twice Ramsey's age) on 8 February 1957 of cancer. Both losses were tragic, especially that of the 26-year-old Frank Ramsey, whose ‘death at the height of his powers deprives Cambridge of one of its intellectual glories and contemporary philosophy of one of its profoundest thinkers’ (Braithwaite's Introduction to Ramsey, 1931, p. ix).
Life

Frank Plumpton Ramsey was born in Cambridge on 22 February 1903. His father was a mathematician, Fellow and later President of Magdalene College (Harrod, 1951, pp. 141, 320), and his brother Michael became Archbishop of Canterbury. He was educated at Winchester and at Trinity College Cambridge, and was a Scholar of both those ancient foundations. In the autumn of 1924 he became Fellow of King's College and University Lecturer in Mathematics and soon afterwards married Lettice Baker, who had been a student in the Moral Sciences Tripos. After his death she became a founder of Ramsey and Muspratt, a firm of portrait photographers that has long been an Oxbridge institution. She survived into the 1980s, in vigorous old age.

In physical appearance Ramsey was tall and portly, the latter a feature he shared with von Neumann; ‘I take no credit for weighing nearly 17 stone [238 pounds]’ (1931, p. 291). All accounts agree as to his simplicity and modesty, qualities which are happily reflected in his engaging literary style. ‘Ramsey reminds one of Hume more than of anyone else, particularly in his common sense and a sort of hard-headed practicality towards the whole business’ (Keynes, 1933, p. 301). But his unfailing cheerfulness did not disguise ‘the amazing, easy efficiency of the intellectual machine which ground away behind his wide temples and broad, smiling face’ (Keynes, 1933, p. 296). ‘He comes down to earth, however, with a satisfying bump, and earth is certainly the natural element of my old friend Lettice’ (Partridge, 1981, p. 129).

Ramsey and Wittgenstein

For many years it was thought that while still an undergraduate Ramsey assisted in the translation of the German text of Wittgenstein's *Tractatus Logico-Philosophicus* (1922). It now appears that ‘the first draft of the translation was produced by F.P. Ramsey alone’ (von Wright, 1982, p. 102). Just 19, he dictated it directly to a stenographer in the University Typing Office in Cambridge in the winter of 1921–2 (reminiscent, on a smaller scale, of the 19-year-old ‘John S. Mill’ beginning in 1825 to edit Bentham's massive Rationale of Judicial Evidence). Wittgenstein seems to have been pleased with Ramsey's translation (1973, p. 77), and a fast friendship was thereby established between the two philosophers that lasted for the rest of Ramsey's short life.

In September 1923 the Tractatus had been published for almost a year. Not only had Ramsey been its main translator but he had also written a long and penetrating review of it for Mind (reprinted in 1931, pp. 270–86). But still there were many passages which remained unclear to him. To remedy this he made a special journey to Austria, where Wittgenstein was teaching in the local school of a small village and living in spartan conditions. The eccentric philosopher and the brilliant undergraduate hit it off immediately. Ramsey stayed two weeks, spending every afternoon from 2 to 7 elucidating the great man's work: ‘we get on about a page an hour’ (Wittgenstein, 1973, p. 79).

In the several letters that Ramsey afterwards wrote to Wittgenstein we can glimpse what Keynes meant in referring to ‘the simplicity of his feelings and reactions, half-alarming sometimes and occasionally almost cruel in their directness and literalness’ (Keynes, 1933, p. 296). Consider for example these passages from his letters of 12 November and 20 December 1923 (Wittgenstein, 1973, pp. 81–3):
I have not been doing much towards reconstructing mathematics; partly because I have been reading miscellaneous things, a little Relativity and a little Kant, and Frege … But I am awfully idle; and most of my energy has been absorbed since January by an unhappy passion for a married woman, which produced such psychological disorder, that I nearly resorted to psychoanalysis, and should probably have gone at Christmas to live in Vienna for nine months and be analysed, had not I suddenly got better a fortnight ago, since when I have been happy and done a fair amount of work.

I think I have solved all problems about finite integers, except such as are connected with the axiom of infinity, but I may well be wrong.

[December 20th] I was silly to think I had solved those problems. I'm always doing that and finding it a mare's nest … I have been trying to prove a proposition in the *Mengenlehre* either $2^{\aleph_0} = \aleph_1$ or $2^{\aleph_0} \neq \aleph_1$, which it is no one knows but I have had no success. (His italics)

In 1924 Ramsey actually did spend six months in Vienna in psychoanalysis (rarer then than now), after which 'I feel that people know far less about themselves than they imagine, and am not nearly so anxious to talk about myself as I used to be, having had enough of it to get bored' (1931, p. 290). The mathematical problem referred to in his second letter was of course the famous Continuum Hypothesis. His lack of success in this is scarcely surprising, since in the 1960s Paul Cohen showed the Hypothesis to be an undecidable proposition within Zermelo–Fraenkel set theory (see, for example, Cohen, 1966). It was, incidentally, a continual disappointment to von Neumann that it was not he but his hero Kurt Gödel who made the startling discovery, in 1930–31, of the necessary existence of such undecidable propositions (Ulam, 1976, pp. 76, 80).

Wittgenstein returned to Cambridge early in 1929 and began those ‘innumerable conversations’ with Ramsey that are acknowledged in the Preface/Foreword (dated January 1945) to his *Philosophical Investigations* (1953, p. x). Unfortunately, these were cut short by Ramsey's tragic death, a moving account of which may be found in Frances Partridge's *Memories* (1981, pp. 169–82); the grieving Wittgenstein was at Ramsey's bedside in the hospital until a few hours before he died. The only other person acknowledged by name in the Preface to the *Investigations*, and for even greater help than Ramsey gave, was Piero Sraffa. The trio of Ramsey, Sraffa and Wittgenstein must have been a formidable discussion group indeed; a treasured piece of Cambridge folklore is a lunch at which the three of them discussed Keynes's theory of probability with its author. The odd pattern of belated recognition of intellectual indebtedness was continued in Sraffa's acknowledgement (1960, pp. vi–vii) of Ramsey's help, a mere 30 years after the fact.

**Works**

Ramsey's early work in philosophy was a continuation of the methods of Russell and Whitehead's *Principia*, but it is clear that the influence of Wittgenstein and the evolution of his own thinking were
moving him towards the end of his life in a quite different, more pragmatic direction. These later contributions were left fragmentary and incomplete at his death, but a very brief account of them and their relations to modern philosophy may be gleaned from the first two Introductions to the revised edition (1978) of (1931).

In mathematics proper, as distinct from the foundations of mathematics, his main contribution is a fundamental theorem which appeared actually as a byproduct of a paper of 1928 on formal logic (reprinted in 1931, pp. 82–111). It reads (1931, p. 82):

**Theorem A**: Let \( \Gamma \) be an infinite class, and and \( r \) positive integers; and let all those sub-classes of \( \Gamma \) which have exactly \( r \) members, or, as we may say, let all \( r \)-combinations of the members of \( \Gamma \) be divided into \( \mu \) mutually exclusive classes \( C_i(i=1, 2, \ldots, \mu) \), so that every \( r \)-combination is a member of one and only one \( C_i \); then, assuming the Axiom of Selections [i.e. the Axiom of Choice], \( \Gamma \) must contain an infinite sub-class \( \Delta \) such that all the \( r \)-combinations of the members of \( \Delta \) belong to the same \( C_i \).

This beautiful result was ignored until 1935, when it was essentially rediscovered by Paul Erdös and Esther Szekeres. Gradually, it led to the formation of a subdiscipline of combinatorial analysis known as Ramsey Theory, which already contains many hundreds of papers and is growing at a remarkable rate (see the survey by Graham, Rothschild and Spencer, 1980).

Ramsey's pioneering paper on optimal taxation seems to have been written in response to a request by Pigou to look into the problem (see Pigou, 1928, pp. 126–8) but his work on the theory of growth was apparently his alone, although greatly admired by and discussed with Keynes.

**Mathematical expectation, probability and utility**

The present discussion of Ramsey's great Chapter VII (1931, pp. 156–98) will consider it quite narrowly, as a contribution only to the theory of choice under uncertainty, and thus neglect the important question of its relation to traditional theories of probability. Ramsey himself adopted throughout a modest and peaceable tone towards probability theory, stressing that ‘the meaning of probability in logic’ may be quite different from ‘its meaning in physics’ (p. 157).

The chapter is entitled ‘Truth and Probability’ and dated 1926; presumably most of it was written then, in spite of a reference which bears the date 1927. It contains almost all of what he has to say on the subject, although further on in Chapter VIII and pages 256–7 there are a few unsystematic comments and glosses on the earlier work. The first ten pages form a critique of Keynes's theory of probability (1921), which may well have stimulated his own interest in the whole subject, so it is not until Section 3 that Ramsey begins his ‘inquiry … [into] … the logic of partial belief’.

Ignoring here all his careful qualifications, the theory outlined in that Section begins as follows (pp. 172–4):

The old-established way of measuring a person's belief is to propose a bet, and see what are the lowest odds which he will accept. This method I regard as fundamentally sound; … I propose to take as a basis a general psychological theory … that we act in the way we think most likely to realize the objects of our desires … The question then arises how … to take account of varying degrees of certainty in his beliefs. I suggest that we introduce as
a law of psychology that his behaviour is governed by what is called the mathematical expectation; ... We thus define degree of belief in a way which presupposes the use of the mathematical expectation. (Italics added).

Ramsey was fully aware of the crucial dependence of his approach on mathematical expectation. Later in the Foundations he asks: ‘The question ... why just this law of mathematical expectation. The answer to this is that if we use probability to measure utility, as explained in my paper, then consistency [for which see below] requires just this law’ (p. 251).

Putting the matter in its crudest (and so necessarily inaccurate) form, mathematical expectation as a principle of choice involves the use for any risky line of action $\alpha$ of a ‘probability’ $\pi_i$ and a ‘valuation’ $\nu_i$ attached to each of the possible outcomes $\alpha_i$ that constitute $\alpha$, in such a way that: (i) the expected valuation $E(\alpha)$ of $\alpha$ is $\sum \pi_i \nu_i$ (or an appropriate integral if $\alpha$ has infinitely many members, an alternative which Ramsey expressly rejects: pp. 183–4); and (ii) $\alpha$ is chosen rather than another risky line of action $\beta$ if and only if $E(\alpha) > E(\beta)$.

Implicit in this crude form is a conflation between events and outcomes. Outcomes depend upon decisions and events, and it is in events and not outcomes that the randomness present is usually held to reside, so that given the occurrence of an event the relevant outcome on which it depends follows deterministically. Nevertheless, the randomness that inheres in the events may be transferred to the outcomes that are conditional upon those events. In the words of Arrow (1951; 1971, p. 26): ‘no matter how complicated the structure of a game of chance is, we can always describe it by a single probability distribution of the final outcomes.’

Notice that because mathematical expectation depends linearly both on the probabilities and on the valuations, choice that follows this principle is made according to a bilinear form; there is however no necessity for the valuations of the possible outcome themselves to depend linearly upon those outcomes.

Essentially, given any two of the three concepts, mathematical expectation, probabilities and valuations, the remaining one follows more or less naturally. For example, in Daniel Bernoulli’s account of the theory of risk (1738), the $\pi_i$ are apparently given ‘objectively’, for example by the tosses of a coin.

Wishing to preserve the principle of mathematical expectation, and citing the St Petersburg Paradox as evidence for the inappropriateness of using money itself as valuation, Bernoulli was thus led to a specific utility function to compute the correct valuations, this being a nonlinear (actually, concave) function of wealth. This did not in fact resolve the basic difficulty of the Paradox (which resides in unboundedness of the mathematical expectation) but it was a novel and important idea that was very influential.

A quite different approach was used by Bayes (1763; 1958), who actually defined probability in terms of mathematical expectation: ‘The probability of any event is the ratio between the value at which an expectation depending on the happening of the event ought to be computed, and the value of the thing expected upon its happening’ (1958, p. 298; Jeffreys, 1961, pp. 30–4, stresses the similarity here between Bayes and Ramsey). Possibly in ignorance of the earlier contribution, Bayes retained monetary valuations rather than replace them by Bernoullian utilities.

Both authors regarded the maximization of the mathematical expectation of gain as the appropriate principle of choice in an uncertain situation. But whereas Bernoulli accepted probabilities from the outside and altered the meaning of valuations so as to achieve consonance between the maximization of
mathematical expectation and rational choice, Bayes started with the outside monetary valuations and thence determined probabilities so as to square rational choice with mathematical expectation. Ramsey was more subtle. He effectively 'bootstrapped' both the valuations and the probabilities from mathematical expectation, at the small cost of: (a) a very general assumption about preferences; (b) an assumed existence of a certain kind of event; and (c) a further principle, original with him, that no agent's subjective probabilities should be inconsistent. To be inconsistent means that 'He could have a book made against him by a cunning better and would then stand to lose in any event' (1931; p. 182); this no-win situation is now usually called a Dutch book.

**Sketch of a proof**

Ramsey provided sufficient detail for a formal proof of the existence of valuations and probabilities to be constructed from his system of axioms, but he did not construct one himself. Such proofs, for varying circumstances, have been given by Davidson and Suppes (1956) and Vickers (1962), while more informal discussions may be found in Jeffrey (1965; 1983, ch. 3) and Luce and Suppes (1965, pp. 291–4). Only the merest sketch is attempted here, and its mild technical detail follows Davidson and Suppes (1956) rather than Ramsey's original treatment, which was couched mainly in the concepts of Wittgenstein's Tractatus and the language of Russell and Whitehead's Principia, both long since unfamiliar.

Ramsey begins by considering the case where the agent has 'certain [that is, sure] beliefs about everything'. He then adopts assumption (a) above, which expressed in modern language says that the agent has a complete preference preordering over 'all possible courses of the world … [though] … we … have no definite way of representing them by numbers' (1931, p. 176). Vickers points out that if different preferences can themselves be parts of different 'courses of the world' then the argument is ambiguous, and if not then the question is begged (1962, pp. 6–11); however, he shows how to resolve these problems by suitable amendment of Ramsey's definitions.

When 'the subject is capable of doubt' (p. 177), the theory proceeds by offering options. Suppose that the agent has two options: the first is $\alpha$, in which he receives $x$ if an event $e$ occurs and a preferentially different outcome $y$ if it does not; and the other is $\beta$, in which he receives $r$ if $e$ occurs and another outcome $s$ if it does not. Assuming that probabilities $\pi(e)$ and $\pi(e')$ can be attached to the events $e$ and to $e'$ (the complement of $e$), respectively, and that valuations $\nu(x), \nu(y)$, and so on, can be placed on the outcomes $x, y, r$ and $s$, then the principle of mathematical expectation says that $\alpha$ is better than, indifferent to, or worse than $\beta$, according as

$$\pi(e) \nu(x) + \pi(e') \nu(y) > ; = ; < \pi(e) \nu(r) + \pi(e') \nu(s). \quad (1)$$

Ramsey's next assumption is (b) above, to the effect that there exists some event, say $e^*$, such that for every pair $(m, n)$ of preferentially distinct outcomes the subject is indifferent between the option $\gamma$
consisting of \( m \) if \( e^* \) and \( n \) if not \( e^* \), and another option \( \delta \) consisting of \( n \) if \( e^* \) and \( m \) if not \( e^* \). According to the principle of mathematical expectation, this implies

\[
\pi(e^*)\nu(m) + \pi(e^*)\nu(n) = \pi(e^*)\nu(n) + \pi(e^*)\nu(m).
\]

(2)

Since \( m \) and \( n \) are preferentially distinct, their valuations must be such that \( \nu(m) \neq \nu(n) \). Then from this and (2) it follows that necessarily

\[
\pi(e^*) = \pi(e^*)\nu(n) = \pi(e^*)\nu(n).
\]

(3)

Although quantitative probabilities have not yet been defined, (3) shows that there is a clear qualitative sense in which event \( e^* \) has a (subjective) probability of 1/2, provided that the subjective probabilities of an event and its complement sum to unity. Ramsey terms ethically neutral any event (in his language, prpt) that has the properties of \( e^* \); the force of the word ‘ethically’ is not explained (p. 177). The assumption that such events (prpts) exist is perhaps the weakest part of his theory of choice under uncertainty, although before it is rejected out of hand the careful philosophical discussion of it by Vickers (1962) and the equally careful empirical applications of it discussed by Davidson and Suppes (1956) should be consulted.

Now take the case of (1) where \( e \) is an ethically neutral event \( e^* \) and the option \( \alpha \) is indifferent to the option \( \beta \). Then from (1) and (3),

\[
\nu(x) - \nu(r) = \nu(s) - \nu(y).
\]

(4)

This says that differences in valuations can be equated, so that the latter are measurable by an interval scale; or what comes to the same thing, that they are measurable up to choice of unit and origin, so that for any other such scale \( \mu \), \( \mu(\cdot) = \alpha + b\nu(\cdot) \), where \( b > 0 \).

A valuation having been obtained in this fashion for each outcome, and assuming again that for any event \( e \), \( \pi(e) + \pi(e') = 1 \), it follows from the case of equality in (1) that
This gives a way of calculating the subjective probability $\pi(e)$ of any event, ethically neutral or not, in a way compatible simultaneously with the principle of mathematical expectation and with the valuations $v(\cdot)$ of the possible outcomes. Thus both valuations (‘utilities’) and subjective probabilities have been bootstrapped, in that order, from the simple assumptions (a) and (b), plus the assumption that any event and its negation have subjective probabilities that add up to 1. Ramsey dispenses with this last, auxiliary assumption by means of his principle (c) of consistency, which in effect insists upon the impossibility of Dutch books.

### Dutch books

Although his paper is crystal clear that consistency means that the subjective probabilities of any set of disjoint and exhaustive events must sum to 1, and it is twice stated explicitly (pp. 182–3) that anyone who is not consistent in this sense can have a Dutch book made against him, Ramsey provided no formal proof of equivalence between these two ideas. Hence this result is usually attributed to de Finetti (1937; 1964), who gave a very neat proof. Not having read Ramsey’s paper, de Finetti like Bayes worked with monetary valuations in his account of personal probability, though he admitted later (1964, p. 102 fn(a)) that ‘Such a formulation could better, like Ramsey’s, deal with expected utilities; I did not know of Ramsey’s work before 1937, but I was aware of the difficulty of money bets.’ What follows is a free adaptation of de Finetti’s proof to Ramsey’s problem.

Let there be $n$ mutually incompatible and together exhaustive events $e_i$, for example, the faces of a die. Suppose then that I, knowing your subjective probabilities $\pi_i$, offer you the following wager: If $e_i$ occurs I pay you $\sigma_i$. In return, you pay me an initial stake of $\sum \pi_i \sigma_i$ valuation units, where the sum is taken over the $n$ events. If you behave according to Ramsey’s theory of choice under uncertainty, then you should be on the margin of accepting this wager, since for you to attach probability $\pi_i$ to $e_i$ is to say that you would be indifferent between the following offers: receive $\sigma_i$ valuation units contingent on the occurrence of $e_i$, and the amount $\pi_i \sigma_i$ for sure. Since by hypothesis the $e_i$ are exclusive events, the separate amounts $\pi_i \sigma_i$ may be added together.

If event $e_h$, occurs, your gain is

$$
\gamma_h = \sigma_h - \sum \pi_i \sigma_i \quad h = 1, 2, \ldots, n.
$$

(6)

These are $n$ linear equations, which can be put into matrix–vector notation. Writing $g$ and $s$ for the...
vectors of the $\gamma_i$ and $\sigma_i$, respectively, $I$ for the $n \times n$ identity matrix, and $P$ for the matrix whose $(i,j)$th element is $\pi_j$, the equations (6) become

$$g = (I - P)s.$$  

(7)

Computation shows that $\det(I-P)=1-\sum \pi_i$. So if $\Sigma \pi_i \neq 1$, then for any desired vector of gains $g$ stakes $s=(I-P)^{-1}g$ can be computed that will guarantee me the vector $-g$. In particular, I can specify $g$ to be strictly negative, thus ensuring that you will lose whatever event occurs.

Conversely, suppose that your subjective probabilities are what de Finetti called coherent (and Ramsey, consistent), so that by definition $\Sigma \pi_i = 1$. Then, multiplying each equation in (6) by $\pi_h$ and adding over all events,

$$\sum \pi_h \gamma_h = \sum \pi_h \sigma_h - \sum \pi_h \sum \pi_i \sigma_i = 0.$$  

(8)

Since each $\pi_h \geq 0$ and their sum is non-zero, it follows from (8) that not all the $\gamma_h$ can be negative. Hence the condition that your subjective probabilities $\pi_i$, sum to 1 for all complete sets of incompatible events $e_i$, that is, that you obey the rules of probability calculus, is necessary and sufficient in order that no Dutch book can be made against you.

The reception of ‘Truth and Probability’

Ramsey's theory of choice under uncertainty was deeply original. Emile Borel, in his review (1924; 1964) of Keynes's theory of probability, had earlier sketched an interesting theory of subjective probability in terms of bets (note in particular his remark that ‘the method of betting permits us in the majority of cases a numerical evaluation of probabilities that has exactly the same characteristics as the evaluation of prices by the methods of exchange’; 1964, p. 57), but nobody had come close to the depth and comprehensiveness of Ramsey's theory. He was characteristically modest about its range of application: ‘I only claim for what follows approximate truth … like Newtonian mechanics … [it] can, I think, still be profitably used even though it is known to be false’ (p. 173).

Perhaps because the theory was too original, such modesty did not help its author, any more than his high reputation as a philosopher. I can find no evidence that anyone, let alone any economist, took any serious notice of Ramsey's work until after von Neumann and Morgenstern's quite separate utility theory had appeared in 1947. The latter theory was very much in the Bernoullian tradition, in which the
probabilities are given from outside, ‘objectively’. Coupling these with a complete preference preordering for such alternatives, suitable continuity, and the principle of mathematical expectation in the form of the independence axiom, the authors were able to deduce the existence of a utility function, unique up to positive affine transformations, which gave valuations compatible both with the outside probabilities and that principle.

The first published reference to Ramsey's theory known to me appears in Little (1950, p. 29, fn.1), who considered it ‘essentially the same’ as that of von Neumann and Morgenstern. Little's reference was soon followed by one in Arrow (1951), who acknowledged that Ramsey was brought to his attention by Norman Dalkey. Though complaining that ‘Ramsey's work was none too clear’ (1971, p. 26), Arrow did see that it originated ‘a new stage’ in decision theory, ‘in which a priori probabilities are derived from behavior postulates’ (1971, p. 22). Thereafter there was a gradual increase in the appreciation of Ramsey's contribution, although even as late as 1954 an excellent collection of papers on decision theory (Thrall, Coombs and Davis, 1954) contained not one reference to his work.

It is a common mistake to suppose that the line of descent in the theory of personal probability is direct from Ramsey to de Finetti (1937) to Savage (1954). We have seen that de Finetti did not know of Ramsey's work, his own remarkable contribution being very much in the Bayesian tradition which takes the valuations from outside and thence derives the probabilities. Moreover, a careful reading of Savage's fine book shows that Ramsey's influence was at best peripheral, the axiomatization of probabilities and valuations proceeding far more along the lines developed by de Finetti.

There have in fact been relatively few explicit exponents of Ramsey's approach. The most notable are probably Davidson and Suppes (for example, 1956) and Anscombe and Aumann (1963), who used an interesting bootstrapping argument to go from assumed probabilities for what they called ‘roulette’ lotteries to valuations, and thence to subjective probabilities for the much wider class of ‘horse’ lotteries, all very much in the Ramsey manner.

The direct heirs to Ramsey's work have been few but there is no doubt that its influence has been pervasive, to such extent that chairs in decision theory at US business schools have been named after him (though with what warrant is hard to say). Arrow (1965, p. 57) claimed that all arguments involving the expected-utility hypothesis ‘are only variations of Ramsey's’, while Savage (1962, p. 10) wrote that the ‘more thorough-going … formulation of Ramsey (1931) … is in no way obsolete’. Even now, not to experience that ‘clear purity of illumination with which the writer's mind is felt by the reader to play about its subject’ (Keynes on Ramsey, 1928) is a sad loss for the modern student.

rational behaviour

Amartya Sen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A clear distinction must be drawn between (a) the type of behaviour that might be described as *rational*, and (b) rational behaviour models that might be useful in making predictions about *actual* behaviour. Neither of the two standard views of rational behaviour – as ‘consistent choice’ or as ‘self-interest maximization’ – has emerged as an adequate representation of rationality or of actuality. The difficulties that these views encounter carry over to rational behaviour models accommodating uncertainty.

Keywords

adaptive expectations; binariness; bounded rationality; cardinal utility; choice; completeness; enforced maximization; Exchange; expectation formation; expected utility; externalities; instrumental rationality; natural selection; Pareto efficiency; preferences; Prisoner's Dilemma; probability; rational behaviour; rational expectations; revealed preference theory; risk; satisficing; self-interest; Sen, A. K.; social norms; strong independence; substantive rationality; sure thing principle; transitivity; uncertainty; utilitarianism

Article

The concept of rational behaviour is frequently used in economic theory. The interest in this concept springs from two quite distinct motivations. First, in so far as economic exercises often take a prescriptive form, it is interesting to know how one could behave rationally in a given situation. This may be called the ‘prescriptive motivation’. It should be warned that the prescription need not be necessarily of an ethical kind. Indeed, the prescriptive motivation is sometimes described in clearly non-ethical terms, involving the pursuit of self-interest only. In a classic presentation of this position, Harsanyi (1977) describes ‘perfectly rational behaviour’ in the context of game theory in the following terms:

… our theory is a *normative* (prescriptive) theory rather than a *positive* (descriptive)
theory. At least formally and explicitly it deals with the question of how each player \textit{should} act in order to promote his own interests most effectively in the game and not with the question of how he (or persons like him) \textit{will} actually act in a game of this particular type. (Harsanyi, 1977, p. 16)

The second motivation concerns the possible use of models of rational behaviour in explaining and predicting \textit{actual} behaviour. This exercise is done, as it were, in two steps. The first step consists in characterizing rational behaviour and the second, following that, bases actual behaviour on rational behaviour. In this way the characterization of rational behaviour may end up specifying the predicted actual behaviour as well. This motivation underlies much of the theory of general equilibrium (see, for example, Edgeworth, 1881; Arrow, 1951; Debreu, 1959; Arrow and Hahn, 1971). The argument is that while actual behaviour can, in principle, take any form, it is reasonable to assume that much of the time it will, in fact, be of the kind that can be described as ‘rational’.

In reviewing the theory of rational behaviour, this duality of motivations has to be borne in mind. Even though the primary concern of this essay is with the way rational behaviour has been characterized, the nature of the second motivation makes it imperative that the possible use of rational behaviour models for explaining and predicting actual behaviour must not be overlooked.

\textbf{Rationalizability, binariness and self-interest}

In the presence of uncertainty, rational behaviour requires an appreciation of possible variations in the outcome of any chosen action, and such behaviour must, therefore, be based on systematic reading of uncertainties regarding the outcome and ways of dealing with them. Rational behaviour under uncertainty will be presently taken up, but before that the more elementary case when there is no uncertainty has to be dealt with. In fact, behaviour under certainty can be formally seen as an extreme case of behaviour under uncertainty when the uncertainty in question is not only small but simply absent. In this sense, rational behaviour under certainty must be subsumed by any theory that deals with rational behaviour in the presence of uncertainty.

Although there are many different approaches to rational behaviour under certainty, it is fair to say that there are two \textit{main} approaches to this question. The first emphasizes \textit{internal consistency}: rationality of behaviour is identified with a requirement that choices from different subsets should correspond to each other in a cogent and systematic way. Various conditions of internal consistency have been proposed in the literature, but the one which seems to command most attention in formal economic theory is \textit{binariness}, which requires that the choices from different subsets can be seen as maximizing solutions from the respective subsets according to some binary relation $R$ (often interpreted as ‘preference’, for example, $xRy$ standing for ‘$x$ being preferred or indifferent to $y$’). Or, to put it another way, rational behaviour, in this interpretation, amounts to our ability to find a binary relation $R$ over the universal set of alternatives such that the choice from any particular subset of that universal set consists of exactly the $R$-maximal elements of that subset. Richter (1971) calls this ‘rationalizability’.

In other formulations – still within the general approach of internal consistency – the condition of rationalizability has been relaxed, demanding only a part of the kind of consistency that binary maximization must entail. On the other hand, in some other formulations, the demands have been made
stronger than that of maximization according to a binary relation by requiring further that the binary relation in question be an ordering, satisfying both completeness and transitivity. An enormous variety of conditions of internal consistency have been proposed in the literature, but it can be shown that many of them are equivalent to each other, and indeed altogether they fall into a number of classes, with each class containing different, but essentially equivalent, demands. Such reductionist analyses can be found, for example, in Houthakker (1956), Uzawa (1956), Arrow (1959), Richter (1971), Sen (1971), Herzberger (1973), Suzumura (1983). For critiques (and arguments for the rejection of) the binary approach to rationality, see Kanger (1976), Gauthier (1985), Sen (1985a; 1986b) and Sugden (1985).

The second common approach to rational behaviour under certainty sees it in terms of reasoned pursuit of self-interest. The origins of this approach are often traced to Adam Smith, and it is frequently asserted that the father of modern economics saw human beings as tirelessly fostering their respective self-interests. As a piece of history of economic thought, this is, to say the least, dubious, since Adam Smith's (1776; 1790) belief in the hold of self-interest in some spheres of activity (for example, exchange) was qualified by his conviction that many other motivations are important in human behaviour in general (on this see Winch, 1978; Brennan and Lomasky, 1985; and Sen, 1987). But it is certainly true that the assumption of the ‘economic man’ relentlessly pursuing self-interest in a fairly narrowly defined form has played a major part in the characterization of individual behaviour in economics for a very long time.

**Self-interest and consistency**

Rational behaviour in the form of maximization in pursuit of self-interest makes the analysis of individual behaviour a good deal more tractable than a less structured assumption would permit. This is certainly one of its appeals. In addition this behavioural assumption is also quite crucial for the derivation of certain central results in traditional and modern economic theory, for example, Pareto optimality of competitive equilibria and vice versa (Arrow, 1951; Debreu, 1959; Arrow and Hahn, 1971). This is sometimes called the ‘Fundamental Theorem of Welfare Economics’. Roughly stated, it claims, first, that every perfectly competitive equilibrium (with each person maximizing utility, given the prices) under certain assumptions (such as no externalities) achieves Pareto optimality, and second, under a slightly different set of assumptions (including the requirement of no externalities, but also some additional requirements, such as the absence of increasing returns to scale), every Pareto optimal state is a perfectly competitive equilibrium with respect to some set of prices and some initial distribution of resources. This correspondence between Pareto optimality and competitive equilibria works neatly given individual self-interested behaviour precisely because Pareto optimality is one characteristic of self-interest maximization of a group, in the sense that in such a situation no one's self-interest can be further enhanced without hurting the self-interest of somebody else. It is the assumption of rational behaviour in the form of the pursuit of self-interest that established the close relationship between competitive equilibria and Pareto optimality (with price-taking behaviour and absence of externalities preventing people from getting in each other's way in their respective pursuit of self-interest). In this result and in many other similar ones, the particular characterization of rational behaviour chosen plays a strategically crucial role.
It can be argued that rational behaviour under the self-interest approach is a special case of that under the consistency approach. If a person does pursue self-interest, it may follow that his or her behaviour will have the consistency needed for maximization of a cogent function. On the other hand, a person can be consistent without necessarily maximizing self-interest, since the maximizing function may have a different interpretation altogether (for example, the pursuit of some moral values or political goals). Thus internal consistency of choice may be taken to be necessary but not sufficient for self-interested behaviour. There is undoubtedly something in this way of seeing the correspondence between the two common approaches to rational behaviour.

However, that alleged correspondence is also somewhat misleading, since the nature of self-interest need not necessarily take the uncomplicated form of being binary in character. Strictly speaking, neither does the self-interest thesis entail the consistency thesis, nor of course the other way round. While this must, in general, be correct, nevertheless the way self-interest has been actually viewed in standard economic theory has made it clearly binary and more typically an ordering (and often seen as being numerically representable). If self-interest must take this form, then it would indeed be the case that the self-interest approach is just a special case of the consistency approach.

In some treatises on rational behaviour, the distance between the self-interest approach and the consistency approach is bridged by some careful definitions. For example, in the ‘revealed preference theory’, pioneered by Samuelson (1938), consistency is demanded in the form of the ‘Weak Axiom of Revealed Preference’, to wit: if \( x \) is chosen from a set containing \( y \), then \( y \) will not be chosen from any set containing \( x \). This type of consistency is, on its own, without a particular substantive interpretation, except that it corresponds generally to some kind of maximization. However, the term ‘revealed preference’ might indicate that the chosen alternative is always also the preferred one. In so far as preference reflects self-interest (as is typically assumed to be the case), this established, through the terminology of ‘revealed preference’, what looks like a congruence of choice and self-interest. The consistency entailed by the Weak Axiom of Revealed Preference does not, in general, entail transitivity, which is a property that might be thought to be a natural one to impose on the relation of self-interest. But that hole can be plugged either by demanding stronger conditions (such as Houthakker’s, 1950, ‘Strong Axiom of Revealed Preference’) or by demanding that the consistency of the Weak Axiom be satisfied over all finite subsets, which makes the strong axiom equivalent to the weak (on this see Arrow, 1959; Sen, 1971). One way or another, the consistency imposed by revealed preference axioms can lead to a ‘preference’ relation that has the regularity properties normally associated with the concept of self-interest, and then the gap between the two could be seen as fully bridged.

However, that entire bridging exercise is based on defining the relation of choice as a relation of ‘preference’ which happens to be ‘revealed’ by the act of choice. But that terminology is arbitrarily imposed, and it is possible that the binary relation of choice, even when fully transitive and complete, may in fact reflect neither the person’s preference, nor his or her self-interest. There is, obviously, scope for methodological arguments on this point, and these issues have often been joined.

In the philosophical literature, it is common to distinguish between ‘instrumental rationality’ and ‘substantive rationality’ (see Latsis, 1976). It is clear that the self-interest view of rational behaviour is one of substantive rationality requiring that rational behaviour must take the form of pursuing some independently defined self-interest. Obviously, this characteristic of substantiveness is not satisfied by the theory of revealed preference, since there the identification of choice with preference or self-interest...
takes the form of defining the relation of choice as a relation of preference, which is not an independent way of characterizing preference or self-interest. But in other theories, the substantive exercise is carefully done, for example, in the typical general equilibrium theory (see Arrow, 1951; Debreu, 1959; Arrow and Hahn, 1971). The starting point of individual behaviour is, then, not a choice function but a utility function, representing the self-interest of the person in question. Choices follow from constrained maximization of that utility function. In this form, the substantive nature of the characterized rationality is strongly asserted, in the shape of pursuit of self-interest.

A number of criticisms have been recently made about the special nature of the assumption of self-interest maximization. Human beings may well have other motivations, and self-interest is just one of various things that a person might wish to pursue. Different types of criticisms of this substantive assumption have been made by such authors as Nagel (1970), Kornai (1971), Sen (1973; 1977; 1987), Scitovsky (1976), Leibenstein (1976), Schelling (1978), Wong (1978). Elster (1979; 1983), Hirschman (1982; 1983), McPherson (1982), Margolis (1982), Akerlof (1984), Schick (1984) and others.

If the assumption of self-interest maximization is seen as too narrow, it can be argued that merely requiring internal consistency is much too permissive. Indeed, it is tempting to think of the consistency approach as belonging to the ‘instrumental’ view of rationality. But this is not quite so, since the instrumental view requires that the person pursues some independently defined objective (even though the objective need not be based on self-interest only). In the consistency view there is no such independently defined function at all, and the binary relation that is precipitated by the choice function is a reflection of choice rather than a determinant of it. It is rather that the consistency approach opens the way to some instrumental view of rationality, involving the maximization of some objective function. Indeed, in this sense, the consistency approach can be seen as permissively admitting the approach of instrumental rationality implicit in the self-interest approach, where the objective function maximized happens to be the self-interest of the person in question.

The consistency approach can be criticized on grounds of inadequacy in characterizing rationality of behaviour. A person's choice function may be internally consistent in the sense that the different things chosen from different subsets correspond to each other in an apparently cogent and coherent way, but this does not in itself indicate that the person's behaviour is consistent with his or her aims or objectives. Indeed, a person who systematically does exactly the opposite of what has to be done for the pursuit of his or her objective function may end up producing a consistent choice behaviour, but the binary relation that will be revealed by the choices – the ‘opposite’ of the person's objective function – will be, clearly, at war with the goals and aims of that person. To describe such a person as behaving rationally would, obviously, lead to some interesting methodological difficulties.

Maximizing, satisficing and bounded rationality

These problems with the standard views of rationality tend to undermine the very foundations of these approaches. Some other approaches have involved more qualified use of the standard presumptions. For example, Herbert Simon (1957; 1979) has argued powerfully that individuals may not actually maximize any function at all, and their behaviour may take the form of what has been called ‘satisficing’. There are various ways of characterizing satisficing, but it can be thought of in terms of a person having a certain target level of achievement, which he or she will try to reach, but beyond which he or she may
not try to improve the achievement any further. There is a genuine problem of interpretation involved in analysing satisficing, and it can be argued that satisficing behaviour really is maximization according to an effectively incomplete relation, such that the states satisfying the target level of achievement are all put in a non-comparable class as far as choice behaviour is concerned. Maximization can indeed be defined in terms of such incomplete relations (see, for example, Debreu's 1959 analysis of ‘maximal’ sets based on ‘pre-orderings’), and, if it is seen in these terms, the gap between satisficing and maximizing may be, at least formally, reduced. However, the content of the claim of satisficing is that the person in question can tell between the different levels of achievement which are all beyond the target level required, and, despite this discernibility, choice behaviour departs from relentless maximization of the level of achievement. In this version of the story, a substantial difference is indeed made by the notion of satisficing, and the implications of satisficing behaviour may, in this interpretation, be quite different from those of maximization.

Variations of the maximization assumption and the related consistency conditions can be justified by seeing the use of reason in human affairs in terms of what has been called ‘bounded rationality’. In this structure human choice is seen not in terms of grand maximizing behaviour, but as a series of particular decisions, not fully integrated with each other, taken in situations of partial information and based on limited reflection. This approach has been developed by Herbert Simon (1957; 1979; 1983) both at a theoretical level and in the context of specific empirical applications. The results differ quite substantially from that of rational behaviour seen in terms of consistency, or in terms of optimization according to self-interest. As Simon puts it:

Rationality of the sort described by the behavioural model [of bounded rationality] doesn't optimize, of course. Nor does it even guarantee that our decisions will be consistent. As a matter of fact, it is very easy to show that choices made by an organism having these characteristics will often depend on the order in which alternatives are presented. (Simon, 1983, p. 23)

**Natural selection and motives**

Supporters of optimizing models have typically used two different types of arguments to defend the practice, against models of the kind characterized by ‘bounded rationality’ and other behavioural departures. One argument takes the direct form of arguing that human beings do optimize and take care to do so. The second argument suggests that natural selection will lead in this result: those who optimize do better, and those who do not get eliminated by natural selection. For example, non-profit-maximizing firms may go to the wall, so that only the profit-maximizing ones may survive (see Friedman, 1953). This type of indirect justification of what has been called ‘enforced maximization’ has many pitfalls, since the analogy with natural selection in biology is at best tenuous (see Helm, 1984; Matthews, 1984), and the biological story itself is far from straightforward (Dawkins, 1982; Maynard Smith, 1982).

It is by no means clear that individual self-interest-maximizers will typically do relatively better in a group of people with diverse motivations. More importantly, when it comes to comparisons of survival of different groups, it can easily be the case that groups that emphasize values other than pure self-interest maximization might actually do better (see Sen, 1973; 1974; 1985b; Akerlof, 1984). It has been
argued that economic success has often come more plentifully in cultures that emphasize norms of conduct quite different from that of persistent maximization of individual self-interest, focusing on other values (for example, what Morishima, 1982, calls ‘the Japanese ethos’; see also Dore, 1983). The relation between social norms and individual conduct is an enormously complex field, and the simple assumptions of self-interest maximization, of straightforward models of apparent ‘consistency’, may overlook important aspects of the individual–society relationships (see, for example, Hirschman, 1970; 1982). This is not to argue that ‘natural selection’ arguments are worthless in economics – they may be far from that – but the results of the selection may lack the simplicity demanded by supporters of simple optimization and may take a more complex form (see Hirshleifer, 1977; Helm, 1984; Matthews, 1984).

In assessing the overall value of standard models of rational behaviour, it is important to pay attention to the distinction made earlier between the value of these structures as representations of rationality and their usefulness in terms of predicting actual behaviour. Some of the deficiencies of the optimizing ‘structure apply specifically to the latter. For example, models of ‘bounded rationality’ are often defended by claims of greater plausibility in explaining actual human conduct.

In fact, the entire enterprise of getting to actual behaviour via models of rationality may itself be seen as methodologically quite dubious. There is scope for argument here on both sides, since the unrealism of rational behaviour may be large, but the unrealism of any specific kind of ‘irrational’ behaviour could be larger still. Whether ‘bounded rationality’ is the right kind of compromise in getting a grip on actuality via limited use of rationality remains an interesting question.

Reason and rationality

As far as the other objective of rational behaviour models is concerned, that is, the ability of these models to capture the essence of rationality (no matter how people do actually behave), there are a number of complex philosophical issues underlying the question. It is easy enough to argue that mere internal consistency of choice cannot be adequate for rationality, nor can self-interest maximization be seen as uniquely rational in a way that pursuing other kinds of objectives (such as altruism, public spirit, class consciousness, group solidarity) must fail to be. What is much harder to do is to develop an alternative structure for rationality that would be regarded as satisfactory for the purpose of capturing what can be demanded of reason in human choice (whether or not it also serves the second purpose of giving us a good guess regarding actual behaviour). This question remains, to a great extent, an open one, which has been as yet rather inadequately explored.

Two difficulties, in particular, may be worth mentioning in this context. First, while ‘instrumental rationality’ must have some place in economics, and the role of reasoned choice of means for serving given ends cannot be dismissed, it is hard to believe that any kind of objectives no matter how bizarre – must be seen as okay, that is, not compromising the rationality of the person pursuing it. The need for rational assessment of objectives and preferences have been analysed by John Broome (1978), Derek Parfit (1984) and others, and both the procedural and substantive features of this type of assessment do deserve serious attention.

Second, even when goals are clearly given, the translation of these into actions depends on the pattern of social interdependence assumed in group behaviour, with members having partly divergent goals. As the discussions on the so-called ‘Newcomb's problem’ and other complex cases have brought out, the
correct individual decision may not be entirely unproblematic even when there appears to exist a strictly
dominant strategy (see Nozick, 1969; Brams, 1975; Levi, 1975; Gibbard and Harper, 1978; Jeffrey,
1983, among others). The nature of beliefs permits alternative interpretations of the nature of the
decision problem, and this philosophical question is of relevance to decision problems in economics as
much as it is in other fields of human choice.
The Prisoner's Dilemma has been frequently used in economic arguments to illustrate the nature of
inefficiencies of atomistic non-cooperative behaviour when the interdependence incorporates both
congruence and conflict of interests in such a way that the combination of each person's dominant
strategies produces an outcome that is inferior in terms of the goals of everyone in the group (see Luce
and Raiffa, 1957). Attempts to resolve the problem by assuming temporal repetition of the game have
not been easy, since it can be demonstrated that with complete knowledge and standard optimizing
behaviour, a finitely repeated Prisoner's Dilemma will continue to produce the inferior outcome
throughout (Luce and Raiffa, 1957, pp. 97–101).
Such non-cooperative behaviour is, however, violated in many experimental games as well as in the
usual readings of many real-life situations. The apparent dissonance between received theory and
observed behaviour has been explained in a variety of ways in the large literature that has developed on
the Prisoner's Dilemma. The 'ways out' have included relaxing the assumption of mutual knowledge, for
example, introducing uncertainty about the number of times for which the game will be played,
admitting ignorance of the players about other people's knowledge and motivation, limiting the range of
alternative strategies that can be considered, and other relaxations (see Howard, 1971; Basu, 1977,
Davis, 1977; Radner, 1980; Smale, 1980; Kreps et al., 1982; Axelrod, 1984). Other analyses have
emphasized more complex features of 'practical reasoning' involving various types of action ethics,
sensitive beliefs, behavioural commitments, and instrumental use of reciprocity; see Sen (1974; 1985b),
Watkins (1974; 1985). Levi (1975), Gauthier (1985), McClennen (1985). If it has done nothing else, the
literature has at least brought out sharply the complexity of the nature of rationality in situations of
interdependence as well as various conceptual and logistic difficulties in using models of rationality to
understand the nature of actual behaviour.
It stems easy to accept that rationality involves many features that cannot be summarized in terms of
some straightforward formula, such as binary consistency. But this recognition does not immediately
lead to alternative characterizations that might be regarded as satisfactory, even though the inadequacies
of the traditional assumptions of rational behaviour standardly used in economic theory have become
hard to deny. It will not be an easy task to find replacements for the standard assumptions of rational
behaviour – and related to it of actual behaviour – that can be found in the traditional economic
literature, both because the identified deficiencies have been seen as calling for rather divergent
remedies, and also because there is little hope of finding an alternative assumption structure that will be
as simple and usable as the traditional assumptions of self-interest maximization, or of consistency of
choice.

Uncertainty and expected utility

The extension of the modelling of rational behaviour from certainly to uncertainty involves both (a) the
characterization of uncertainty, and (b) taking note of uncertainty thus characterized in making actual
decisions over alternative courses of actions. The model that has been most extensively used in this context is that of ‘expected utility’. This takes the form of weighing the value of each of the outcomes by the respective probabilities of the different outcomes. The probability-weighted overall ‘expected value’, thus derived, is then maximized in this approach to rational choice under uncertainty.

The use of probability calculus involves interpretational problems as to what the probabilities stand for. While the view of probability as a measure of relative frequency is a natural one to consider, there is clearly much cogency in interpreting probability as a measure of the degree of belief (as argued by Fisher, 1921, and Keynes, 1921).

Actual decision-taking operations involve a reading of the likelihood of different outcomes and an assessment of the different outcomes in the light of the respective likelihoods. In a pioneering contribution in axiomatizing conjointly characterized probabilities and utilities, Frank Ramsey (1931) provided the structure (and a possible derivation) of the expected utility calculus. Another major contribution in this area came from von Neumann and Morgenstern (1947). Given the probabilities of different outcomes, consistent and complete rankings of the possible lotteries over the outcomes (including lotteries of lotteries and so forth) permit the construction of cardinal utility functions for the respective rankings associated with the outcomes, provided the rankings in question satisfy certain regularity properties which were specified by von Neumann and Morgenstern (see also Marschak, 1946). The assigned cardinal utility numbers of the respective outcomes, weighted by the respective probabilities, when summed together, yield the expected values of the lotteries, and provide numerical representations of the overall goodness of the respective lotteries. Rational behaviour under expected utility maximization takes the form of choosing that lottery which has the highest overall value, thus calculated. The expected utility approach can be and has been used extensively both in economic theory and in applied economics (see, for example, Friedman and Savage, 1948; Arrow, 1971).

Independence and consistency

The axioms underlying the derivation of expected utility maximization have been subjected to a good deal of examination and scrutiny. There is scope for disputation about both the exact content and the plausibility of the expected utility axioms (for a very helpful introduction see Luce and Raiffa, 1957; see also Fishburn, 1970; 1981).

The axiom that has perhaps attracted the most criticism is the so-called ‘strong independence’. This independence condition can be stated in several different ways, but a rather immediate one is the following. If in a combined lottery over, say, lotteries L^1 and L^2, the latter L^2 is replaced by another lottery L^3 which is preferred to L^2 (leaving the probabilities and L^1 unchanged), then the modified combined lottery (over L^1 and L^3) would be preferred to the original one (over L^1 and L^2). And vice versa.

Another axiom, related to this one, is sometimes called ‘the sure thing principle’, which, in one version, requires that anything that raises the probability of the preferred component in a two-alternative lottery would improve the lottery. These axioms are implicit in expected utility maximization, even though the ‘independence’ condition can be dispensed with in a more limited (‘locally’ valid) version of expected utility behaviour (as has been shown by Mark Machina, 1982).

Various ‘counter-examples’ to expected utility maximization have been proposed in the literature, often
on the basis of considering interesting ‘hypothetical’ cases, but sometimes on the basis of experimental observations as well. In assessing these objections, we must distinguish, once again, between the claims to rationality of this model, and the claims of the model to explain actual behaviour via rationality. It is certainly clear that very often people do act in a way that cannot be made consistent with expected utility maximization. (An early critique, with an alternative framework for choice behaviour, came from Shackle, 1938; 1952.) Observations of behaviour and articulated judgements under uncertainty have indicated different types of violations of expected utility behaviour (see, for example, Kahneman, Slovik and Tversky, 1982). There seem to be problems both in risk perception as well as in the utilization of probability information in making actual decisions. These departures from rational behaviour in the form of expected utility maximization have considerable implications on the way economic models may have to be constructed involving uncertainty (on this see Arrow, 1982; 1983). As a framework for understanding actual behaviour, the merits and demerits of the expected utility model are certainly becoming clearer on the basis of recent work. But the ‘bottom line’ of overall judgement continues to vary. While some have been extremely sceptical, others (such as Harsanyi) continue to emphasize, with some justice, the usefulness of this model in ‘explaining or predicting real-life human behaviour’ (1977, p. 16).

The need for departures – small or great – from the expected utility model in explaining actual behaviour does not, of course, settle the question of the rationality or irrationality of maximization of expected utility. However, a number of telling and powerful arguments have also been presented in the literature giving reasons for departing from ‘consistency’ of the kind demanded by the expected utility model (for arguments on both sides, see the collection of papers in Daboni, Montesano and Lines, 1986). Allais (1953) has followed up his empirical critique of expected utility model as representation of actual behaviour by arguments in favour of the reasonableness of the departures, and more arguments on this have been outlined in recent years (see Allais and Hugen, 1979; Stigum and Wenstop, 1983; and Daboni, Montesano and Lines, 1986). Also, the possibility of ‘state-dependent utilities’ has raised questions of a different sort, requiring reformulation of the original model (see Drèze, 1974).

One of the important considerations that the expected utility model may leave out consists of ‘counterfactual’ information. One’s ‘disappointment’, ‘regret’, and so on may well depend on what one anticipated and what did not occur. Earlier discussions of such criteria as ‘minimax regret’ (see Savage, 1954) have been followed in recent years by various models of disappointment and regret (see, for example, Bell, 1982; Loomes and Sugden, 1982).

It is arguable that something which has not happened, but could have, should not really affect one's decision, and in particular, it is irrational to regret and sigh about what could have happened. But while it is indeed possible to argue that it is irrational to regret a past decision on the ground of what could have happened in the light of later information, nevertheless, if it is the case that one would willy-nilly regret the past decision if it turns out to be unfortunate, then it is not in any sense obviously irrational to recognize that fact and take that inescapable feeling into account. Clarity of analysis requires that we distinguish between (a) the rationality of what psychology we ought to have, and (b) the rationality of decisions, taking note of what psychology we might not be able to escape. Many counter-examples to expected utility behaviour presented in the literature relate – directly or indirectly – to mental-state considerations, for example, Allais (1953), MacCrimmon (1968), Bernard (1974), Drèze (1974),
Tversky (1975), Machina (1981), McClennen (1983) and others. One reason why the inclusion of mental states among the influences on choice is resisted is the idea that mental state is a particular interpretation of utility of which another – alternative – interpretation is given by the numerical representation of choice, with which the expected utility model is concerned. In the context of utilitarianism, the mental-state utility and the numerical representation of choice can indeed be seen as alternatives, as they have been viewed in the ethical literature. However, in terms of the description of the world, both mental states and choices are distinct parts of the reality, and the acknowledgement of the existence of one does not deny the existence of the other. Indeed, it is not unreasonable to ask how each might relate to the other. The states of affairs over which choices may be considered (including choices over lotteries of those states) may, quite importantly, include the mental states of the parties involved.

On the other hand, including such mental states in the description of states of affairs makes the scope of such conditions as ‘strong independence’ rather limited. Varying an alternative lottery (for example, L³ vis-à-vis L²) might affect the description of the ‘prize’ of a given lottery (L¹) through variations of mental states (now included in the outcome of L¹) related to considering and reflecting on the nature of the alternative (L¹ vis-à-vis L²) and the corresponding disappointment, regret, and so on. If L¹ is no longer ‘the same’ in the two cases, then ‘strong independence’ would make no demand. Thus ‘strong independence’ may be saved only at the cost of making it often trivially fulfilled (see Sen, 1985a). The same difficulty applies if strong independence is ‘rescued’ by including counterfactual information in describing states of affairs.

The basis of rationality implicit in expected utility calculation does, however, require descriptions of states of affairs in sufficient detail such that choices can be made taking all the relevant considerations into account. It can be argued, as indeed Peter Hammond (1986) has, that ‘consequential’ reasoning, taking into account all the relevant considerations, will push us in the direction of expected utility maximization. The important question is whether the relevant considerations would include either counterfactuals or mental states, and, if they do so, whether enough scope for the use of such conditions as ‘strong independence’ can be found to build up utility numbering in a way that would make the expected utility model work in practice. This is not a matter, obviously, of pure theory only, and much depends on the nature of people’s psychology and what considerations might be regarded as rational, in taking note of the complexities of our psychology.

Concluding remarks

Attempts at constructing models of rational behaviour have certainly played a creative part in reducing the intractability of unstructured assessment of (a) the demands of rationality, and (b) facts of actual behaviour. On the other hand, models of rational behaviour actually presented have tended to ignore some of the complexities that have to be faced. This problem arises even when no uncertainty is introduced into the picture.

Neither of the two standard views of rational behaviour – as ‘consistent choice’ or as ‘self-interest maximization’ – has emerged as being really adequate as representations of rationality or of actuality. Various suggestions as to the directions in which we might go were reviewed earlier. Although none of the suggestions are unproblematic, many fruitful avenues of investigation have certainly been identified.
in the critical literature.

These difficulties carry over to rational behaviour models accommodating uncertainty. The limitations of characterizing rational behaviour in terms of just internal consistency, as discussed in the context of choice under certainty, obviously would apply to the modelling of choice under uncertainty as well. Similarly, pursuit of self-interest cannot be seen us being *uniquely* rational in models of uncertainty, any more than they can be so seen when everything is certain. However, it is not really necessary that expected utility models be seen in terms of self-interest maximization, and indeed some writers, for example, Ramsey (1931), have explicitly repudiated that interpretation. In fact, what the expected utility models do concentrate on is ‘consistency’ in a very demanding sense, and in this context objections similar to the ones raised in models of choice without uncertainty can be raised a fortiori with uncertainty.

Rationality may be seen as demanding something other than just consistency of choices from different subsets. It must, at least, demand cogent relations between aims and objectives actually entertained by the person and the choices that the person makes. This problem is not eliminated by the terminological procedure of describing the cardinal representation of choices as the ‘utility’ of the person, since this does not give any independent evidence on what the person is aiming to do or trying to achieve.

A more difficult issue, as discussed in the context of certainty, concerns the *assessment* of aims and objectives pursued by a person, even if they are fully reflected in the choices actually made. As Patrick Suppes has put it, the standard normative model of expected utility ‘can be satisfied by cognitive and moral idiots … Put another way, the consistency of computations required by the expected-utility model does not guarantee the exercise of judgement and wisdom in the traditional sense’ (1984, pp. 207–8).

Suppes argues in favour of moving to the Aristotelian view that the rational person acts ‘in accordance with good reasons’, and is not embarrassed by the fact that this leaves a certain amount of ‘pluralism’ in the possible approach to rationality.

In addition to those problems of rationality that are shared by models of certainty as well as uncertainty, there are some special problems that apply particularly to considerations of uncertain outcomes. The status of counterfactuals, and their influences on mental states, raise interesting and important questions as to what may or may not be relevant to take into account in rationally assessing alternative courses action.

While these problems were addressed earlier on in this paper, one issue that has not yet received much attention here concerns the nature of uncertainty itself. Reference was made earlier to the distinction between interpreting probabilities as degrees of belief, and interpreting them as frequencies. There are also other issues (see, for example, Levi, 1982; 1987). Even the very idea of having beliefs about possible outcomes in the form of probabilities in a situation of partial ignorance raises some interesting philosophical questions. At the very least, it is possible to make a distinction that was made by Frank Knight (1921) between ‘risk’ and ‘uncertainty’, with probability distributions being specified in the case of the former but not in the latter case. Whether arguments such as ‘insufficient reason’ can permit one to *construct* probability distributions even when we do not start with them remains a hard question to settle.

The area of expectation formation is also one in which the demands of rationality are not easy to specify. In some models of rational behaviour, no requirements of rationality are imposed on expectations at all, and the problem of rationality arises only in taking note of the actual expectations in arriving at decisions regarding action. In models of ‘adaptive expectations’ a step is taken in the direction of
making expectations responsive – in an intelligent way – on experience. What goes very much further than this is the assumption of ‘rational expectation’ by which each person anticipates what can, in some sense, be described as objective probabilities; see Muth (1961) and Lucas and Sargent (1982).

This approach not only raises the question as to what the philosophical status of objective probabilities might be, but also whether it is really a matter of rationality as such whether one is successful in guessing what the objective probabilities are. It is fair to say that the assessment of models of ‘rational expectation’ cannot be based on the idea of rationality alone, since the demands of such a theory go well beyond the requirements of the use of reason, especially in a situation of ignorance. It is sensible enough to think that there are problems in models of behaviour in which people’s expectations are systematically wrong, but to try to move from that recognition to one in which everyone manages to take note of objective probabilities fully is quite a dramatic step. Whether that step is worth taking in predicting actual behaviour might well be discussed and assessed in the light of the ability of such a theory to explain actual behaviour, but that, as we have already discussed, is a rather different problem from assessing the rationality of such behaviour.

In addition to the issue of the role of rationality involved in ‘rational expectation’ models, even the basic rational behaviour model (without such expectational assumptions), widely used in economics, raises, as we have seen, difficult – sometimes perplexing – questions. It is not hard to see the merit of trying to reduce a complex reality by characterizing rationality in rather narrow terms, but nor is it hard to fathom that such a narrowing might do grave injustice to the notion of rationality, which is, after all, one of the central concerns of human life.

We have to make a clear distinction between (a) what type of behaviour might be described as rational, and (b) what rational behaviour models might be useful in making predictions about actual behaviour. These different questions are not, of course, independent of each other. But the first step in pursuing their interrelations is to recognize the distinction between the two questions. What issues respectively arise in facing these distinct questions, and how they might possibly be related, were discussed earlier on in this article in the light of the existing literature. There was, however, no escape from noting the fact that the existing literature is indeed deeply incomplete in that real difficulties have been identified without providing an adequate structure for solutions. The need to go beyond the existing literature is apparent enough, but where to go is less clear.

rational choice and political science

Susanne Lohmann

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Rational choice in political science’ stands for the application of the economics approach in the study of political phenomena. The research program is to rationalize collective behaviour that comes across as stupid or counterproductive. In its high-brow (esoteric) variant, rational choice is on the way out in political science. In its low-brow (sensible) variant, rational choice is here to stay, not as the dominant approach, but as one of three equal, and complementary, approaches: the rationalist approach, which focuses on individual agency; the culturalist approach, which centres on collective identities; and the structuralist approach, which emphasizes historical institutionalism.

A.; Aristotle; Hobbes, T.; Coase Theorem; collective action; complex systems approach in social science; complexity; Congressional committees; culturalist approach in political science; historical institutionalism; collective identities; individual agency; institutionalism; agency; public choice; externalities; government intervention; politics of monetary policy; logic of collective action; supply of and demand for collective action; greed, rationality, and equilibrium; Keynesian approach; Hayekian approach; developing countries; social complexity; post-autistic economics movement; political science; deadweight loss; development economics; experimental economics; free-rider problem; game theory; government failure; independence of irrelevant alternatives; market failure; political economy; positive political theory; preference aggregation; rational choice; rational choice in political science; representative agent; self-interest; social choice; social welfare function; special interests; structuralist approach in political science

Article
Chemical plants are vulnerable to terrorist attacks. Two of the most dangerous facilities are located in Dallas, in the US state of Texas, right next to Joe Barton's Congressional district. They constitute a risk for more than one million people. In 2005, Barton used his clout as chair of the House Energy and Commerce Committee to block chemical plant security legislation. A Republican, Barton served as a consultant for an oil and gas company before he was elected to Congress in 1984, and in the following decades he received more than $1.8 million in campaign contributions from the energy and chemical industries. Barton routinely sides with the energy industry at the expense of his constituents, and you can forget about the welfare of the people represented by his colleagues in Congress (Cohen, 2005).

For Barton to be in the position to benefit a special interest at the expense of a multitude, he must enjoy majority support in both his district and Congress. What is the logic whereby he gains such support?

‘Rational choice in political science’ stands for the import of the economics paradigm into the political science discipline, or the application of the economics approach in the study of political phenomena. The research programme is to rationalize collective behaviour that comes across as stupid or counterproductive. My purpose here is to spell out how this research programme is playing out in political science – or rather how it played out, for the research programme has recently lost much of its vitality (in its extreme form it is dead).

Economists and political scientists often use the same labels to denote different things and different labels to denote the same thing. For this reason, it is useful to start with some definitions: what do social choice, public choice, political economy, and positive political theory stand for, and how do they relate to ‘rational choice in political science’?

I shall illustrate these labels in the context of the scientific life cycle of rational choice in political science, which describes the usual arc of fringe, vibrancy, maturity, ossification, and renewal. Over time, the research programme cycled in its emphasis on external and internal scientific progress, as it moved from solving real-world puzzles to theoretically refining the solutions and back again; the cycle includes a forward movement.

In the economics discipline, behavioural and experimental economics have recently relaxed some of the more extreme greed-and-rationality assumptions. In political science, rational choice took a different turn. Today, rational choice in its high-brow (esoteric) variant is on the way out, in part because leading rational choice theorists are ‘holier than the Pope’ in their refusal to join the rather more relaxed approach to economics. In its low-brow (sensible) variant, rational choice is here to stay, but it has largely shed its imperialist ambitions. Instead of emerging as the dominant approach, rational choice coexists more or less peacefully with one of three complementary approaches: the rationalist approach, which focuses on individual agency; the culturalist approach, which centers on collective identities; and the structuralist approach, which emphasizes historical institutionalism. (My description of rational choice scholarship as ‘high-brow’ and ‘low-brow,’ or ‘esoteric’ and ‘sensible,’ is not meant to express approval or disapproval; the two types of scholarship complement each other as they contribute to internal and external scientific progress.)

The scientific life cycle of social choice, public choice, and political economy in the economics discipline

Because the scientific life cycle of rational choice in political science is an offshoot of the scientific life cycle of social choice, public choice, and political economy in the economics discipline, it is useful to start with an account of the latter.
Social choice was research-active from the 1950s through the 1970s; public choice, from the 1970s through the 1990s; political economy, from the 1980s through the 2000s. Dennis Mueller’s textbook *Public Choice III* (2003) covers social choice and public choice. (*Public Choice III* is the third, and most comprehensive, edition of *Public Choice*, which was published in 1979.) Torsten Persson and Guido Tabellini’s textbook *Political Economics* (2000) lays out the political economy programme.

When social choice started out, the reigning practice in economics was to derive normative statements about economic policy by maximizing a social welfare function subject to a set of economic constraints. At the time, it was taken for granted that people's preferences could be summarized by a social welfare function. Kenneth Arrow demonstrated, to the contrary, that it is impossible to represent people's preferences with a social welfare function that fulfills plausible criteria such as independence of irrelevant alternatives; this impossibility result holds if people's preferences are diverse. (The independence-of-irrelevant-alternatives criterion prohibits the social preference over two alternatives from switching places if the individuals' preferences over the two alternatives stay the same even as a third alternative is added to, or dropped from, the set of alternatives under consideration.) Social welfare functions subsequently went out of fashion among economists. (Actually, in many subfields of economics they returned through the side door; for example, in macroeconomics the illegitimacy of assuming a social welfare function was elegantly circumvented by assuming that the macroeconomy can be summarized by a representative agent.)

Social choice also demonstrated that voting rules affect voting outcomes. If people's preferences are sufficiently diverse, there exists no such thing as a neutral voting rule that will ‘simply’ aggregate people's preferences. At first blush, this result seems rather worrisome because of its potential to undercut the legitimacy of outcomes arrived at by democratic means. But we shall see how this insight would get picked up productively – after all, if institutions can warp democratic decision-making, this raises the possibility of designing political institutions to serve a corrective function.

Social choice consisted largely of mathematical exercises with little economic content; its concern with preference aggregation does not relate all that well to the standard economic concern with scarcity and constraint. Public choice, in comparison, employed microeconomic theory, and it was geared towards extending economic assumptions of self-interest and rationality to the political arena, with the idea of treating political and economic actors symmetrically. Before public choice entered the fray, economists were in the habit of spelling out what actions a benevolent dictator should take when he or she (or it?) encounters *market failure* due to externalities, information asymmetries and the like.

One early argument against government intervention consisted of the Coase Theorem, which implies that the system of economic actors will endogeneously adjust to internalize externalities (assuming that there exists a system of well-defined property rights and negligible transaction costs). The Coase argument can be – has been – exported to the political sector. For example, if the underlying problem in the political market consists of an information asymmetry between policymakers and voters, then information providers will have incentives to enter the political market, and voters will have incentives to take information cues from them (Wittman, 1989).

Public choice theorists, most prominently among them James Buchanan and Gordon Tullock, refused to see market failure behind every bush – in economic markets, that is. At the same time, their minds would surely boggle at the idea of political markets being self-correcting. In their eyes, *government failure* loomed large. The public choice argument against government intervention is that government consists of self-serving politicians, bureaucrats, and special interests who are poorly held in check by...
ignorant voters. Public policy is thus riddled with biases and loopholes benefiting special interests at the expense of consumers and taxpayers.

Public choice theorists also proposed institutional solutions to government failure. Examples are the flat tax, the gold standard, and constitutional limits on government borrowing. The typical proposal seeks to tie the hands of politicians and bureaucrats and to create transparency vis-à-vis voters or other audiences. It forgoes the benefits of efficiency, equity and flexibility. That is, it does not offer the best solution for some idealized world lorded over by benevolent experts; it does not go out of its way to do good for the poor; and it disallows Keynesian-style economic stabilization and micro-intervention. It does, however, come with the potential to prevent self-serving politicians and bureaucrats from doling out goodies to special interests precisely because voters, or other audiences, can easily monitor slippages, make a public fuss, and ‘vote the bastards out’. The simplicity and transparency of the proposed institutions create a political cost of defecting from them.

It is worthwhile appreciating public choice for driving home this important point: as we compare different institutional solutions, we must take into account their relative political corruptibility. Public choice spelled out how the policy process is warped by collective action and political institutions. For example, if small groups have an easier time solving the free-rider problem of collective action than do large groups, then policy will be biased in favour of special interests (Olson, 1965); for example, too, the power of special interests is the result of Congressional committees being captured by high demanders, that is, members of Congress who represent constituencies (voters and campaign contributors) with a high demand for certain kinds of government handouts (Shepsle and Weingast, 1987).

From the outset public choice thus stood on two legs: one leg was about inserting politics into apolitical models of economic policy, as in, ‘the politics of monetary policy’; the other was about applying rational choice to political behaviour and institutions, as in, ‘the logic of collective action’.

Where public choice applied microeconomic theory, as in, ‘the supply of and demand for collective action’, political economy made use of game theory, as in, ‘greed, rationality, equilibrium’. The result was a higher standard of spelling out the rationality of political actors, including their informational states, and of making sure that all of their strategies and beliefs are consistent with each other so that the strategies and beliefs constitute an equilibrium.

For example, the story that policymakers pander to special interests at the expense of voters does not necessarily make sense if voters follow a voting strategy by which they vote for the incumbent when they are well off and for the challenger when they are hurting. To make this story fly, one has to specify how a policymaker can increase her re-election chances by taking something of value from the large mass of voters; losing a little of bit of it along the way (this is the deadweight loss created by redistribution, which generally distorts people’s economic choices); and giving the remainder to special interests: why wouldn’t the policymaker lose more votes among the large mass of voters than she would gain among the special interests (Lohmann, 1998)? And if special interests are powerful because of campaign contributions, why wouldn’t voters reject a policymaker who is loaded with campaign contributions – after all, campaign contributions are a sign that the policymaker is pandering to special interests at their expense? In the same vein, if special interest handouts are the result of high demanders hogging Congressional committees, why would a majority in Congress go along with bills that benefit the committee members' constituents at the expense of their constituents? And why does a Congressional majority allow high demanders to self-select onto Congressional committees in the first place?
Political economy also differed from public choice by taking a balanced view of market and government failures. For example, when economic markets fail to aggregate distributed information about the mapping of economic policy into policy outcomes, then special interests or high demanders on Congressional committees may well supply the requisite information, with the result that the quality of economic policy improves (because policymakers are well-informed) even though policy outcomes are biased (because policymakers pander to special interests or high demanders) (Gilligan and Krehbiel, 1987). The implication is that we should not automatically assume that special interests and high demanders on Congressional committees are a Bad Thing; we need to consider the workings of the economic and political system as a whole, in which case a Political Bad might cancel out an Economic Bad, and the net effect is a Good Thing. Because political economy traded off the gains and losses of imperfect markets and imperfect politics, it came up with more complex and more flexible institutions than did public choice.

By the mid-1990s, the newly prominent subfield of experimental economics had amassed enough evidence to challenge the assumptions and predictions of standard economics models, and behavioural economics proceeded to explain the anomalies by relaxing the assumptions of greed and rationality (less so the assumption of equilibrium) in favour of a richer set of psychological motivations and cognitive limitations. All of this activity served to undercut the political economy programme of producing ever more refined rationality-and-equilibrium explanations of market-cum-government failure. Today, the extreme application of the game theory paradigm to political phenomena is passé. The cutting edge lies in employing richer models of human behaviour to understand the various forms of collective action we observe in reality, that is, in laboratory experiments and in the field.

Even as the one kind of political economy (the kind that applies old-style game theory to political phenomena) is intellectually stagnant, the other kind of political economy (the kind that inserts politics into models of economic policy) has been busy expanding into the political economy of development. Whereas public choice was largely focused on the developed countries, or the rich capitalist democracies, political economy increasingly included the developing countries, many of which were governed (some still are) by tin-pot dictators, military cliques, and the like. Whereas public choice was concerned about the discrepancy between economic theory and practice in developed democracies, the political economy of development worried about the disparities in economic performance across countries and sought to explain why and how some countries grew rich (why these countries, why now?) even as others remained poor.

Development economists who pushed this story, or variants of it, naturally appreciated the fact that well-functioning market economies rely on well-functioning governments, just as they naturally appreciated the fact that government in developed countries is functioning extremely well, both in historical and cross-country comparison. Such appreciation is a 180-degree reversal of the anti-government bias that permeated the public choice programme.

Whereas public choice had a Hayekian flavour to it (put into place simple institutions and let the economy do the rest), political economy took a rather more Keynesian approach (derive optimal institutions that will surgically correct the political economy). We are experiencing another reversal right about now, that is, a revival of the Hayekian approach. William Easterly's *The White Man's Burden: Why the West's Efforts to Aid the Rest Have Done So Much Ill and So Little Good* (2006) stands for the new bottom-up thinking (government is ‘governance by the local people’), though it is clear from
the popularity of Jeffrey Sachs's *The End of Poverty* (2005) that the old top-down thinking (government is ‘management by benevolent experts’) is not quite dead yet. The emerging new approach – let us call it social complexity – stands in a tension with behavioural economics. The latter likes to make complicated assumptions about what is going on in people's heads even as it preserves the assumption of equilibrium, which implies that people have a complete and shared understanding of their environment (people might suffer from cognitive biases, but they best-respond to each other cognitive biases, and it all comes together very neatly). In contrast, social complexity likes to make simple assumptions about what going on in people's heads: people are relatively fixed in their behaviours, and their ‘ways of seeing’ the world are incomplete and diverse and partially inconsistent with each other (Hayek, 1945). Social complexity is actually closer to what the economics discipline used to stand for historically:

> If social phenomena showed no order except insofar as they were consciously designed, there would indeed be no room for theoretical sciences of society and there would be, as is often argued, only problems of psychology. It is only insofar as some sort of order arises as a result of individual action but without being designed by any individual that a problem is raised which demands theoretical explanation … (Hayek, 1955, p. 39)

### The scientific lifecycle of rational choice in political science

Now that I have reviewed how rational choice evolved in the economics discipline, let me examine how it spilled over into the political science discipline.

In the political science discipline, social choice and public choice led a peripheral existence for decades; they still do. It was only in the late 1980s and early 1990s that political economy and positive political theory exploded onto the stage. Indeed, rational choice briefly looked as if it would take over political science, only to lose influence in the early 2000s, especially in its high-brow variant; the low-brow variant has been folded into political science for the long run. Low-brow rational choice theorists, including the political economy crowd, like to use the Persson and Tabellini textbook. The high-brow crowd prefers the two-volume effort by David Austen-Smith and Jeffrey Banks, *Positive Political Theory I: Collective Preference* (1999) and *Positive Political Theory II: Strategy and Structure* (2005).

The two legs of public choice and political economy – inserting politics into models of economic policy and using the economics paradigm to model political phenomena – can be found in political science, albeit with different labels assigned to them. The label ‘political economy’ has come to stand for inserting politics into models of economic policy, as in ‘political economy of international trade’; this is typically done in a rational choice fashion, though there are some Marxist leftovers who call themselves political economists. The label ‘positive political theory’ denotes the use of rational choice to model political phenomena, as in ‘positive political theory of Congressional committees’. Why positive? To distinguish positive political theory from political theory, a subfield of the political science discipline that corresponds to the subfield political philosophy in the philosophy discipline, which is concerned with, for example, interpreting Aristotle's *Politics* or Hobbes's *Leviathan* – and also with expanding the culturalist approach, which I shall describe later. Why did political economy and positive political theory succeed in gaining significant market share in
the political science market even as social choice and public choice were reduced to eking out a peripheral existence? Social choice modelled political behaviour and institutions in a way that was quite simply too abstract relative to the thick knowledge of political behaviour and institutions held by practising political scientists: at the time there was no research tradition in political science that could latch onto the idea that it might be interesting to prove the impossibility of a social welfare function; and as for the possibility of manipulating voting outcomes by fiddling with voting rules, what else is new? Public choice was rather more practical in its orientation, but it was for the longest time rejected as a right-wing enterprise (Lowi, 1992).

Political economy, with its more balanced take on market versus government failure, turned out to be politically more palatable. Perhaps more importantly, political economy – sailing under the flag of positive political theory – supported more refined models of political behaviour and institutions: from the perspective of a political scientist, it is not terribly interesting for a benevolent dictator to be replaced by a unitary-actor self-serving politician; it is exciting to explain why a majority in Congress would rationally constrain itself by applying closed rule to votes on proposals coming out of Congressional committees and to spell out the conditions under which the majority would allow for closed rule versus open rule (Gilligan and Krehbiel, 1987). (Under closed rule, a committee proposal must be voted up or down, with amendments prohibited. Open rule allows for amendments.)

The mid-1990s saw the first stirrings of a counter-reaction to rational choice. Donald Green and Ian Shapiro's *Pathologies of Rational Choice Theory* (1994) took potshots at rational choice. Leading rational choice theorists fought back, their responses were collected in a special issue of *Critical Review* (Friedman (1995; 1996). The two sides pretty much talked past each other, with Green and Shapiro emphasizing the empirical silliness of many rational choice models (and getting some of the models wrong) and the rational choice elite celebrating the theoretical rigour of rational choice models (and rejecting Green and Shapiro for not understanding their models).

In the early 2000s, in parallel to the post-autistic economics movement in the economics discipline, the Perestroika movement (Monroe, 2005) emerged seeking to liberate political science from rational choice. But if rational choice lost steam in political science, it was for a different reason than in the economics discipline. The behavioural and experimental economics revolution is not happening in political science because the leading rational choice theorists are all too heavily invested in the hyper-rational variant of the research programme. There exist political scientists who combine psychology and politics, but they are coming out of a different research tradition, one that is oblivious to economics: they rely on surveys to study mass opinion, and they are uninterested in running laboratory experiments on games that relax greed and rationality while preserving equilibrium for the simple reason that it never occurred to them that greed-rationality-equilibrium is an interesting benchmark in the first place. Instead, people got fed up with rational choice for its esotericism. Its practitioners increasingly scored points by refining each others' theoretical models rather than by relating their models to urgent substantive problems in the real world.

Political science, as compared to the economics discipline, has a tendency to let a thousand flowers bloom: it has always supported a greater diversity of approaches in the leading doctoral programmes. Consistent with this diversity, rational choice is not actually going out of business. But it is the low-brow variant of rational choice that is surviving by combining ‘sensible’ rational choice arguments (such as the idea that collective action is subject to a free-rider problem) with an in-depth substantive
understanding of the issues. In parallel to the emergence of the political economy of development in the economics discipline, the focus of attention in political science has shifted away from the kind of positive political theory that mostly made its living in the subfields of American politics (especially in the subfield of Congressional studies) and international relations, and towards applying rational choice in the field of comparative politics, with an emphasis on developing countries.

Rational choice in its extreme form came with imperialist ambitions. Today, there is a firm understanding, at least in political science if not in the economics discipline, that rational choice is just one approach, with strengths in some domains and weaknesses in other domains, which is where alternative approaches come to life. Complementing the rationalist approach are the culturalist and structuralist approaches (Lichbach and Zuckerman, 1997; Lichbach, 2003).

By way of illustrating the culturalist approach, consider the massive social change that occurred in the United States over the second half of the 20th century – consider the civil rights movement, the women's movement, and assorted sexual liberation movements (gay, lesbian, bisexual, transgender), and contemplate the prevailing attitudes ‘then and now’ towards assorted ethnic minorities (African-American, Jewish, Native-American, Asian-American, Hispanic). Economists will glibly talk about herding effects and information cascades. But a discipline that is (variously) defined as being about scarcity or individual agency or greed-rationality-equilibrium simply does not carry much purchase when it comes to explaining such dramatic changes in collective identities.

Today, society is mired in religious conflict, both domestically and internationally. Think of the divide between the red states and blue states in the United States, that is, the states located in the vast middle of the country, whose voters predominantly back the Republican Party, and the states located on the East and West Coasts, whose voters for the most part support the Democratic Party. Think also of the divide between Islam and the West. We can talk about ‘the supply of and demand for religion’ or ‘the rational choice of religion’, but the intellectual action clearly lies someplace else, where a culturalist approach gives us a better purchase on reality.

By way of illustrating the structuralist approach, let us take a look at the current popularity of exporting democracy and building democratic institutions. In the West, the emergence of democracy took a couple of centuries (more if you include Greece and Rome). Why so long? It turns out that institutions are not designed by experts and plunked down by bureaucrats in the same way that, say, bridges are conceived by engineers and built by construction workers. Institutions are the product of social conflict and social movements, and they come into existence by spreading across the minds of a people. Social movements resolve social conflicts by locking in structures which subsequently are taken for granted, as if they exist ‘naturally’. In a well-functioning democracy, not everything is up for grabs all the time. There are huge swathes of society in which people simply play out the roles assigned to them by the structures they are embedded in. In these domains, ‘rational choice’ and ‘individual agency’ are grossly inadequate concepts. (Indeed some of the more disastrous interventions of academic economists in the real world – I have in mind the post-Communist transition to capitalism and democracy – derive from an impoverished understanding of historically evolved structures.)

We are coming full circle here, for the structuralist approach has a Hayekian touch to it. There are numerous indicators suggesting that a complex systems approach is on the rise in the social sciences. For example, as of 2006 UCLA supported a new undergraduate interdepartmental degree programme on Human Complex Systems, George Mason University, a new doctoral programme on Social Complexity.
those of the economics approach. Rational choice promises to make political science more scientific, as in: universally applicable, theoretically rigorous, cumulatively progressive. Thanks to the scholarship in social choice and public choice and political economy, which spilled over into political science, our understanding of collective action and political institutions is light years ahead of where it was in the 1950s.

Just like economics, however, rational choice in its extreme form (greed, rationality, equilibrium über Alles) is a problem. It is blind to thick and local knowledge; it disdains culture and history; and it has a tendency to degenerate into internal scientific progress rather than producing external scientific progress. Rational choice deserves to survive in political science, but it is just as well that it no longer overshadows complementary ‘ways of seeing’ the political world.

rational choice and sociology

Peter Hedström and Charlotta Stern
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Rational-choice theorizing has a long tradition within sociology, but has always been controversial and contested. Yet it has influenced the theoretical vocabulary of the discipline at large and has made deep inroads into some important sociological areas such as social movements, social mobility, and religion. Most sociological rational-choice theories assume that actors act rationally in a broad sense, and focus on the aggregate outcomes that individual actors in interaction with one another are likely to bring about. This article reviews the most important contributions to the rational-choice tradition in sociology, and briefly discusses its historical past and its likely future.

Article

Rational-choice sociology is the branch of sociology which is most thoroughly influenced by economic theory. Yet it is not simply an application of economic theory to the explanation of social phenomena. Rational-choice sociology consists of a diverse set of theories only some of which can be said to have been imported from economics. The common denominator of rational-choice sociologists is that they use explanatory models in which actors are assumed to act rationally, in a wide sense of that term. Unlike in many other sociological theories, actors are not assumed to be governed by causal factors operating behind their backs, but are seen as conscious decision makers whose actions are significantly influenced by the costs and benefits of different action alternatives.

Most rational-choice sociologists do not seek to explain the actions of single individuals. The focus instead is on explaining macro-level or aggregate outcomes such as the emergence of norms, segregation patterns, or various forms of collective action. To make sense of outcomes like these, however, rational-choice sociologists focus on the actions and interactions that brought them about.

The emergence of rational-choice sociology

Rational choice-inspired theorizing has a long tradition within sociology. Max Weber, one of the founders of sociology, argued for the importance of basing sociological explanations on clearly articulated ideas about rational action (Weber, 1922). Only since the 1980s, however, have we seen the emergence of a more clearly defined rational-choice approach within sociology. Given the constraints imposed by the format of this article, we are not able to give due attention to the range of work produced by rational-choice sociologists. We instead single out a few contributions that have been particularly important for the development of the approach.

Some of the contributions that proved important for the development of rational-choice sociology were not themselves based on rational-choice assumptions. One case in point is the...
work of George Homans (for example, 1958; 1964). At the height of his career Homans was a highly visible and influential sociologist who made many substantive and theoretical contributions to the discipline. Unlike many of his contemporaries he argued that sociological explanations should take the form of deductive arguments based on clearly explicated micro assumptions. In this respect he had much in common with current-day rational-choice sociologists. But unlike them he did not base his analyses on assumptions about rational actors. Instead he maintained that sociological theories should be based on assumptions derived from behavioural psychology: ‘the principles of behavioral psychology are the general propositions we use, whether implicitly or explicitly, in explaining all social phenomena’ (Homans, 1969, p. 204). Despite these differences between Homans's type of sociology and contemporary rational-choice sociology, Homans's emphasis on precise and deductive actor-based explanations meant that he paved the way for what later was to become rational-choice sociology (see Coleman, 1990a).

Another early work which was important for the emergence of rational-choice sociology was Peter Blau's Power and Exchange in Social Life (1964). The book covers a range of topics, but Blau was particularly interested in what we today would call implicit contract theory, and he focused in particular on the role of reciprocity in explaining the patterns of social interactions that are likely to emerge within a group of individuals. He also was interested in how differences in power and status emerge over time as the result of such exchanges (see also Emerson, 1962; Cook and Emerson, 1978).

Also of considerable importance was the economist Mancur Olson's (1965) analysis of the logic of collective action. In the pre-Olson era, most sociological theories of social movements and collective action did not problematize the distinction between individual and collective interests. Using standard microeconomic theory to analyse individuals' decisions whether or not to join an organization for collective action, Olson showed that one often should expect rational individuals to be free riders even when they would have been better off had they all joined the organization. In the light of Olson's contributions, social movement researchers started to pay much more attention to the role of individual incentives, and as a consequence, rational-choice ideas came to have a great deal of influence. Hechter's (1987) influential book on the principles of group solidarity exemplifies this trend.

In European sociology, one of the key contributors to the rational-choice tradition is Raymond Boudon (for example, 1981; 2000; 2003). In numerous publications he argued for the importance of explanations which assume that individuals act rationally. Boudon always has emphasized the importance of basing explanations on realistic theories of action, however. According to Boudon, it is important to recognize the cognitive limitations of real individuals. Individuals often act rationally in the sense of having good reasons for doing what they do, even if these actions may not necessarily be those prescribed by expected utility theory.

Other European sociologists who were important for the development of rational-choice sociology include Lindenberg (for example, 1985; 1990) and Opp (for example, 1986; 1989; see also Raub and Weesie, 1990; Abell, 1991). Lindenberg (a student of Homans) was one of the founders of the Interuniversity Center for Social Science Theory and Methodology (ICS), a Dutch graduate school built on the foundations of rational-choice theory, and he was also a driving force behind the establishment of rational-choice sections within the International Sociological Association (ISA) and the American Sociological Association (ASA).

Jon Elster is another social scientist who has been of considerable importance for rational-choice sociology. Elster's relation to rational-choice theory always has been somewhat ambivalent, however. On the one hand, he always has considered rational-choice theory to be the best available general theory of action (for example, Elster, 1986); on the other hand, most of his writings have been concerned with the limitations of rational-choice explanations. Much of his work since around 1980 has been concerned with the relationship between rationality, social norms, and emotions (for example, Elster, 1979; 1983; 1989; 1999). His writings in these areas have been widely read by sociologists and have established important links between sociological theory, the philosophy of action, and behavioural economics.

The single most important person to influence rational-choice sociology has been James Coleman. Coleman did early work on public choice theory (1966) and on the mathematics of collective action (1973), but his Foundations of Social Theory (1990b) is by far his most important contribution (see also Coleman, 1986, which is an important programmatic statement of his rational-choice position). This treatise of nearly 2,000 pages summarizes and extends much of the work he did during the preceding two decades. In Foundations, he shows how a range of traditional sociological concerns such as norms, authority systems, trust, and collective action can be addressed from a rational-choice perspective. In the final third of the book he uses a slightly modified general equilibrium model borrowed from economics to formalize many of the ideas discussed in earlier parts of the book. It is often said that Foundations is a book admired by many but read by few, but to judge from Marsden's analyses of citation statistics we may not yet have seen its full impact: ‘As of late 2004, more than 1850 indexed works have referenced it, the trend generally increasing over time’ (Marsden, 2005, p. 18).

**Empirical research**

Sociology is an empirically oriented discipline in which the success of a theoretical approach ultimately depends upon its ability to inspire new empirical research and/or to explain important empirical observations. There is a long tradition of implicit use of rationality-like assumption in empirical research, but in some areas, most notably in those concerned with social movements, social mobility, and religion, explicit rational-choice theorizing is closely allied with empirical research, and in these areas rational-choice has become an important part of the intellectual agenda.

As mentioned above, sociological research on social movements was much influenced by the work of Olson (1965), and this is clearly the area of sociology in which rational-choice...
The standing of rational-choice sociology within the discipline

Although many well-known sociologists work within the rational-choice tradition, rational-choice sociology remains controversial. In part this is because rational choice raises important questions about the very identity of sociology as an academic discipline. Classic sociologists such as Pareto (1915–16), Weber (1922), and Parsons (1937) sought to define the core identity of the discipline by contrasting it with economic theory in general, and with the micro-level assumptions of economic theory in particular. From such a perspective rational-choice sociology may appear more like an example of economic imperialism than as ‘real’ sociology, and as a consequence many contemporary sociologists consider the use of rational-choice assumptions to be a violation of a ‘disciplinary taboo’ (Baron and Hannan, 1994). The title of a recent book edited by Archer and Titter, the former being an influential social theorist and past president of the International Sociological Association, describes the situation in a nutshell: Rational Choice Theory: Resisting Colonisation (Archer and Titter, 2000). These concerns about the discipline being ‘colonized’ by rational-choice theorists appear unfounded, however. Currently there are only about 200 members in the rational-choice sections of the ASA and the ISA. Although rational-choice sociology has attracted many visible and productive sociologists, these numbers suggest that rational-choice sociology is more of an endangered species than a species likely to invade the discipline at large. This is in sharp contrast to the situation in political science, where the reception of rational choice has been positive and this approach is now widespread especially in the United States.

A recurrent theme in the criticisms advanced against rational-choice sociology concerns the realism of its assumptions. Concerns for realism are also present among many of those close to the rational-choice tradition. As mentioned above, Boudon (for example, 2003) has always emphasized the importance of realistic assumptions about the individual's social situation, incentives, and cognitive abilities. Similarly, Hedström (2005) has argued that knowingly accepting false assumptions because they lead to better predictions or to more elegant models threatens the explanatory value of the rational-choice approach because it gives incorrect answers to why we observe what we observe. Far from all sociologists are concerned about this, however. Some rational-choice sociologists take a similar position to that of Friedman (1953) and argue that the realism of the assumptions are rather irrelevant (for example, Jasso, 1988), and others argue that deviations from rationality can be ignored because they tend to be like random error terms that cancel out in the aggregate (for example, Opp and Gern, 1993; Hedström, 1994; Sandell and Stern, 1998). An empirical regularity that has inspired a great deal of sociological research is the persistent influence of class background on educational choice. Boudon (1974) was an early attempt to use rational choice-inspired ideas to understand why this is so. Similarly, the educational choices of Italian youth was studied by Gambetta (1987) seeking to distinguish between the importance of choice-related factors and factors operating behind the back of the individuals.

Goldthorpe, one of the leading social mobility researchers of the last few decades, in an influential article argued for the importance of establishing closer ties between rational-choice theory and the type of statistical analyses that most social-mobility researchers were engaged in (Goldthorpe, 1996; see also Goldthorpe, 1998, and Blossfeld and Prein, 1998). Many others have followed in his path and rational-choice theory is now fairly central to this research community (for example, Breen, 1999; Jonsson, 1999; Morgan, 2002). Breen and Goldthorpe (1997), for example, developed a formal model aimed at explaining the class differential in educational attainment which assumed that families from different classes develop strategies which seek to minimize the risk of downwards mobility. This model has generated a great deal of empirical research (for example, Becker, 2003; Davies, Heinesen and Holm, 2002; Need and de Jong, 2001).

Perhaps somewhat surprisingly, sociology of religion is another area of sociology in which rational-choice theory has had a great deal of influence. For years, it was believed that modern, ‘rational’ thinking and exposure to alternative religious views would lead people to question the validity of religious belief systems and that religion would lose its foothold (for example, Berger, 1969). The situation in Europe was cited as evidence. Rational-choice sociologists, however, pointed to the United States and suggested that pluralism of religious alternatives instead is likely to increase the appeal of religion. They assumed that there exists a market for religious goods which is similar to any other market in that competition can be expected to breed efficiency and entrepreneurial activity which in turn is likely to lead to a more attractive range of religious goods and to higher consumption levels. Rational choice theorists suggested that the European situation with low religious participation was due to state regulation and ‘lazy’ religious monopolists running the churches, and these ideas have inspired a great deal of empirical research (for example, Iannaccone, Finke and Stark, 1997; Finke and Stark, 1992; Stark and Finke, 2000).

Economic sociology is another increasingly important sociological area in which rational-choice theory plays a significant, although not dominant, role. The best work in this tradition has a strong empirical grounding and explains social and economic outcomes in terms of actions constrained by the normative, institutional, and structural contexts in which the actors are embedded (see, in particular, Granovetter, 1985; Brinton and Nee, 1998). The standing of rational-choice sociology within the discipline
In an often-cited paper, Duesenberry (1960, p. 233) described the difference between sociology and economics as follows: ‘Economics is all about how people make choices. Sociology is all about why they don’t have any choices to make.’ Although this is an obvious exaggeration of the differences between the disciplines, and particularly the differences between economists and rational-choice sociologists, it captures an important difference between the disciplines. This difference can be described using Coleman’s (1986) so-called micro-macro graph (see Figure 1).

**Figure 1**
Coleman’s (1986) micro–macro graph

**A**: Actions of others or other relevant environmental conditions

**B**: Individual reasons or other orientations to action

**C**: Individual action

**D**: Social outcome
As mentioned above, rational-choice sociologists are macro-oriented but they are methodological individualists in the same sense as economists are, that is, they seek to explain macro outcomes and correlations, such as outcome A or the relationship between A and D in Figure 1, in terms of the intended and unintended outcomes of individuals' actions. Typically this entails explicating three causal links: (a) how individuals' orientations to action – their beliefs, preferences, and so on – are influenced by the social environments in which they are embedded (A → B); (b) how these orientations to action influence how they act (B → C); and (c) how these actions bring about the social outcomes to be explained (C → D).

As suggested by Duesenberry, sociologists tend to pay more attention to the macro-to-micro link (A → B) than to the latter two links. Sociologists tend to focus on how networks, social norms, socialization processes, and so on influence how individuals act by shaping their preferences, beliefs, opportunities, and so on (for example, Boudon, 1988; Burt, 1992; Coleman, 1990b; Granovetter, 1985; Hedström, 2005; Raub and Weesie, 1990). This choice of focus does not mean that sociologists believe that choices are unimportant, however; it simply is the result of an analytical focus on those aspects of the choice process which are closest to the intellectual heritage of the discipline, and therefore are perceived to be of particular sociological interest.

Another important difference between the disciplines concerns the ways in which one typically goes about analysing the type of processes described in Figure 1. While economic theory is highly mathematized, sociological theory, including sociological rational-choice theory, tends to be much more inductive and empirically oriented. For example, while most economists would specify some mathematical model in order to analyse these types of processes, most rational-choice sociologists rather would take their point of departure in the results of an empirical study. In the sociological analysis, the role of the rational-choice assumption would not be that of an assumption or a postulate of a formal model, but it would be a guide to the type of narrative used for interpreting the empirical results (see Goldthorpe, 1996, for a further discussion of this strategy).

These differences between the disciplines mean that rational-choice sociologists often use ‘broader’ notions of rational choice than economists typically do. As suggested by Camerer and Fehr (2006), the rationality assumption underlying most economic analyses consists of two components: (a) individuals are assumed to form, on average, correct beliefs about the world in which they are embedded, and (b) individuals are assumed to choose those actions that best satisfy their preferences, given these beliefs. In addition, it is typically assumed that the preferences are self-regarding, exogenously given, and stable through time. Given the sociological interest in how individuals' orientations to action – their beliefs, preferences, and so on – are influenced by the social environments in which they are embedded (the A → B link in Figure 1), assumptions about stable preferences and non-biased beliefs appear empirically problematic and they would seem to remove from the analysis some of the most interesting and intriguing aspects of the social sciences. From the economic side of the fence, the more empirically and verbally oriented sociological approach may appear lacking in rigour, while from the sociological side of the fence there is considerable scepticism about analytical results derived from models which, at least in part, are based on assumptions that lack firm behavioural foundations. It seems likely that these disciplinary differences will become less important in the years to come because of converging trends within each discipline. Within economics, there is a growing interest in traditional sociological concerns such as norms, social interactions, and social networks, and experimental approaches are becoming increasingly more important. And within sociology there is a growing recognition of the importance of the type of formal deductive modelling that currently characterizes so much of economic theory.

**Concluding remarks**

At this point in time it is difficult to tell whether rational-choice sociology is destined to become an influential force within sociology. It has established itself within the discipline, and more so in Europe than in the United States, but there are no indications, to judge by the size of the rational-choice sections of the ASA and the ISA, that the number of rational-choice sociologists is increasing. Nevertheless, rational-choice theory has had and continues to have an important influence on the discipline, at least in forcing dissenters to clarify better their theoretical tools. One indication of this is that the mainstream sociological vocabulary now includes a range of concepts originating in rational-choice theory, such as free-riders, transaction costs, and collective goods. In addition, largely because of the influence of rational-choice theory, empirically oriented sociologists increasingly acknowledge the need for solid micro theories, and sociologists in general are increasingly concerned with the role of incentives in explaining actions and the collective outcomes that these actions bring about.

Abstract

Rational expectations impose cross-equation restrictions that have important implications for the estimation of models. These implications have lead to the development of new estimation and testing techniques. More recently, this development has generated techniques that handle models that cannot be solved analytically. Together with the rapid increase in computing power, these methods offer insights in to the working of these models and thereby enable their refinement.

Keywords

Bayesian methods on macroeconometrics; cross-equation restrictions; distributed lags; estimation; Euler equations; generalized method of moments; maximum likelihood; rational expectations; simulation-based estimation; term structure of interest rates; testing; vector autoregressions

Article

Most dynamic models in economics assume that agents form expectations rationally. An equilibrium of a dynamic model can typically be described by a probability distribution over sequences of data. The rational expectations assumption says that every agent's subjective belief about the data is a conditional of this equilibrium probability distribution, where the conditioning is on the agent's information set. Expectations are thus consistent with outcomes generated by the model. They are also optimal, in the sense that they correctly use all information available to the agent.

The rational expectations assumption was first proposed by John F. Muth in the early 1960s in his analysis of linear macroeconomic models. Prior to Muth's work, expectations in those models had been parametrized distributed lags. In the early 1970s, Robert E. Lucas Jr. studied the rational expectations equilibrium of a model with optimizing agents who have different information sets. It was recognized early on that taking rational expectations models to data required new techniques. Building on the early work on tests of the natural rate hypothesis by Sargent (1971), there has been much progress in rational
Rational expectations impose cross-equation restrictions that have important implications for the estimation of models, which I will describe below. These implications have lead to the development of new estimation and testing techniques. More recently, this development has generated techniques that handle models that cannot be solved analytically. Together with the rapid increase in computing power, these methods offer insights in to the working of these models and thereby enable their refinement.

Cross-equation restrictions

The rational expectations assumption implies cross-equation restrictions that constrain parameters and shocks different places of the model. There are (at least) three reasons for why these restrictions have important implications for estimation. First, cross-equation restrictions constrain the parameters associated with agents’ expectations to be consistent with the parameters from the equilibrium probability distribution. These restrictions reduce the overall number of parameters that have to be estimated. In particular, they eliminate any free parameters associated with expectations. To see why, consider a dynamic model with an agent who maximizes some objective function subject to constraints. To solve this optimization program, the agent needs to form expectations about future variables such as growth rates. In a model without rational expectations, these expectations might be based on some subjective belief about the future. This belief introduces free parameters that need to be estimated in addition to other model parameters, such as preference parameters.

Take, for example, an endowment economy populated by a representative agent with time separable power utility. The agent may be optimistic and believe in high mean growth rates for the endowment. This optimistic belief will have an affect on equilibrium outcomes. For example, the agent's Euler equation will only hold for a high short real rate, because the high mean growth rate implies a strong consumption smoothing motive. However, the actual mean growth rate in this economy may be lower than what the agent believes (so that the agent will be disappointed by the endowment realizations.)

The estimation of the model with an optimistic agent involves two parameters, the subjective mean of endowment growth and its true mean, which is the mean of the data generating process of endowment growth. The assumption of rational expectations reduces the number of parameters to estimate, because the two mean parameters collapse: the agent's subjective belief is equal to the true data-generating process. In this simple example, the cross-equation restrictions only eliminated one parameter. In more realistic examples, the agent's subjective belief may involve many parameters (for example, because it is described by a vector autoregression in many variables and with many lags), so that the restrictions are important for keeping the estimation tractable.

The second important implication of cross-equation restrictions is that the processes for different endogenous variables often involve the same parameters and shocks. As a consequence, different data series are informative about the same set of parameters. This implication can be used to increase the efficiency of the estimation. Going back to the example of a representative agent endowment economy, the equation describing the equilibrium process of an interest rate on a bond with m-period maturity is intimately related to the equation describing the process of an n-period interest rate for some m ≠ n. The relationship between different interest-rate equations, or restrictions across equations, consists of
parameters that enter both equations (for example, expected growth) and also shock processes that affect both equations (for example, surprises in growth). These restrictions help in the estimation and can be tested empirically with data on interest rates with different maturities.

Some of the earliest tests of cross-equation restrictions were indeed tests of the implications of rational expectations for the term structure of interest rates. Sargent (1979) specifies a vector autoregression (VAR) for short and long rates. Assuming Gaussian disturbances, Sargent estimates this VAR using maximum likelihood and performs likelihood ratio tests to see whether the restrictions imposed by the expectations hypothesis are satisfied. Subsequently, these tests were further refined, and the expectations hypothesis (which is a stronger assumption than rational expectations) was rejected in many empirical studies. The lessons from these statistical rejections have resulted in refined models with rational expectations but time-varying risk premia (for example, Ang and Piazzesi, 2003).

The third important implication of rational expectations is that the data-generating process that underlies agent beliefs is equal to the true data-generating process. This enables the estimation of rational expectations models using the generalized method of moments based on moment conditions derived from Euler equations (see Hansen, 1982; Hansen and Singleton, 1982; generalized method of moments estimation). Using the law of iterated expectations, such a GMM estimation also allows for the case that agents in the model have more information than the econometrician.

**Estimation methods**

Estimation methods for rational expectations models can be distinguished by the amount of information they require. Generally speaking, there are full information methods and limited information methods. The goal of full information methods is to estimate the entire model by exploiting all its cross-equation restrictions. This estimation method is efficient and produces estimates for all the parameters in the model. These methods are maximum likelihood and its Bayesian counterparts (see Bayesian methods in macroeconometrics). To apply these methods, the econometrician needs to specify the entire structure of the model, including the distribution of shocks.

Limited information methods require less structure. The goal of these methods is to exploit only some of the restrictions imposed by the model and to obtain estimates for only some of the model parameters. These methods lose some of the efficiency of the full information methods, but they help the researcher to avoid contaminating the estimation results by model misspecification in parts of the model that are not of interest. For example, Hall (1978) and Hansen and Singleton (1982) use the Euler equations from a single agent model as moment conditions for GMM and measure the empirical counterparts of these moments using data on consumption and financial returns. This procedure gives estimates for preference parameters and does not depend on any specific assumption on the distribution of shocks in the model.

Faced with the difficulty that many models do not have analytical solutions and have to be solved numerically, there has been progress regarding simulation-based estimation methods. These methods compare moments of data simulated from the model using some parameter values with their empirical counterparts. For a textbook treatment of these methods, see Gourieroux and Monfort (1996), Gourieroux and Jasiak (2001), and Singleton (2006).

Bibliography

Rational expectations is an equilibrium concept that attributes a common model (a joint probability distribution over exogenous variables and outcomes) to nature and to all agents in the model. The rational expectations equilibrium concept makes parameters describing agents' belief disappear as components of a model, giving rise to the cross-equation restrictions that offer rational expectations models their empirical power.

Article

‘Rational expectations’ is an equilibrium concept that can be applied to dynamic economic models that have elements of ‘self-reference’, that is, models in which the endogenous variables are influenced by the expectations about future values of those variables held by the agents in the model. The concept was introduced and applied by John F. Muth (1960; 1961) in two articles that interpreted econometric distributed lag models. Muth used explicitly stochastic dynamic models and brought to bear his extensive knowledge of classical linear prediction theory to interpret distributed lags in terms of economic parameters. For Muth, an econometric model with rational expectations possesses the defining property that the forecasts made by agents within the model are no worse than the forecasts that can be
made by the economist who has the model. Muth's first concrete application of rational expectations was to find restrictions on a stochastic process for income that would render Milton Friedman's (1957) geometric distributed lag formula for permanent income an optimal predictor for income. Muth showed that, if the first difference of income is a first-order moving average process, then Friedman's formula is optimal for forecasting income over any horizon. The independence of this formula from the horizon makes precise the sense in which Friedman's formula extracts from past income an estimator of 'permanent' income. In working backwards from Friedman's formula to a process for income in this way, Muth touched Lucas's critique (1976). Given any distributed lag for forecasting income, one can work backwards as Muth did and discover a stochastic process for income that makes that distributed lag an optimal predictor for income over some horizon. Similarly, Sargent (1977) reverse engineered a joint inflation-money creation process that makes Cagan's (1956) adaptive expectations scheme for forecasting inflation a linear least squares forecast.

Solving a few such inverse-optimal prediction problems in the fashion of Muth and Sargent quickly reveals the dependence of a distributed lag for forecasting the future on the form of the stochastic process that is being forecast. In 1963, Peter Whittle published a book that conveniently summarized and made more accessible to economists the classical linear prediction theory that Muth had used. That book repeatedly applies the Wiener–Kolmogorov formula for the optimal $j$-step ahead predictor of a covariance stationary stochastic process $x_t$ with moving average representation $x_t = c(L) \varepsilon_t$. The Wiener–Kolmogorov formula displays the dependence of the optimal distributed lag for predicting future $x$ on the form of $c(L)$. That dependence underlies Lucas's critique of econometric policy evaluation procedures that were common when Lucas composed his critique in 1973. Those procedures had assumed that distributed lags in behavioural relations would remain invariant with respect to alterations in government policy rules, alterations that took the form of changes in $c(L)$ for government policy instruments. Although the formulas in Whittle's book were used extensively by Nerlove (1967) to work out additional examples along the lines of Muth, it was not until the writing of Lucas's critique in 1973 and its publication in 1976 that the implications for econometric practice of Muth's ideas and the prediction formulas in Whittle began to be widely appreciated.

Lucas and Prescott (1971) clarified and extended rational expectations as an equilibrium concept and also pointed the way to connecting theory with observations. They described the partial equilibrium of an industry in which there exists a fixed number of identical firms, each subject to costs of adjustment for a single factor of production, capital. The industry faces a downward sloping demand curve for its output that shifts randomly due to a demand shock that follows a Markov process. The representative firm maximizes the expected present value of its profits by choosing a contingency plan for investment. To state the firm's optimum problem, it is necessary to describe what the firm believes about the motion of variables that influence its future returns even though they are beyond the firm's control. The price of output is such an uncontrollable variable, but the demand curve for output and the hypothesis of market clearing make price a function of the capital stock in the industry as a whole. It follows that to state the firm's decision problem requires the firm's view about the law of motion of the industry-wide capital stock be stated. The representative firm's optimum problem can then be solved, yielding a law of motion for the capital stock of the representative firm in which both the individual firm's capital stock and the market-wide capital stock are both state variables. Multiplying this law of motion by the number of
firms then gives the actual law of motion for capital in the industry. In this way, the firm's optimization problem and the hypothesis of market clearing induce a mapping from a perceived law of motion to an actual law of motion for the industry's capital stock. A rational expectations equilibrium is a fixed point of this mapping. By studying an artificial planning problem that maximizes consumer plus producer surplus, Lucas and Prescott pursued an indirect approach to describing conditions under which a unique fixed point exists. In this way, they formulated a recursive competitive equilibrium.

From a practical perspective, an important property of a rational expectations model is that it imposes a communism of models and expectations. If we define a model as a probability distribution over a sequence of outcomes, possibly indexed by a parameter vector, a rational expectations equilibrium asserts that the same model is shared by (1) all of the agents within the model, (2) the econometrician estimating the model, and (3) nature, also known as the data generating mechanism. Different agents might have different information, but they form forecasts by computing conditional expectations with respect to a common joint density, that is, a common model. Communism of models gives rational expectations much of its empirical power and underlies the cross-equation restrictions that are used by rational expectations econometrics to identify and estimate parameters. A related perspective is that, within models that have unique rational expectations equilibria, the hypothesis of rational expectations makes agents' expectations disappear as objects to be specified by the model-builder or to be estimated by the econometrician. Instead, they are equilibrium outcomes.

The equilibrium law of motion for capital induces a stochastic process for capital that assumes the form of a Markov process. Lucas and Prescott showed that this Markov process converges in distribution to a unique invariant distribution. That justifies an asymptotic distribution theory adequate for doing time series econometrics, in particular, a mean ergodic theorem that guarantees that sample moments converge to the corresponding population moments. Lucas and Prescott's notion of a recursive competitive equilibrium thus takes a big step towards integrating dynamic theory and econometrics because it supplies an explicit mapping from economic parameters describing preferences, technology, and information sets to the population moments of observable sequences of economic time series. The task of econometrics under rational expectations is to 'invert' this mapping by using time series data to make inferences about economic parameters.

Hansen and Sargent (1980) used linear versions of Lucas–Prescott and Brock and Mirman (1972) models as laboratories for working out econometric techniques for estimating rational expectations models. They studied both generalized method of moments (GMM) and maximum likelihood approaches. They described how desirable statistical properties including consistency and asymptotic efficiency for estimators of the model's economic parameters induce a metric for measuring distance between the sample moments and the theoretical population moments implied by the equilibrium of the model at given parameter values. Typical metrics are those associated with the generalized method of moments, a special case of which is associated with the first-order conditions for maximizing a Gaussian likelihood function. Parameter estimates are obtained by minimizing the metric with respect to the parameter values, a nonlinear minimization problem.

Econometric identification of parameters means uniqueness of the minimizer of distance between the theory and the observations. Identification is partially achieved by the rich set of cross-equation restrictions that the hypothesis of rational expectations imposes (the same parameters appear in many equations, in highly nonlinear ways). These cross-equation restrictions achieve identification in a different manner from the Cowles Commission's ‘rank and order’ conditions, which explicitly excluded
cross-equation restrictions. Dynamic rational expectations models subvert such ‘exclusion restrictions’, and thereby destroy the neat division between ‘supply’ and ‘demand’ curves that underlay the ‘exclusion’ approach to identification.

Minimum distance estimation of a rational expectations model requires recomputing an equilibrium for each set of parameter values used during a descent with respect to the data-fitting metric. Except for linear models, Bellman’s ‘curse of dimensionality’ makes it challenging to compute an equilibrium, so developing improved computational methods has become an important research area. Judd (1998) describes a variety of numerical approaches. Methods for computing equilibria are required not only for parameter estimation, but also for quantitatively evaluating the effects of proposed interventions, for example, new policies for setting government instruments. A new government policy implies, via the cross-equation restrictions, new laws of motion for all the endogenous variables in the models. It is no coincidence that full information estimation methods require calculations closely connected to those needed to evaluate policy.

Good computer programmes for solving and estimating complete rational expectations models have recently become available. A suite of Matlab programmes called Dynare was written by Michele Juilliard and colleagues and is available on the Internet. Dynare solves linear models as systems of expectational difference equations using methods originally described by Sargent (1979), Blanchard and Khan (1980), and Whiteman (1983). Dynare estimates models by either maximum likelihood or a Markov chain Monte Carlo procedure to construct a Bayesian posterior density over free parameters. Dynare also knows how to compute and estimate various linear and log-linear approximations to nonlinear models.

Hansen and Singleton (1982) suggested a short-cut estimation method capable of estimating the parameters of a subset of preference and technologies without computing or estimating a complete equilibrium. Their idea was to use back out parameter estimates from conditional moment restrictions implied by the first-order necessary conditions (Euler equations) for an agent’s dynamic optimization problem. Hansen and Singleton pointed out that their GMM method requires special restrictions on the stochastic process of disturbances to the function being estimated, and that it typically fails to estimate enough parameters to permit evaluating many kinds of interventions. Nevertheless, its ease of use and presumed robustness to features of the environment that a researcher prefers not to specify have made it a very popular and fruitful approach.

As already mentioned, a rational expectations equilibrium is a fixed point from a perceived to an actual law of motion. It is tempting to hope that iterations on that mapping converge to a fixed point. But that is asking for too much because the mapping is not a contraction and it is easy to construct examples in which iterations diverge. Nevertheless, the mapping from a perceived to an actual law of motion plays an important role in studying how a rational expectations equilibrium can emerge as the limit point of a system of adaptive agents who use least squares on historical data to forecast the future, rather than the population moments from the equilibrium that are handed to them within a rational expectations equilibrium. By applying the theory of stochastic approximation, Marcet and Sargent (1989) and Woodford (1990) derived an ordinary differential equation (ODE) for beliefs that describe the limiting behaviour of such an adaptive system. That ODE expresses how the gap between the perceived and implied actual law of motion governs a limiting rate of change of beliefs. Necessary and sufficient conditions for convergence to a rational expectations equilibrium are stated in terms of the stability of
rational expectations: The New Palgrave Dictionary of Economics

...the associated ode. These conditions have been dubbed the E-stability conditions by Evans and Honkapohja (2001) and are useful for constructing algorithms for computing rational expectations equilibria via least squares learning algorithms or direct attacks on the ordinary differential equation governing E-stability. This is in effect what Krusell and Smith (1998) do, though they do not connect their method to the learning literature.

The literature on least squares learning and adaptive learning in games (for example, Marcet and Sargent, 1989; Woodford, 1990; Fudenberg and Levine, 1998) began partly as a response to a widespread scepticism about the plausibility of the communism of expectations imposed by rational expectations. How could people possibly come to learn to share a common model with each other, the econometrician, and nature? The learning literature offers an explanation. But the learning literature falls short of implying a communism of models as extensive as the one typically imposed in macroeconomics. A meta-theorem is that, if a system of least squares agents converges, it converges to a self-confirming equilibrium (see Fudenberg and Levine, 1998; Sargent, 1999). In a self-confirming equilibrium, agents' models agree about events that occur frequently enough (infinitely often) within the equilibrium. But agents can have different subjective distributions about events that occur infrequently because they are off the equilibrium path. For those events, a law of numbers just doesn't have enough observations to work on. In a macro model, it is typically irrelevant that private agents' beliefs can be wrong off an equilibrium path because, being atomistic, all that matters for them are their conditional forecasts along an equilibrium path. But for the government, its beliefs about off-equilibrium paths events influence its choices in important ways: designing government policy is all about evaluating the effects of alternative hypothetical outcome paths, most of which will not be observed. Kreps (1998) defends the concept of self-confirming equilibrium.

Lucas and Prescott's model can be used to study aspects of the theory of policy. Their model generates a stochastic process for output, price and industry capital that exhibits recurrent but aperiodic 'cycles', as realizations of stochastic difference equations do. Thus, Lucas and Prescott's model is an alternative to the 'cobweb' mechanism for generating fluctuations in commodity markets. Two-industry versions of the model can readily be constructed to model 'corn-hog' cycles. Models along the lines of Lucas and Prescott's reveal a different perspective on these cycles than do cobweb models. Lucas and Prescott show that, despite cyclical fluctuations, the equilibrium of their model is optimal in the sense that it maximizes the expected present value of consumer surplus net of producer surplus. Therefore, unlike cobweb models, in which cycles partly reflect erroneous and readily improved upon perceptions of private agents, matters cannot be improved by government interventions designed to smooth out the cycles. Models of this kind have been calibrated to price and quantity data from markets for cattle, housing, and engineers by Rosen, Murphy and Scheinkman (1994), Topel and Rosen (1988), and Ryoo and Rosen (2004).

For studying a variety of macroeconomic questions, researchers have used what can be interpreted as a version of Lucas and Prescott's model, suitably modified and reinterpreted to apply to an aggregative economy. Brock and Mirman (1972) analysed a centralized version of such an economy that took the form of a stochastic version of a one-sector optimal growth model. The planner in their model seeks to maximize the expected discounted value of utility of consumption subject to a technology for transforming consumption over time via investment in physical capital. Brock and Mirman gave conditions under which the optimal plan for capital and consumption induces a stochastic process that
converges in distribution, so that, like Lucas and Prescott's model, theirs is prepared for rigorous
treatment econometrically. It is possible to decentralize Brock and Mirman's model into an equivalent
economy consisting of competitive firms and households who interact in markets for labour and capital
and who have rational expectations about the evolution of the wages and interest rates that they face.
Decentralized versions of Brock–Mirman models have been used to construct equilibrium theories of
stock prices and interest rates, typically by computing particular shadow prices associated with the
planning problem (Lucas, 1978; Brock, 1982). Decentralized versions of the Brock–Mirman model form
the backbone of the modern version of ‘real business cycle theory’ that was initiated by Kydland and
Prescott (1982). Since the stochastic optimal growth model has a stochastic difference equation for
capital as its equilibrium, it shares with the Lucas–Prescott model the property that it readily generates
realizations for capital, output and consumption that display recurrent but aperiodic fluctuations of the
kind observed in aggregate time series data. Kydland and Prescott embarked on the task of taking
seriously the possibility that the preferences and technology of a small stochastic optimal growth model
could be specified so that it would approximate closely the moments of a list of important aggregate
economic time series for the United States. Kydland and Prescott have constructed several such models,
each driven by a single unobserved shock, which they interpret as a disturbance to technology. This
research strategy is charged with meaning, since it undertakes to explain aggregate time series data with
a model whose equilibrium is optimal, and in which there is no government. The government is neither a
contributing source to economic fluctuations nor a potential modifier of those fluctuations. Real business
cycle models of this kind are capable of determining a long list of real variables, while remaining silent
about all nominal variables.
But central banks are supposed to determine nominal variables, which has created an interest in adapting
real business cycle models to include interactions among nominal and real variables. By directly
imposing parameterized versions of wage and price inertia, Smets and Wouter (2003) and Woodford
(2003) have formulated rational expectations models with enough shocks and rigidities to fit macro data
well enough to be useful to research departments of leading central banks. These models can be
estimated and simulated with Dynare.
The idea of rational expectations was essential for formulating the problem of time inconsistency in
macroeconomics. Three ideas underlie the time consistency problem in multi-agent dynamic games and
macroeconomic models: (1) the communism of models brought by rational expectations, (2) backward
induction by all agents, and (3) the observation that different timing protocols generally imply different
outcomes. The time inconsistency ‘problem’ was recognized in macroeconomics by Kydland and
Prescott (1977) and Calvo (1978), who studied macro models in which a competitive economy with a
representative agent confronts a benevolent government. These papers compare outcomes under two
timing protocols. In one timing protocol, private agents choose sequentially but the government has a
commitment technology that allows it once and for all at time zero to choose an entire history contingent
sequence of actions (for example, tax rates or money supplies). In the other, the government, or a
sequence of government administrations if you prefer, must choose sequentially, that is, anew each
period. Outcomes under these two timing protocols typically differ, with outcomes being better under
the timing protocol that allows the government to choose once and for all at time 0. The difference in
outcomes shows the value of being able to commit at time 0. In the problem under commitment, among
the constraints that the government faces at time 0 are a sequence of private agents’ Euler equations that
rational expectations: The New Palgrave Dictionary of Economics

involve their (rational) expectations of future government actions. The equilibrium time \( t \) values of the Lagrange multipliers on these ‘implementability constraints’ encode the costs in terms of the government's time \( t \) continuation value of confirming the time \( t \) expectations that the government's time \( 0 \) plan had induced private agents to expect. The presence of those implementability conditions in the government's constraint set gives rise to a conflict between the preference orderings of the government and the representative agent over outcomes. That conflict is the ultimate source of the timing inconsistency problem. Recursive methods for computing the optimal plan under commitment were first suggested by Kydland and Prescott (1980) and are surveyed in Ljungqvist and Sargent (2004). These methods are used extensively in the literature on rational expectations monetary models with ad hoc inertial wages and prices that Woodford (2003) catalogues and extends.

An important literature studies whether reputation can overcome the time inconsistency problem. The finding of this literature is that, by allowing history-dependent strategies, reputation can substitute for the ability to commit if the discount factor is sufficiently close to one. This literature, which is surveyed critically in Ljungqvist and Sargent (2004), exploits the communism of expectations inherent in rational expectations.

rationality, bounded

Herbert A. Simon
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Bounded rationality’ refers to rational choice that takes into account the cognitive limitations of the decision-maker – limitations of both knowledge and computational capacity. It is a central theme in the behavioural approach to economics. Theories of bounded rationality can be generated by relaxing one or more of the assumptions of subjective utility theory underlying neoclassical economics. They insist that the model of human rationality must be derived from detailed and systematic empirical study of human decision-making behaviour in laboratory and real-world situations. For example, a satisficing strategy may be postulated instead of the maximization of a utility function.

behavioural approach to economics; bounded rationality; choice; cognitive limits; expected utility; money illusion; neoclassical economics; optimal search; probability; rational expectations; satisficing; Simon, H. A.; subjective utility theory; substantive vs. procedural rationality; uncertainty

Article

The term ‘bounded rationality’ is used to designate rational choice that takes into account the cognitive limitations of the decision-maker – limitations of both knowledge and computational capacity. Bounded rationality is a central theme in the behavioural approach to economics, which is deeply concerned with the ways in which the actual decision-making process influences the decisions that are reached.

The theory of subjective utility (SEU theory) underlying neo-classical economics postulates that choices are made: (1) among a given, fixed set of alternatives; (2) with (subjectively) known probability distributions of outcomes for each; and (3) in such a way as to maximize the expected value of a given utility function (Savage, 1954). These are convenient assumptions, providing the basis for a very rich and elegant body of theory, but they are assumptions that may not fit empirically the situations of economic choice in which we are interested.
Theories of bounded rationality can be generated by relaxing one or more of the assumptions of SEU theory. Instead of assuming a fixed set of alternatives among which the decision-maker chooses, we may postulate a process for generating alternatives. Instead of assuming known probability distributions of outcomes, we may introduce estimating procedures for them, or we may look for strategies for dealing with uncertainty that do not assume knowledge of probabilities. Instead of assuming the maximization of a utility function, we may postulate a satisficing strategy. The particular deviations from the SEU assumptions of global maximization introduced by behaviourally oriented economists are derived from what is known, empirically, about human thought and choice processes, and especially what is known about the limits of human cognitive capacity for discovering alternatives, computing their consequences under certainty or uncertainty, and making comparisons among them.

**Generation of alternatives**

Modern cognitive psychology has studied in considerable depth not only the processes that human subjects use to choose among given alternatives, but also the processes (problem-solving processes) they use to find possible courses of action (i.e., actions that will solve a problem) (Newell and Simon, 1972). If we look at the time allocations of economic actors, say business executives, we find that perhaps the largest fraction of decision-making time is spent in searching for possible courses of action and evaluating them (i.e., estimating their consequences). Much less time and effort is spent in making final choices, once the alternatives have been generated and their consequences examined. The lengthy and crucial processes of generating alternatives, which include all the processes that we ordinarily designate by the word ‘design’, are left out of the SEU account of economic choice.

Study of the processes for generating alternatives quickly reveals that under most circumstances it is not reasonable to talk about finding ‘all the alternatives’. The generation of alternatives is a lengthy and costly process, and one where, in real-world situations, even minimal completeness can seldom be guaranteed. Theories of optimal search can cast some light on such processes, but, because of limits on complexity, human alternative-generating behaviour observed in the laboratory is usually best described as heuristic search aimed at finding satisfactory alternatives, or alternatives that represent an improvement over those previously available (Hogarth, 1980).

**Evaluation of consequences**

Cognitive limits, in this case lack of knowledge and limits of ability to forecast the future, also play a central role in the evaluation of alternatives. These cognitive difficulties are seen clearly in decisions that are taken on a national scale: whether to go ahead with the construction of a supersonic transport; the measures to be taken to deal with acid rain; Federal Reserve policies on interest rates; and, of course, the supremely fateful decisions of war and peace.

The cognitive limits are not simply limits on specific information. They are almost always also limits on the adequacy of the scientific theories that can be used to predict the relevant phenomena. For example, available theories of atmospheric chemistry and meteorology leave very wide bands of uncertainty in estimating the environmental or health consequences of given quantities and distributions of air pollutants. Similarly, the accuracy of predictions of the economy by computer models is severely limited
by lack of knowledge about fundamental economic mechanisms represented in the models’ equations.

Criteria of choice

The assumption of a utility function postulates a consistency of human choice that is not always evidenced in reality. The assumption of maximization may also place a heavy (often unbearable) computational burden on the decision maker. A theory of bounded rationality seeks to identify, in theory and in actual behaviour, procedures for choosing that are computationally simpler, and that can account for observed inconsistencies in human choice patterns.

Substantive and procedural rationality

Theories of bounded rationality, then, are theories of decision making and choice that assume that the decision maker wishes to attain goals, and uses his or her mind as well as possible to that end; but theories that take into account in describing the decision process the actual capacities of the human mind. The standard SEU theory is presumably not intended as an account of the process that human beings use to make a decision. Rather, it is an apparatus for predicting choice, assuming it to be an objectively optimal response to the situation presented. Its claim is that people choose as if they were maximizing subjective expected utility. And a strong a priori case can be made for the SEU theory when the decision making takes place in situations so transparent that the optimum can be reasonably approximated by an ordinary human mind.

Theories of bounded rationality are more ambitious, in trying to capture the actual process of decision as well as the substance of the final decision itself. A veridical theory of this kind can only be erected on the basis of empirical knowledge of the capabilities and limitations of the human mind; that is to say, on the basis of psychological research.

The distinction between substantive theories of rationality (like the SEU theory) and behavioural theories is closely analogous to a distinction that has been made in linguistics between theories of linguistic competence and theories of linguistic performance. A theory of competence would characterize the grammar of a language in terms of a system of rules without claiming that persons who speak the language grammatically do so by applying these rules. Performance theories seek to capture the actual processes of speech production and understanding.

The question of the desirability and usefulness of a procedural theory of decision involves at least two separate issues. First, which kind of theory, substantive or procedural, can better predict and explain what decisions are actually reached. Does SEU theory predict, to the desired degree of accuracy, the market decisions of consumers and businessmen, or does such prediction require us to take into account the cognitive limits of the economic actors?

Second, are we interested only in the decisions that are reached, or is the human decision making process itself one of the objects of our scientific curiosity? In the latter case, a substantive theory of decision cannot meet our needs; only a veridical theory of a procedural kind can satisfy our curiosity.

Bounded rationality in neoclassical economics
It should not be supposed that mainstream economic theory has been completely oblivious to human cognitive limits. In fact, some of the most important disputes in macroeconomic theory can be traced to disagreements as to just where the bounds of human rationality are located. For example, one of the two basic mechanisms that accounts for under employment and business cycles in Keynesian theory is the money illusion suffered by the labour force – a clear case of bounded rationality. In Lucas's rational expectationist theory of the cycle, the corresponding cognitive limitation is the inability of businessmen to discriminate between movements of industry prices and movements of the general price level – another variant of the money illusion. Thus the fundamental differences between these theories do not derive from different inferences drawn from the assumptions of rationality, but from different views as to where and when these assumptions cease to hold – that is, upon differences in their theories of bounded rationality.

What distinguishes contemporary theories of bounded rationality from these ad hoc and casual departures from the SEU model is that the former insist that the model of human rationality must be derived from detailed and systematic empirical study of human decision making behaviour in laboratory and real-world situations.

rationality, history of the concept

Esther-Mirjam Sent  
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article offers a historical and methodological perspective on the concept of rationality. It gives an overview of the various interpretations of the notion, from self-interest to rational choice and expected utility to strategic rationality and rational expectations. It pays special attention to the ethical dimensions of the concept. The article further places rationality within a long-ranging discussion concerning the status of assumptions within economics. It explicitly considers efforts to test rationality directly. The article concludes with an evaluation of recent efforts to replace rationality with the notion of bounded rationality.

Article
Economics has always relied on some notion of rationality. Unlike philosophers, economists are not concerned with the rationality of beliefs, which are taken as data (Tisdell, 1975). In the 18th century, economics was integrated into the great scheme of the natural law and a rationalistic world view (Daston, 1983; Weber, 1904). During this time, the moral sciences aimed to reveal the rational grounds for action and belief. Overall, their focus was individualistic, psychological, and prescriptive. During the 19th century, a transition took place from a psychological framework to a sociological one. At the same time, the search for inexorable social laws replaced the computation of rational self-interest. However, economics continued to cling to rationality. Throughout much of the 20th century, many economists would separate economics from sociology upon the basis of rational or irrational behaviour (Samuelson, 1947).

Rationality is usually combined with a variety of other concepts (Arrow, 1987; Sen, 1987). Indeed, the force of the hypothesis comes from the addition of supplementary hypotheses. What has changed over time, then, is the interpretation of rationality. While it was initially associated with self-interest, in later readings, such as rational choice and expected utility, it became linked with ideas such as consistency and indifference. Recent appeals to it include strategic aspects of behaviour. Within macroeconomics, rational expectations economists have taken rationality to its extreme. Interpretations of rationality cover a wide range that includes it having the status of axiom, a priori truth, self-evident proposition, useful fiction, utopia, ideal type, analytical construct, heuristic construct, indisputable fact of experience, and typical behavioural pattern under capitalism.

Rationality is ubiquitous in modern economics, with the result that economists frequently make the assumption that it has the same meaning in all the contexts in which it is used. However, this is not the case. The assumption of rationality may be motivated by an appeal to the notion of self-interest, with due allowance made for the fact that preferences may extend to the welfare of others, but its use in expected utility theory, the analysis of strategic behaviour, rational expectations, and so on raise issues that are sufficiently profound that the meaning of the concept of rationality is fundamentally changed. Rationality may further be interpreted as either a positive or a normative notion. Efforts to test rationality interpret the notion in a descriptive manner. That is, rationality is presumed to characterize how people actually go about the business of reasoning. In response, one may investigate the psychological mechanisms and processes that underlie the patterns of reasoning that are observed. By contrast, a normative interpretation of rationality is concerned not so much with how people actually reason as with how they should reason (Suppes, 1961). The goal is to discover rules or principles that specify what it is to reason rationally – to specify standards against which the quality of human reasoning can be measured.

In the remainder of this article we first take a closer look at historical debates concerning the overall status of the rationality assumption. We then consider methodological concerns associated with the various historical interpretations of rationality, and subsequently address efforts to test rationality. After this, we take the historical debates up to the present, where we find that more and more economists are moving away from rationality towards the notion of bounded rationality.

**The rationality assumption**

Since rationality is such a central notion within economics, many of the debates about the status of
assumptions within economics are related to it. In the early 19th century, John Stuart Mill (1836) argued that economics is an abstract science because it reasons from assumed premises, such as rationality. As a result, its conclusions are true in the abstract. Moreover, Mill continued, that which is true in the abstract is always true in the concrete with proper allowances. This view found support among Nassau Senior, John Elliott Cairnes, and John Neville Keynes. In a similar vein, in the early 20th century, Lionel Robbins (1935) argued that the basic postulates of economics, such as rationality, are simple and indisputable facts of experience. In the opinion of Robbins, the propositions of economic theory are deductions from a series of such self-evident postulates. These insights came under serious attack by Terence Hutchison (1956). First, Hutchison claimed, the propositions of pure theory are empty. Second, maximization and equilibrium require perfect expectations. Third, economics needs more extensive use of empirical techniques. Finally, economists can use the psychological method of a priori facts, the method of *Verstehen*, and the method of introspection only for suggesting hypotheses, in Hutchison's opinion, and not for establishing them. He concluded that the rationality postulate was treated as analytic by economists, meaning that it is a priori true yet with empirical content. Instead, he claimed that it must be synthetic, meaning that it must be stated in testable form.

Hutchison's arguments about the status of the rationality assumption found a serious critic in Fritz Machlup (1956). First, Machlup argued, rationality is a theoretical construct. Second, empirical studies judge applicability. That is, they confirm rather than offer complete verification. Third, economists need to focus on ‘realistic’ assumptions embedded in a system of interrelated hypotheses. Finally, they need a suitable replacement in case of ‘rejection’. Machlup agreed with Hutchison that testing is important. However, whereas Hutchison wanted to test all statements, Machlup restricted this to specific assumptions and low-level hypotheses. And whereas Hutchison was after verification, Machlup sought confirmation.

A contrasting perspective on the status of the rationality assumption in economics came from Milton Friedman (1953), who argued that assumptions are largely irrelevant to the validation of theories. Instead, the latter should be judged, in Friedman's opinion, almost solely in terms of their instrumental value in generating accurate predictions. He did consider other criteria besides valid and meaningful predictions, but these were subsidiary. They included logical consistency, categories with meaningful empirical counterparts, advancing a substantive hypothesis capable of being tested, and simplicity and fruitfulness. Friedman argued that the standard theory in economics is successful due to its countless applications. He further claimed that the positive record follows from the dynamics of competition over time. In his opinion, the role of assumptions such as rationality is limited. They specify the conditions of validity, but do not determine these. They offer an economical mode of describing or presenting a theory. And indirect evidence may follow if assumptions are the implications of related hypotheses. In a similar vein, Armen Alchian (1950) had argued that individuals who act in a rational fashion will be successful and ‘selected’ for survival by the economic system.

Herbert Simon (1963) endeavored to rescue interest in the rationality assumption in economics by criticizing Friedman's so-called principle of unreality. According to Simon, one cannot use the validity of the market level to support the actor level. Instead, economists need to explain the market level through the use of the actor level. In Simon's opinion, valid theories about the market level follow from empirically valid assumptions about actors together with empirically valid composition laws. He therefore suggested the so-called principle of continuity of approximation instead. This holds that, if the
conditions of the real world approximate sufficiently well the assumptions of an ideal type, the derivations from these assumptions will be approximately correct. Simon argued that the unreality of premises is not a virtue but a necessary evil – a concession to the finite computing agency of the scientist that is made tolerable by the principle of continuity of approximation.

We return to Simon's alternative when we follow the historical narrative to the present towards the end of this article. We now look at methodological concerns associated with the various historical interpretations of rationality.

Rationality as self-interest

If rationality is interpreted in terms of self-interest, one of the questions that arises concerns the status of norms (Elster, 1989). Are norms rationalizations of self-interest? No, because some norms override self-interest. And norms need to have some kind of grip to be manipulated. Are norms followed out of self-interest? No, because norms do not need external sanctions. Moreover, some sanctions are performed for other motives. Do norms exist to promote self-interest? No, because followers of norms abide by them even when it is not in their interest to do so. Do norms exist to promote common interests? No, because not all norms are Pareto-improvements. In addition, some norms that would be Pareto-improvements are not observed. Do norms exist to promote genetic fitness? No, because self-interest and fear of sanctions do not provide the full explanation for adherence to norms. And we need to study emotions, envy, honour, and conformism. Additional questions arise with the later interpretations of rationality.

Rational choice and expected utility

Within expected utility theory, rationality was associated with (a) subjective probability, (b) Bayesian learning, and (c) maximization of expected utility (Sugden, 1991). In this interpretation, preferences are revealed by choice, and choices are supported by reasons. Efforts have been made to develop philosophical foundations of expected utility theory by appealing to Hume's instrumental rationality. According to the latter, actions can be motivated only by desires, and no desire can be brought into existence by reason alone. That is, reason is an instrument for achieving ends that are not themselves given by reason. However, there are two problems when it comes to linking expected utility theory with Hume's instrumental rationality. First, determinacy is not implied by Hume's theory of motivation. Second, consistency also does not follow from it. That is, the axioms associated with expected utility are much stronger than instrumental rationality. First, there is no justification for the completeness of preferences presumed within expected utility theory. Evidence for this can be found in framing effects, according to which the alternative framing of information in positive or negative terms affects judgments and decisions. Second, there is no justification for transitivity and sure-thing axioms due to the restricted interpretation of consequences. Evidence for this can be found in regret theory, according to which people take anticipated regret into account when they decide, which probably makes them loss averse.

Some have criticized the rational choice interpretation of rationality for presuming economic agents to be rational fools due to the severe constraints on the nature of the models that can be admitted into analysis (Sen, 1977). On the one hand, rational choice presumes too little. This is because choice may
reflect a compromise among a variety of considerations of which personal welfare may be just one. Rational choice has further come under attack for circularity because behaviour is explained in terms of preferences defined by behaviour. And it has been criticized for having too little structure; that is, it does not consider sympathy and commitment. With sympathy, which is egoistic, concern for others directly affects one's own welfare, which can be seen as an externality that would upset some standard results. With commitment, which is non-egoistic, concern for others does not affect one's own welfare but does cause action. Such action can be seen as involving counter-preferential choice requiring reformulation of the economic models, since personal choice can no longer be equated with personal welfare. In response, it has been argued that commitment needs to be accommodated as a part of behaviour by considering meta-rankings of preference rankings to express our moral judgments.

Similar concerns arise as a result of a wide range of impossibility results, such as Arrow's impossibility theorem, according to which supra-individual entities such as societies and nations cannot be said to have well-behaved preferences of the sort attributed to individual agents in rational choice approaches, under fairly general circumstances (Arrow, 1987). This devastated the hope that statements about collectivities could have solid microfoundations in individual rationality. We will return to ethical and justice matters after taking a closer look at the appeals to rationality within game theory.

**Strategic rationality**

Nash equilibrium, the basis for much game theory, goes further in assuming not only rationality but also common knowledge of rationality (Sugden, 1991). That is, it presumes that there is common knowledge of the mathematical description of the game, of the rationality of the players, and of the logical or mathematical theorems. However, common knowledge of rationality is not sufficient for Nash equilibrium. In addition, it is incoherent since it requires subjective probabilities to be formed, which may not be possible. Moreover, it is circular, though it establishes internal consistency of the infinite chain of reasoning, since it cannot explain choice because the outcome is not determinate. As a result, common knowledge of rationality should be seen as an equilibrium concept, where equilibrium may not exist.

Arguments have been made that the rationality associated with Nash equilibrium is self-defeating (Sent, 2004a). That is, all kind of frictions have been encountered within the Nash program. First, the folk theorem illustrates the (very real) possibility of encountering multiple equilibria in repeated games. The folk theorem states that in infinitely repeated games, for a range of discount factors that are high enough – though less than 1 – any payoff vector that is feasible in the set of payoffs between two players who are simultaneously individually rational is a Nash equilibrium payoff. Second, intuitively unreasonable equilibria may be selected in the finitely repeated Prisoner's Dilemma game, the chain store paradox, and the centipede game. As a result, the standard game-theoretic solutions yield results that are considered quite unintuitive. Finally, under certain conditions, theorems concerning the non-existence of trade and the impossibility of ‘agreeing to disagree’ about an event have been proved for Nash equilibria. Moreover, speculative trade cannot be explained as an outcome of different information structures. One possible resolution is to disconnect Nash equilibrium and common knowledge of rationality. It has been shown that common knowledge could generate many non-Nash equilibria. Likewise, it has been shown that even with common knowledge of rationality there may be no Nash equilibrium. Overall, however,
Rational expectations

In recent economics, there has been much concern with how expectations are formed. The dominant approach argues that the rules of thumb, such as adaptive expectations, which fail to use available information optimally are hard to reconcile with the idea of rationality that was the foundation of most economic analysis (Muth, 1961). Instead, it is argued that, since agents are claimed to be optimizers, it is only natural to presume that they will also form their expectations rationally. Hence, some argue that the rational expectations hypothesis is nothing but a direct application of the rationality principle to the problem of expectations of future events. In particular, optimizing over perceptions implies that agents do the best they can and form their views of the future by taking account of all available information, including their understanding of how the economy works. If perceptions were not optimally chosen, there would exist unexploited utility or profit-generating possibilities within the system. The implication is that all such unexploited possibilities must disappear. When applied to macroeconomics, this appeared to be in sharp contrast with Keynesian theories, which modelled firms and consumers in ways that were seen as being ad hoc and inconsistent with the idea of rational behaviour. The typical Keynesian assumptions that markets did not clear and that economic agents did not always pursue optimizing strategies could be criticized on similar grounds, as implying ad hoc departures from the axiom of rational behaviour. From this perspective, to adopt rational expectations is thus to replace earlier ad hoc treatments with an approach squarely based on the microfoundations of incentives, information, and optimization.

A variety of problems have arisen within rational expectations economics as a result of its rationality assumption (Sent, 1997). First, how can there be trade among economic agents who are all rational? One suggestion, following a line of research started by Robert Lucas, is that equilibrium probability beliefs differ and that agents actually trade on the basis of different information. However, a whole series of no-trade theorems overrule this common-sense intuition (Varian, 1987). The second obstacle encountered by rational expectations economists involved error-term justification. In particular, close scrutiny of the justification of error terms revealed that the econometrician needed to be outwitted by the agents (Sargent, 1981). Finally, how can policy recommendations be made when agents, economists, and governments are put on an equal footing based on rational expectations? When policy recommendations are possible, symmetry is impossible. For making recommendations for improving policy amounts to assuming that in the historical period the system was not really in a rational equilibrium. When symmetry is possible, policy recommendations are impossible. For making the assumption that in the historical period the system was in a rational equilibrium raises the question of why we study a system that we cannot influence (Sargent, 1984).

Having considered methodological concerns associated with the various historical interpretations of rationality, we now take up ethical concerns explicitly, since they bear upon rationality in general.

Ethics

Some have criticized economists for focusing narrowly on rationality while ignoring ethics (Hausman
They claim that ethics is relevant to economists for a variety of reasons. First, economists need to know some morality to know what questions to ask. Second, economists evaluate moral commitments while describing them. Third, economists affect what they see by how they describe it. Fourth, economists are influenced by their moral values and their attitudes towards the values of the agents they study. Hence, ethics is part and parcel of economics, even when economists fail to acknowledge this in their focus on rationality. An additional concern is that they oftentimes mistakenly identify well-being with preference satisfaction. This is problematic for a variety of reasons. First, what people prefer may not be good for them. Second, people make mistakes. Third, people may prefer to sacrifice their own well-being in pursuit of some other end. As a result, appraisals of economic institutions and outcomes must consider moral concerns, such as freedom, rights, and justice, besides rationality.

Rationality, which is central to the notion of a competitive equilibrium, is a key element in the two fundamental theorems of welfare economics. The first states that any competitive equilibrium leads to an efficient allocation of resources. The second asserts the converse, that any efficient allocation can be sustainable by a competitive equilibrium. The first theorem appears to make a case for non-intervention: let the markets do the work and the outcome will be desirable. The second theorem states that out of all possible efficient outcomes (of which there may be many) one can achieve any particular efficient outcome by enacting a lump-sum wealth redistribution and then letting the market take over. It has been argued that perfectly competitive markets with individual factor endowments and private goods, free market activity and mutual concern, and the absence of rationality are morally free zones (Gauthier, 1991). Because of the free activity, there is liberty. Due to the absence of externalities, there is impartiality. And as a result of the first welfare theorem, there is optimality. This morally free zone, the argument goes, arises in a deeper moral framework, according to which moral constraint is compatible with mutual unconcern and rationally required. In addition, morality as a system of rationally required constraints makes possible the realization of one's interests and the fulfilment of one's preferences. This perspective has been criticized on four accounts. First, there are market failures. Second, the initial distribution is relevant. Third, there may be multiple equilibria. Fourth, no account of social policy is given. Instead, it has been claimed that markets are political, cultural and economic. First, they support a well-defined structure of power. Second, they shape our culture. Third, they foster or thwart desirable forms of human development. Fourth, they allocate resources and distribute income. Since rationality is only one element in these arguments, we shall not dwell on these concerns further.

Having considered ethical concerns explicitly, we now turn to efforts to test rationality, since they also bear upon rationality in general.

Testing rationality

As cautioned in the introduction of this article, efforts to test rationality interpret the notion in a descriptive manner. With this in mind, much energy has also been put into trying to test rationality directly (Blaug, 1992). According to some, this involves stating the problem situation, testing the predictions, assessing the evidence, considering the nature of explanation, considering alternative theories, and stating the hard core and heuristics. However, these steps are more difficult than appears at first sight. As philosophers of science have argued, immunizing stratagems are sometimes defensible,
rationality, history of the concept: The New Palgrave Dictionary of Economics

verisimilitude is difficult to implement, and there is no metric of corroboration. Economics poses additional problems, because narrow falsificationism is too restrictive and broad falsificationism has no prescriptive force. Moreover, economics is characterized by many initial conditions and no general laws. Testing its models is not the same as testing theories. Its data do not correspond to the concepts. Finally, falsificationism is hardly ever practiced in economics. Indeed, in response to these problems with the Popperian position, Popper himself accorded a special status to the rationality principle within his situational logic as a ‘zero principle’. This situational logic is used to explain actions and events in social science. According to Popper, the rationality principle is an integral part of every, or nearly every, testable social theory. At the same time, he believed there to be good reasons for the rationality principle to be false, while a good approximation to truth. Still, he felt that social scientists should retain it despite the fact that it is false. This is because he believed that we learn more if we blame our situational model. Indeed, he saw the policy of upholding the rationality principle as part of our methodology. After this methodological ‘detour’, we now return to the historical narrative by evaluating recent efforts to replace rationality with the notion of bounded rationality.

Bounded rationality

Recently, especially game theorists and rational expectations economists have embraced the notion of Bounded rationality. Game theorists have looked towards Bounded rationality in their efforts to save the rationality of the Nash equilibrium. This was needed because of frictions within the Nash program (Aumann, 1997; Rubinstein, 1998). First, the folk theorem illustrates the (very real) possibility of encountering multiple equilibria in repeated games. Second, intuitively unreasonable equilibria may be selected in the finitely repeated Prisoner's Dilemma game, the chain store paradox, and the centipede game. Finally, under certain conditions, theorems concerning the non-existence of trade and the impossibility of ‘agreeing to disagree’ about an event have been proved for Nash equilibria. It could be argued that one response of game theorists to these problems has been to incorporate Bounded rationality (Sent, 2004a). First, Bounded rationality functioned as a dynamic for selection among multiple equilibria by promising to ‘refine’ equilibria. Moreover, the evolutionary stable strategy concept of evolutionary game theory may be viewed as a further refinement of perfect equilibrium, one of the most common notions used to refine the Nash equilibrium. Second, Bounded rationality has been used to rule out unintuitive equilibria in the Prisoner's Dilemma game, the chain store paradox, and the centipede game. Third, absence of a fully rational treatment of knowledge may circumvent the no-trade theorems by allowing speculative trade. These attempts to strengthen Nash, then, lead to the paradoxical observation that rationality in games depends critically on irrationality.

Likewise, rational expectations economists have sought to reinforce the rational expectations hypothesis by focusing on convergence to this equilibrium through boundedly rational ‘learning’. They have also used Bounded rationality to deal with some of the problems associated with rational expectations such as multiple equilibria and the computation of equilibria (Sargent, 1993).

Economists have tried to capture Bounded rationality by replacing rational players with computing devices such as Turing machines, finite automata, or neural network algorithms. Players' rationality is bounded in the sense that they cannot consider strategies other than those that can be played by these computing devices. Rationality is bounded in Turing machines because these machines will sometimes compute for ever to give correct answers. In order to come up with a solution, the output follows an
arbitrary guessing rule after the machine has been stopped. Bounded rationality in finite automata is captured by imposing constraints on the number of states of the automata or assuming that states are costly. Neural networks, finally, increase the computational capability of a finite automaton by increasing the states of the machine.

Both game theorists and macroeconomists have developed models of boundedly rational learning (for example, Bray and Kreps, 1987). The basic idea in these models is that boundedly rational agents utilize one of three procedures for making and changing their choices on the basis of past outcomes. First, Bayesian learning assumes that players update their subjective probabilities in the face of inconsistencies through the use of Bayes' rule until consistency is achieved. This technique has been used in the problem of equilibrium selection. It has been criticized for not accurately representing ‘true’ learning. Second, least squares or adaptive control learning assumes that players use standard statistical or econometric procedures for estimation. These procedures are boundedly rational in that economic agents use models that are misspecified and forecasting procedures that are not part of the optimal decision making of these individuals. This approach has been used in the context of rational expectations models. It has been criticized for requiring the agents to still be quite smart. Third, neural network learning assumes that individuals construct explicitly approximate models of their environment which are updated as their information improves. In contrast to least squares or adaptive control learning, agents here know they hold misspecified models of reality. This technique has been used to explore how boundedly rational players can achieve consistent beliefs and, possibly, a Nash equilibrium.

**Behavioural economics**

Developments within game theory and rational expectations economics combined with the rise of behavioural economics suggest that economics as a whole is moving away from rationality and towards Bounded rationality (Sent, 2004b). In the 1960s, appeals to Bounded rationality on the part of behavioural economists were designed to develop an alternative to the mainstream model (for example, Simon, 1955). We could label these endeavours as old behavioural economics. At that time, few economists exhibited any interest in these efforts. In the 1970s, cognitive psychologists suggested ways to incorporate behavioural insights in ways that provided less of a threat to the standard model (for example, Kahneman and Tversky, 1974). We could label these efforts as new behavioural economics. At the same time, the mathematical foundations of the mainstream started showing some flaws. In the 1980s, disagreements emerged between old and new behavioural economists with the latter emerging as the victors in the 1990s, partly because Herbert Simon abandoned his efforts and partly because new behavioural economists suggested ways in which their insights may help rebuild the mainstream stronghold.

Bounded rationality is not a field in itself, but rather an approach to doing economic research (Simon, 1976). There are many interpretations of Bounded rationality and these are not always consistent. Herbert Simon, the father of Bounded rationality, used the term ‘Bounded rationality’ to highlight limitations of both knowledge and computational capacity. These bounds affect human cognitive capacity for discovering alternatives, computing their consequences under certainty and uncertainty, and making comparisons among them. Theories of Bounded rationality, then, are generated by analysing processes for generating alternatives, procedures such as heuristics for evaluating consequences, and
strategies such as satisficing for making choices. Decision making is characterized as a selective search in which heuristics are used to determine what paths should be taken, and the search halts when a satisfactory solution has been found. In this process, aspiration levels are adapted in response to success or failure.

To distinguish behavioural economics from neoclassical economics, Simon introduced a distinction between procedural and substantive rationality (Simon, 1976). He argued that psychologists have considered the former concept while economists have focused on the latter. Whereas the former involves decision makers following specific rules or procedures, the latter has decision makers consider their own total preference ordering. That is, procedural rationality is about the rationality of the procedure used to reach a decision, while substantive rationality is about the rationality of the decision itself. While procedural rationality is interested in how individuals make decisions, substantive rationality focuses attention on why they do so. That is, the former focuses on the methods individuals employ, whereas the latter considers the outcomes that follow. On the one hand, procedural rationality helps decision makers decide how to get there, but not where to go. On the other hand, substantive rationality tells them where to go, but not how to get there. Simon used the concept of Bounded rationality to explain why substantive rationality is often inappropriate as well as impossible.

While models of Bounded rationality have not always appeared as attractive as the axiomatized certainties of neoclassical economics, more and more economists are embracing one form or another of Bounded rationality. Models of Bounded rationality owe their revival partly to attempts to develop a viable alternative to neoclassical economics and partly to attempts to strengthen neoclassical economics. Whereas the first reason is in the spirit of Simon's contributions, Simon certainly would have opposed the second.

**Conclusion**

In adopting Bounded rationality, rational expectations economists and game theorists found themselves in the paradoxical position of using Bounded rationality to define rationality. In addition, they were confronted with the question how much Bounded rationality is admitted and how it is clarified. In fact, the dependence of the definition of rationality on irrationality is reminiscent of debates in philosophy concerning the definition of concepts in terms of their opposites, which has led to efforts to destabilize dichotomies. In addition, there is the practical challenge of overcoming the Bounded rationality of economists in modelling the Bounded rationality of economic agents. Ironically, when economists made the agents in their models more bounded in their rationality, they had to be smarter because these models became larger and more demanding econometrically. Bounded rationality researchers face innumerable decisions about how to represent decision-making processes and the ways that they are updated, which requires a large amount of rationality on their part.

Overall, the efforts of rational expectations economists and game theorists to embrace one form or another of Bounded rationality have more to do with intellectual puzzles than empirical anomalies (Aumann, 1997; Rubinstein, 1998; Sargent, 1993). Hence, in effect, economists have replaced one set of puzzles, concerning, for instance, the non-existence of trade, with another paradox, concerning the dependence of rationality on irrationality (Aumann and Sorin, 1989).

The move from rationality to Bounded rationality is part of the observation that the present situation in economics could be characterized as one of moderate pluralism. That is, recent years have witnessed not
only efforts to incorporate Bounded rationality approaches and behavioural insights, but also chaos theory, complexity approaches, evolutionary insights, experimental methods, and neuroeconomics. Therefore, the benchmark from which new behavioural economics considers deviations may itself be evolving – none of which alone or in combination appears yet to have established a new orthodoxy, leading to debate over the direction and future content of economics. Elaborating these, however, interesting, would take us beyond the scope and word limit of this article.

Abstract

Economic theory takes the individual consumer and firm as a primitive unit of analysis, and so a theory of individual agency is required to derive hypotheses about the behaviour of markets and other systems of economic interest. One such theory is the principle of rationality, whereby agents act in their perceived best interest. This article surveys the implementation of this principle in economic models, and discusses the critiques of the rationality principle and some proposed alternatives from the perspective of the economic modeller.

Article

I shall not today attempt further to define the kinds of material I understand to be embraced within that shorthand description; and perhaps I could never succeed in intelligibly doing so. But I know it when I see it, …

(Justice Potter Stewart, 378 U.S. 184, 197)
Rationality is for economists as pornography was to the US Supreme Court, undefinable but nonetheless easily identified; and yet, like the Justices of the Court, no two economists share a common definition. This article details some of the common meanings of individual (as opposed to social) rationality and discusses their uses. Our point of view is that of working economists rather than that of psychologists. Economics is committed to methodological individualism, the claim that social phenomena must be explained in terms of individual actions which in turn must be explained through individuals' motivations. This commitment requires a theory of human action. The rationality principle, that individuals act in their best interest as they perceive it, provides such a theory. In this article we evaluate the rationality hypothesis and its alternatives from the perspective of how they explain social phenomena such as the behaviour of a market. Our interest is in social life rather than in the psychology of an individual.

History and description

The use of the rationality principle in economics certainly predates the utilitarianism with which it is so often conflated. Adam Smith (1789, p. 19) describes, in his discussion of the division of labour, a tribe of hunters in which one person is particularly deft at making bows and arrows. ‘He frequently exchanges them for cattle or for venison with his companions; and he finds at last that he can in this manner get more cattle and venison, than if he himself went to the field to catch them. From a regard to his own interest, therefore, the making of bows and arrows grows to be his chief business …’ Moving from intuition to analysis, however, requires a sharp understanding of what it means to regard one's own interest, and this has become a source of endless debate for rational-actor social scientists.

The utility-maximization version of rationality springs from the utilitarianism of Bentham and Mill. According to Bentham (1789, p. i),

Nature has placed mankind under the governance of two sovereign masters, pain and pleasure. It is for them alone to point out what we ought to do, as well as to determine what we shall do. On the one hand the standard of right and wrong, on the other the chain of causes and effects, are fastened to their throne.

Although many thinkers toyed with utilitarian approaches to economic analysis, it was not until the 1870s, through the work of Jevons, Menger and Walras, that utility maximization began to assume the important role in economic analysis it has since held. For this trio, utility was a short cut to a theory of value. Perhaps this is why they were not overly concerned with the issues of measurable utility and the possibility of interpersonal utility comparisons which so exercised their successors. Utility for Bentham, on the other hand, was a physical measure of pain and pleasure which could be computed according to his ‘felicific calculus’. Although utility as a merely hedonic measure was rejected even by Mill, only in the 1930s, and after a half century's work beginning with Fisher (1892) and Pareto (1895) was it generally recognized that properties of demand derived from the shape of indifference curves, and so utility could admit a purely ordinal interpretation. This ‘shift in emphasis away from the physiological and psychological hedonistic, introspective aspects of utility’, as Samuelson (1947, p. 90–1) put it, led to the ‘purging out of objectionable, and sometimes unnecessary, connotations … of the Bentham …
variety’. The ultimate expression of this non-psychological view is the theory of revealed preference, whose purpose is ‘…to develop the theory of consumer’s behavior freed from any vestigial traces of the utility concept’ (Samuelson, 1938a, p. 71). The result is a mathematical structure that Edgeworth would have understood, interpreted in a manner completely foreign to his way of thinking. Expected utility in the theory of choice under uncertainty is older than Benthamite utilitarianism. Both an expectation argument and a dominance (admissibility) argument for the existence of God were carefully laid out by Pascal (1672, p. 233). These remarkable few paragraphs touch on many important issues in contemporary decision theory, including the principle of insufficient reason, the problem of infinite utility payoffs, and incomplete preferences: ‘Yes; but you must wager. It is not optional. You are embarked. Which will you choose then?’ Even the concept of marginal utility predates Bentham, in Gabriel Cramer's and Daniel Bernoulli’s famous near-resolutions of the St. Petersburg paradox. But despite this early progress, the formalization of the modern theory of choice under uncertainty begins only with Wald (1939), who at one go describes the key structures of statistical decision theory: loss functions, a priori distributions, and Bayes, admissible, and minimax decision rules. Interest quickly coalesced, however, around the expected utility models described in the two great testaments of decision science, von Neumann and Morgenstern (1947) and Savage (1956). Expected utility (EU) quickly became such a dominant paradigm for choice under uncertainty that research into alternatives was a backwater for 20 years. But criticisms of the expected utility models emerged almost before the ink was dry on the two manuscripts, in Allais’ (1953) experiments and Cyert, Simon and Trow's (1956) empirical studies of firm behaviour, and by the late 1970s behavioural economics and non-EU decision theory were active areas of research.

Psychological utilitarianism and decision theory are the two traditions which most inform the modern economist’s thinking about ‘rationality’, and yet, despite the long intellectual history of these ideas, no single vision of what it means to be a ‘rational actor’ has emerged. In the remainder of this article we single out several sources of confusion and disagreement. We discuss five models of rationality.

**General choice theory (GCT)**

A set $A$ of alternatives is given, along with a collection $\mathcal{B}$ of non-empty subsets of $A$. The set $A$ is the set of possible alternatives and any member $B$ of $\mathcal{B}$ is a set of feasible alternatives, a set from which the decision-maker must choose. A *choice function* $C$ assigns to each $B \in \mathcal{B}$ a nonempty subset of $B$, the objects chosen by the decision-maker from the feasible set. In the theory of demand, for instance, $A$ is the consumption set, $B$ is the collection of possible budget sets and the choice function is the demand function. A textbook treatment of the rational decision-maker requires that she have a *preference relation* $\succ$ on $A$, and we understand $a \succ b$ to mean that she finds $a$ to be ‘at least as good as’ $b$. By ‘preference relation’ we mean a binary relation which is complete, all alternatives can be compared, and transitive. Transitivity means that if $a$ is at least as good as $b$ and $b$ is at least as good as $c$, then $a$ is at least as good as $c$. Chosen objects in a set $B$ of feasible alternatives are those maximal with respect to the preference relation; $b$ is chosen from $B$, that is, $b \in C(B)$, if and only if $b \succ a$ for all $a \in B$. Preference is the primitive expression of rationality. The role of utility is to provide a convenient *representation* of preference. A utility function $u$ is a real-valued function on $A$, and to say that $u$ represents $\succ$ means that $u(a) \succ u(b)$ if and only if $a \succ b$. While the decision theory toolkit of the working economist mostly
specializes this model, much contemporary economic theory does not require this much of rationality. In particular, the completeness and transitivity assumptions can be done away with in general equilibrium theory, and numerical representations for incomplete and non-transitive preferences are available. See, for instance, Aumann (1962), Chipman et al. (1971), and Gale and Mas-Colell (1975).

**Expected utility theory (EU)**

Expected utility is a specialization of GCT in which the set $A$ and the preference relation have a specific structure. In EU theory, $X$ is a finite set of prizes or outcomes, and the alternative set $A$ is the set of all probability distributions on $X$. Preferences have the following representation: A payoff function $v$ is a real-valued function on $X$, and any two probability distributions $p$ and $q$ in $A$ are compared according to their expected values of $v$; that is $p \succ q \iff \mathbb{E}_p v \succ \mathbb{E}_q v$. The content of this theory is that, geometrically speaking, indifference curves are parallel straight lines (hyperplanes). The first characterization of EU preferences was provided by von Neumann and Morgenstern (1947); today’s standard axiomatic characterization of EU preference orders is due to Herstein and Milnor (1953).

**Subjective expected utility theory (SEU)**

When we choose whether to play roulette or a slot machine, we are choosing among probability distributions. When we bet on the outcome of a horse or political race, we are betting on the realization of uncertain outcomes, but not objects to which probabilities are necessarily attached. Savage's (1956) contribution was to provide a theory of what he called ‘personal probability’, a specialization of GCT, here interpreted as a decision-maker’s degree of belief in the occurrence of some event. He characterized those preference relations which could be represented by the expectation of some payoff function with respect to a personal probability. In Savage's subjective expected utility (SEU) theory, $S$ is a set of states, such as the possible outcomes of the election. There is also a set $X$ of outcomes. A bet on the election is a function which assigns an outcome to every state. Savage called such functions $f : S \rightarrow X$ acts, and the set of acts is the alternative set $A$. A preference relation $\succeq$ on the set $A$ has an SEU representation if there is a payoff function $v$ on outcomes $X$ and a probability distribution $p$ on states $S$ such that $f \succeq g$ if and only if $\mathbb{E}_p \{v(f(s))\} \succeq \mathbb{E}_p \{v(g(s))\}$.

Methodological individualism requires the analysis of social phenomena to be ‘bottom-up’, that is, to begin with individuals. It is a stronger statement to claim, however, that the description of the individual is entirely pre-social; that in economic models, for instance, that individuals come to the market with preferences and beliefs already formed. Most modern economists do not make this claim, and instead work with models in which the description of the individual is an equilibrium outcome. The two most prominent examples of this method are rational expectations equilibrium and non-cooperative game theory.

**Rational expectations equilibrium (REE)**

The rational expectations hypothesis supposes a population of individuals solving decision problems which have a common state space, and furthermore that the state will be chosen according to the ‘true
distribution’ $\mu$, which is determined by the individuals’ choices. The payoff $v(c,s)$ to a choice $c$ depends on the state realization $s$, and preferences over choices are EU: $U_i(c) = E_U(v(c,s))$. The hypothesis asserts that all beliefs will be correct; that is, that all SEU decision-makers have preference representations in which the beliefs are in fact the probability distribution $\mu$, and $\mu$ in turn is the distribution of states which is determined by their actions. Rational expectations is a misuse of the adjective. Unfortunately it is probably too late to abandon the term. There is no connection between the rationality principle, which claims that individuals act in their perceived best interest, and the rational expectations hypothesis, which claims that those perceptions meet some *ex ante* standard of correctness. But so labelling a theory is certainly a nice rhetorical move for how it structures subsequent debate.

**Non-cooperative game theory (NGT)**

A population of individuals chooses actions. Individual $i$’s payoff to action $c_i$, $v(c_j, c_{-i})$ depends upon the choices $c_{-i}$ of the others. He holds probabilistic beliefs about the actions of others, and evaluates a choice according to EU. The social construction of the individual is seen in the determination of beliefs. *Undominated strategies* are those which can be rationalized by some choices of beliefs. *Rationalizable strategies* are those which can be justified by some beliefs satisfying a belief restriction, that it be common knowledge that all members of the population are EU-rational with some beliefs, and that payoffs be common knowledge (see epistemic game theory: an overview). Nash equilibrium requires, like REE, that everyone's beliefs are correct. Various Nash equilibrium refinements also have belief interpretations (see Nash equilibrium, refinements of).

**Rationality and mind**

The merits of the rational choice foundation of economics have been much discussed, both by its practitioners and by its critics. This discussion is often confused, in part because economists are not consistent in how they understand the contents of the rationality hypothesis. Economic theory holds two views of rationality. One is that rationality is consistency of choice, that the tools of choice theory are just an alternative encoding of certain choice functions; the other is that rationality is a theory of intentional behaviour, in which beliefs and desires are meaningful constructs.

Revealed preference theory is the sharpest formulation of the consistency view. It takes demand as primitive and asks if it is consistent with the maximization of a preference order. It recovers desires from choice, and only to the extent that choices are different can two desires, preference orders, be distinguished. This view permeates the foundations of decision theory. For Savage (1956, p. 17), ‘It is possible that the person prefers $f$ to $g$. Loosely speaking, this means that, if he were required to decide between $f$ and $g$, no other acts being available, he would decide on $f$. In this account, preference is defined by choice. This means specifically that if the choice function $C$ on a collection $\mathcal{B}$ of choice sets satisfies certain conditions, then there is a complete and transitive binary relation such that for every $B \in \mathcal{B}$, $C(B)$ contains exactly the elements of $B$ which are maximal in $B$ with respect to the relation. The binary relation is nothing more than an alternative description of $C$ on $\mathcal{B}$. Suppose a new choice set $B' \not\in \mathcal{B}$ is considered. What can we guess about the contents of $C(B')$? Knowing that the decision-maker is consistent on $B$ allows the observer to infer nothing at all about $C(B')$.\"
If revealed preference represents at all a psychology of choice, that psychology is a form of radical behaviourism. Radical behaviourism asserts that two mental states are distinguishable only to the extent that some observable behaviour distinguishes them. Behaviours are all that one can theorize about. Samuelson (1938b, p. 344) writes ‘of a steady tendency toward the removal of moral, utilitarian, welfare connotations …’ and of ‘the rejection of hedonistic, introspective, psychological elements’. Although the behaviourist position seems extreme, the leading graduate microeconomics textbook writes approvingly of revealed preference: ‘Perhaps most importantly, it makes clear that the theory of individual decision making need not be based on a process of introspection but can be given an entirely behavioral foundation’ (Mas-Colell, Whinston and Green, 1995, p. 5). Consistency is often justified as discipline. It requires a minimum of assumptions about the beliefs and desires of individuals, and minimizes the possibility of researchers' values and beliefs slipping unbidden into their analyses. It allows the data maximal scope to speak for itself.

Although received economics talks approvingly of rationality as mere consistency, this is not in fact what most economists do. Much of economics involves invisible-hand explanations; aggregate market behaviour emerges from the decisions of many agents. Whether the invisible hand lifts the cup aloft or knocks it over, economic explanation entails explaining how it coordinates for good or ill the motives and interests of diverse individual actors. These kinds of question call for explanations based on the motivations of economic actors, which purely behaviouralist explanations cannot provide. So economists in practice take an intentional view.

The intentional view holds that rational choice theory is a common-sense or ‘folk’ (as opposed to ‘scientific’) psychology. Just as in our everyday transactions we use the language of beliefs and desires to interpret and forecast the behaviour of others, so do economists interpret choice behaviour. The investor believes that the asset price will be higher tomorrow. She wants greater wealth tomorrow. So she acts by purchasing the asset. In this view belief and desire are in fact mental states that are connected to action. The folk psychology is a theory of mind which is presumed by economists to be both adequate for a descriptive psychology of decision and accurate enough in its predictions of individual behaviours for the uses to which it is put. Although utility does not exist as a psychophysical quantity, rational choice models provide a representation of the mental states involved in judgment and decision. (The stronger claim that mental process is a more or less efficient utility maximization algorithm is a view held only by the straw man regularly beaten up by rationality's critics.)

The economist's folk psychology goes further than everyday folk psychology by specifying analytic representations of beliefs, desires, and how they interact. No matter what representation is ultimately chosen by the textbook economist, his folk psychology rests on two points. (1) Rationality is instrumental. Its concern is the efficient pursuing of ends by available means, not the sensibility of the ends. (2) Desire is not anchored by any other aspect of the decision problem, whether the feasible set or the context of choice. Formally, desires are captured by a preference ordering on possible objects of choice whose existence is independent of the feasible set or the context of choice. This is the content of GCT.

The tension between the demands for a parsimonious behavioural theory and the need for an intentional theory of choice is often resolved by holding that, of course beliefs and desires exist, but we economists have access to them only as they are revealed in observed choice behaviour. In a recent critique of neuroeconomics, two well-known theorists write, ‘In standard economics, the testable implications of a theory are its content; once they are identified, the non-choice evidence that motivated a novel theory...
becomes irrelevant’ (Gul and Pesendorfer, 2005, p. 6). This view has a long history, perhaps with origins in the defence of marginal analysis against its early critics. Machlup (1946, p. 537) writes, ‘Psychologists will readily confirm that statements by interviewed individuals about the motives and reasons for their actions are unreliable or at least incomplete’, and also raises the oft-heard incentive problem of eliciting survey data, namely, that survey respondents may choose answers to meet their own goals, which may not include truth.

One source of confusion in evaluating claims for and against the economist’s psychology is that the theory has both positive and normative components. According to Marshak (1950, p. 111), ‘The theory of rational behavior is a set of propositions that can be regarded either as idealized approximations to the actual behavior of men or as recommendations to be followed’. Savage’s early work with Milton Friedman (1948; 1952) was explicitly descriptive, but Savage (1956) is just as explicitly normative. It is not surprising that a description of decision in terms of beliefs and desires should have a normative component which evaluates how well goals are achieved. Confusion arises, however, when the descriptive and prescriptive positions are inappropriately conflated to justify the rationality assumptions as a statement of fact. Many undergraduate microeconomics texts justify transitivity assumptions by a money pump argument as a prelude to demand theory. The Dutch book is used to defend probabilistic descriptions of belief. But both of these arguments are, at their source, explicitly normative (see Davidson, McKinsey and Suppes, 1955, p. 146; Ramsey, 1931).

A descriptive theory of choice which is grounded not in empirical reality but in logical deductions from normative principles, like Dutch books and money pumps, is not science, but metaphysics. Furthermore, normative justifications are implicitly introspective. A money pump argument really says, ‘you wouldn't fall into this trap, would you?’ Significant empirical work in psychology (Nisbett and Wilson, 1977), however, indicates that introspective evidence is simply unreliable. When individuals turn to review and justify their decisions, they may have no access to the mental states which guided their choice. On the other hand, it seems to us quite reasonable to build models of financial asset pricing which assume that traders are probabilistically sophisticated, on the supposition that traders who are not will either not long survive in the market or not, as a group, be large enough to have a significant effect on prices. Financial markets, unlike Dutch books, actually exist, and the claim that individuals with probabilistically incoherent beliefs do not fare well is a claim of fact, to be tested against market data.

The conflation of positive and normative concerns in decision theory is more fundamental than simple carelessness in an argument. In his criticism of the fact/value dichotomy, Putnam (2002) asks us to consider the word ‘cruel’. He observes that the word often has both descriptive and normative content, and in most uses they cannot be separated. The same could be said of the adjective ‘rational’ in economists’ usage. Marshak (1950, p. 111) illustrates this perfectly when he writes that the purpose of EU is ‘… to describe the behavior of men who, it is believed, cannot be “all fools all the time”….’ When the word ‘rational’ is used to describe a system in which all agents hold accurate probabilistic beliefs, the implication is that someone holding inaccurate beliefs gets it wrong. REE is often informally defended by the assertion that, if an economic actor's beliefs were incorrect, he would observe this and form new ones. The assertion is either a positive assertion, that actors do indeed have such beliefs, or a normative assertion, that they should hold such beliefs. The normative assertion is a metaphysical defence of the validity of the rational expectations hypothesis. The positive assertion is a claim of fact whose validity could in principle be put to test, but testing the claim would in fact require so rich a set of
ancillary maintained hypotheses that practically it is infeasible.

Given all the problems of the two views of rationality, one might wonder why economics needs a rational actor. Dennett (1971, p. 92) provides perhaps the best defence of belief/desire explanations. He contrasts what he calls the *design stance*, predicting behaviour from an understanding of how an agent is designed, or built, with the *intentional stance*, attributing to the agent beliefs and desires, and predicting from them. The intentional stance is useful, he writes, ‘Whenever we have reason to suppose the assumption of optimal design is warranted, and doubt the practicality of prediction from the design … stance’. Warranting the optimal design assumption means for Dennett not that the system actually be designed to achieve a fixed set of goals, but that this assumption is a useful first approximation. ‘Not surprisingly’, he observes,

> as we discover more and more imperfections …, our efforts at intentional prediction become more and more cumbersome and undecidable, for we can no longer count on the beliefs, desires, and actions going together that ought to go together. Eventually we end up, following this process, by predicting from the design stance; we end up, that is, dropping the assumption of rationality. (p. 95)

This movement, from rationality to realism, is the motivation for taking behaviour more seriously.

**Rationality and behaviours**

Game theory and general equilibrium theory are ‘system frameworks’. They imagine a collection of individual agents interacting in some systematic way, strategically in game theory, as described by the normal or extensive form of the game, and through markets in general equilibrium theory. In each case, the model produces an ‘equilibrium’ of the system. The first stage in the development of a system framework involves determining its consistency and internal coherence, that is, conditions which guarantee the existence of equilibrium. This analysis will be as abstract and general as possible, to encompass as large a repertory of behaviours as possible. The second stage is the application of the framework to derive useful statements about the world. This requires explicit behavioural assumptions about agent behaviour and describing the resulting equilibrium. These statements – predictions about market or game behaviour – can be examined empirically.

There are two difficulties with the received models of decision theory such as expected utility and dynamic programming in this kind of research program. First, as these models are formulated, behaviours are not accessible. For example, using expected utility to derive home bias in financial asset markets – that is, investors tend not to take positions in foreign assets – requires complicated assumptions about traders' beliefs. Second, these models are insufficiently rich to capture all the behaviours one might want to examine. For instance, the additively separable intertemporal expected utility model conflates time preference and risk aversion because the model is too thinly parametrized. Behavioural economics is a research program which will, its proponents argue, replace rational actor models with a more psychologically informed view of human decision making. Much of behavioural economics, however, is less ambitious (and thus, perhaps, more useful). This work can be described as reformulating or extending rational actor models so as to make those observable behaviours whose
implications we wish to examine more accessible. While much of this work is at the core of behavioural economics, many who do this work eschew the label; not only behavioural economists are interested in behaviour. Here we discuss four categories of research which cover much work on behaviours, both by behavioural economics and by its critics.

Recontextualizing decision

GCT is a very parsimonious simplification of a decision problem. In modelling there is a trade-off between behavioural accuracy and parsimony in the description of decision problems. In general equilibrium models, for example, behavioural accuracy may improve descriptive and explanatory power, but parsimony is required because individual decisions are only one piece of the analysis, and complicated models of individual behaviour may generate only intractable market models. One implication of GCT is that preferences are not choice-set dependent. Even in the early days of decision theory, important models such as minimax regret (Savage, 1951) violated the requirement of a single preference order on a universal space of potential choices. Furthermore, many choice-set effects appear to be perfectly rational. Consider the behaviour of a well-mannered but very hungry person at a dinner party. A plate is passed to him with three pieces of the main course, ordered in size such that \( a < b < c \). Being both well-mannered and hungry, he chooses the second largest piece, \( b \). Suppose now that the plate had been passed around the table in the other direction, so that when it comes to him there remains only \( a \) and \( b \). Now according to his rule he chooses \( a \). Is he called irrational by the GCT theorists at the table?

Kahneman and Tversky's (1979) prospect theory illustrates another way in which decision problems can be recontextualized. Here additional context, a status quo, is added to the description of the decision problems. Gambles are viewed as probability distributions over gains and losses relative to the status quo. Given a status quo, a preference order over all possible final outcomes exists, but that preference order varies with the status quo. There is, however, a stable preference order over the universe of all possible gains and losses; more context is added by redefining the objects of choice. A similar transformation is accomplished in Gul and Pesendorfer's (2004) model of choice with self-control problems. In the conventional infinite-horizon optimal consumption problem, the objects of choice are consumption paths. Gul and Pesendorfer, on the other hand, take the objects of choice to be pair consisting of a current period consumption and a decision problem to be solved tomorrow. Gul and Pesendorfer's model is an example of a menu choice model. Although used somewhat earlier, the first formal development of such models was by Kreps (1979) to describe preferences for flexibility.

Constructing rationality

The economist's conventional view of market interaction posits a collection of individuals with well-formed preferences meeting in a marketplace. The preferences, along with endowments and technologies, are exogenous to the system. On the other hand, some attendees at a large outdoor concert are there because they like the music, while others are there because of the crowd. Teenagers' evaluation of clothing style has perhaps as much to do with who wears such clothes as with their cut and pattern. These are all examples of socially constructed preferences.
Socially constructed preferences are a part of conventional economic theory. Both NGT and REE are models of socially constructed preferences. In each case desires are fixed, but beliefs adjust. However, neither of these equilibrium concepts is particularly well-supported by belief adjustment (learning) processes. The literature on learning Nash equilibrium is huge, and the state of the art is that, while one can construct learning dynamics that will find a Nash equilibrium, many intuitive learning processes will often fail. Blume and Easley (1982) show that rational equilibrium can easily fail to be reached by any reasonable learning process.

Restricting the socially determined component of preferences only to beliefs is an artificial constraint, and to limit social influence on preference formation to learning is to miss most of the interplay between the individual and the group. Manski (2000) observes that the implications of social interactions through learning and through tastes are distinct, and the difference is significant for policy analysis. Any theory of the interaction of desires requires a new set of primitives which describe the preference formation mechanism. One popular approach has been to model the evolution and workings of pro-social norms of cooperation and trust. Bowles (1998) is an engaging survey of this work. Much less has been done on the evolution and workings of anti-social norms, such as discrimination and stigmatization. Others have turned to biological metaphors. Here one might look at the population dynamics of rules or preferences on a game form or market where game or market outcomes (not utilities) determine the composition in the next round of the population's decision rules or preference orders (Güth and Kliemt, 1998; Blume and Easley, 1992; 2006). Pro-social behaviour such as reciprocity and altruism has also been investigated from the biological standpoint (Bergstrom, 2002; Sethi and Somanathan, 2003). One lesson of this literature is that the nature of the interaction between agents is at least as important as the model of choice in determining system outcomes. About the embeddedness of economic action in social life, Granovetter (1985, p. 506) writes,

The notion that rational choice is derailed by social influences has long discouraged detailed sociological analysis of economic life and led revisionist economists to reform economic theory by focusing on its naive psychology. My claim here is that however naive that psychology may be, this is not where the main difficulty lies – it is rather in the neglect of social structure.

The content of preferences and beliefs

It has been conventional in economic analysis to construe self-interest very narrowly. No ‘other-regarding’ values are expressed in preferences, and conventionally to do otherwise is frowned upon. For instance, it is hard to explain why an individual votes in an election by her effect on the outcome, without referring to the psychic rewards of the act of voting. Yet the claim that people vote because of norms of citizenship and the like is often regarded as ‘nearly tautological’ (Ordeshook, 1986, p. 50.). On the other hand, critics of economic man often incorrectly assert that rational actors are excessively self-interested; incorrectly, because the existence of preferences and the content of preferences are distinct issues. The rationality hypothesis does not preclude other-regarding desires. Interest in those externalities that arise from ethical concerns, social norms, and other social constructions has increased enormously since the mid-1990s. Much of the literature on social interactions is a study of the
consequences of other-regarding preferences. Not surprisingly, other-regarding preferences usefully model both altruism and racism. This is not a fix for those critics who see the selfishness of traditional neoclassical models as a moral failing rather than a behavioural one.

A distinct problem which, unfortunately, has not been much addressed by behavioural economics is the use of individual preferences in the economist’s version of moral philosophy. The same preferences which are revealed through shopping behaviour at the grocery store are supposed to be informative for the ethical questions posed by welfare economics. One could, in fact, distinguish ‘ethical preferences’ from ‘subjective preferences’ as Harsanyi (1955) has done, and it would be interesting to know if social psychology has anything to say about the relationship between the two types of decision problems, individual and social, which economists address.

**Different psychologies**

Some economists look to replace the folk psychology of beliefs and wants with something altogether different. Neuroeconomics is one such attempt, although the neuroeconomics literature seems to eschew drawing economic conclusions from imaging data. Unfortunately, the link between brain and mind is elusive. Eliminative materialism is a position taken by some cognitive scientists, which claims that beliefs and desires do not exist as mental states, and will have no place in an accurate account of the mind. Theoretical and methodological arguments in its support can be found, for instance, in Churchland (1981). An economics which takes its microfoundations entirely from cognitive science could look extremely different than the economics of today. But even if one is more hopeful than Churchland for the utility of the economist’s folk psychology, the goal is far off. As one leading neuroimaging specialist puts it, ‘Despite fantastic technical developments, lingering methodological and conceptual limitations hinder progress in understanding how mental processes (wrapped up in folk psychology) reduce to or emerge from neural processes’ (Schall, 2004, p. 44). Savoy (2001, p. 36) has a bleaker view:

> Do the new discoveries about human brain function based on neuroimaging experiments really teach us things that are relevant for the study and understanding of behaviour? That is a question which you must answer. My own impression is that, at present, the overwhelming thrust of these data are toward understanding brain organisation, rather than human behaviour. Of course, we assume that when brain organisation is sufficiently well understood, it will lead to increases in our understanding of behaviour. But I do not think, as yet, there is a great deal of progress in that direction.

Neuroeconomics hopes to replace the belief/desire folk psychology that informs most of modern analytical economics with a more accurate scientific psychology. Alternatively, one could construct a different folk psychology which, like utility maximization, has no scientific pretensions, but is more descriptively accurate. Models of *intrapersonal* conflict are the most familiar example of this kind of framework. Strotz (1955) demonstrated the possibility of time-inconsistent planning in intertemporal utility maximization problems, and Pollak (1968) subsequently displayed the essentially strategic nature of the planning problem as a problem of competition between the selves choosing at different dates. Schelling (1984) described a variety of decision problems with aspects of intrapersonal conflicts, and
discussed them from a game-theoretic perspective. He, for instance, wrote about the competition between that part of him which desires nicotine and that part which wants to give it up. This is a contest for self-control. The literature today contains a number of intertemporal models which, following Pollak (1968) distinguish two kinds of behaviour. Sophisticated behaviour chooses today with full knowledge that her future selves may try to undo her decision. A choice is a subgame perfect equilibrium of a game played by all her selves. Naive behaviour chooses today assuming, perhaps incorrectly, that her future selves will stick with her decisions. These two models are intrinsically no more realistic than GCT, just different.

For the working economist, the ultimate test of a psychologically more accurate theory of individual choice is how it performs in explaining market and other social outcomes rather than how well it predicts the behaviour of an individual. Could theory A, more informed with insights from psychology and cognitive science, possibly be less useful for economists? Here are three possibilities: (1) Theory A might be extremely complex. Its application to a heterogeneous-agent financial market model, for instance, is simply impossible to work with, and no conclusions can be derived. (2) Theory A might require for its application data that we can observe in a controlled and heavily instrumented setting but simply cannot collect in the field. (3) Theory A may not be posed with concepts which are useful for the economist's interpretation of social outcomes. For instance, theory A might be couched in terms of chemical states of the brain, and not speak at all about agents' intentions, beliefs or desires. While it may be possible to construct a biochemical model of the invisible hand, it would not be useful for welfare economics.

Evidence on the question of whether these models lead to better market analyses is sparse, and mixed, and there is no evidence on how these models perform relative to menu choice models, which address the same questions from a rational choice perspective. More generally, more work needs to be done in evaluating behavioural models with respect to their economic performance. How useful are they for deriving implications about the performance of aggregate economic variables such as prices? This kind of research is already under way. Two examples are Kocherlakota (2001) and Laibson (1997).

An instance of point (3) can be seen in the time-inconsistency literature. Pollak (1968) and his followers (O'Donoghue and Rabin, 1999) see choice not as the expression of a single desire, but as the outcome of conflict, perhaps inefficient and destructive, between competing desires. Now the Pareto ranking of alternatives in a social interaction either becomes dependent on which of the many competing preference orders we modellers choose for each individual or it becomes empty if we try to respect them all. The advantage of menu choice models, the rational-choice approach to modelling problems of self-control, is that there is a well-defined notion of preference for each agent, from which a Pareto ranking can be constructed. To be fair, rational choice modelling also poses problems for welfare economics. If individuals make consistent errors in a class of choice problems, what can revealed preference say about intentions? In the presence of systematic error, a welfare economics built from revealed choice is at best misleading.

Conclusion

The purpose of decision models in economics is to explain the behaviour not of a single individual but of aggregates of individuals. Sometimes economists explain by appeal to ‘Laws’, such as ‘the Law of
Supply and Demand’. But this mode of explanation is mostly an intermediate product; useful, perhaps, for generating back-of-the-envelope predictions about the effects of a tax on market price, but not a source of understanding. There are few natural laws in the social sciences, and the domains of the few we can identify are very limited.

More often, economists appeal to ‘mechanism’. We try to understand economic phenomena, such as the determination of prices in different kinds of markets, in terms of the mechanisms which generate them. Given our commitment to methodological individualism, this requires an explanation of how individual economic actors interact with one another. This is where rational actor theories are employed, and it is with respect to how these models do in this discussion rather than how they do in other domains, such as explaining individual behaviour, that the rationality principle should be evaluated.

Unfortunately, perhaps, at this point there are no serious alternatives to the rationality principle. For all of its buzz, proponents of bounded rationality, by which we mean models of behaviour that consider beliefs and desires but that do not optimize, have so far failed to deliver decision models which are robust and not tightly tied to a small class of decision problems. It is perhaps too early in its intellectual history to ask for as much from cognitive models. We are sceptical about the value for social and economic systems analysis of unpacking the black box of consumer behaviour by deploying a rich and sophisticated model of cognitive process within a general equilibrium or game theoretic model. There is a point to reductionism. On the other hand, we are enthusiastic about the possibility that cognitive science will contribute to sharpening the rationality principle. The focus of much modern decision theory, such as Kahneman and Tversky (1979), Gilboa and Schmeidler (1989) and Gul and Pesendorfer (2004), has been to make the black-box model better by looking for formulations of rational choice models that better conform to the data. A better understanding of decision mechanism will doubtless suggest constraints on black-box behaviour which can be captured in reduced-form decision models, and perhaps it will uncover constraints that cannot be observed from behaviour alone.

Evolutionary models have also been proposed as an alternative framework to rational choice decision-making. Market forces, or a combination of markets and biology, favour some decision rules over others. In the long run, the market will be populated mostly by those decision rules that are ‘most fit’, rational or not. One can indeed ask if the forces of market selection favour rational decision rules (Blume and Easley, 1992; Sandroni, 2000), but the study of market population dynamics is complementary to rather than a substitute for rational choice models. Blume and Easley (2006), for instance, demonstrate how market forces select within the class of rational decision rules, favouring some kinds of preferences and beliefs over others.

Although there appear no be no serious alternatives to the rational choice paradigm on the near horizon, there is much to regret in how the rationality principle is discussed. The following statements should be self-evident, but clearly are not, judging by our reading of the literature: (1) Rationality does not mean complete or symmetric information. In fact, much of rational actor social science attempts to understand social outcomes when these conditions do not obtain. (2) Rationality does not require individuals to be entirely selfish. While much effort has been made to understand social norms from the point of view of entirely individualistic preferences, the insistence on relying on self-regarding rather than pro-social preferences is a matter of the content of preferences, rather than an axiom of rationality per se. (3) Rationality does not mean expected utility. Expected utility is one small class of decision models for choice under uncertainty. Its dominance in application was understandable in the 1970s, when few...
alternatives were on the table. Since then decision theorists have been creative in developing better-behaved alternatives, and equilibrium and game theorists have been clever in applying them. (4) Rationality does not mean ‘rational expectations’. For a belief restriction to be a requirement of rationality, it must be clear that all those who are not ‘all fools all the time’ must have correct beliefs. No research into learning in economics suggests this is the case in any kind of complex environment. There is also much to regret in how the rationality principle has been deployed in economic analysis. Given the explosion of decision-theoretic research since the 1970s, it is surprising how little this research has affected market and game theoretic analysis. The norm still seems to be self-interested preferences, expected utility and rational expectations (or Nash equilibrium). At this point the question of whether contemporary decision models such as Choquet expected utility and cumulative prospect theory have anything new to say about, say, asset pricing, is open. The value to economists of new decision theories, rational choice or not, is not in how they perform in a laboratory but how they perform in the analysis of markets and other social systems. Too rarely have modern decision theories been exposed to this test.

Rational actor social science is a broader tent than both its supporters and its critics make it out to be. We expect the rational choice framework to be as dominant when the next edition of the *New Palgrave* goes to press as it is today. But we also expect the set of decision-theoretic models deployed in the analysis of social systems will be quite different, and probably more diverse, than it is now.

**How to cite this article**

Rationing refers to any situation in which economic agents face quantity constraints on their demand for or supply of particular commodities, unlike the standard situation in which they are free to purchase unlimited quantities subject only to fixed prices and a linear budget constraint. Quantity constraints may impose consumption levels either below or above those that would be freely chosen: goods rationing in wartime illustrates the former, while examples of the latter include precommitted expenditures and unemployment (which may be viewed as ‘forced consumption’ of leisure). From an analytic point of view, the two cases are identical and may be described by the general term ‘rationing’. This article outlines the principal results of the microeconomic theory of consumer rationing and then notes some of its applications. Similar results apply to producer rationing, with the added simplification that income effects do not arise for a profit-maximizing firm. I concentrate throughout on ‘simple’ rationing (that is, exogenous restrictions on the consumption of particular commodities); some work has also been done on ‘points’ rationing (where the consumer has a number of ration ‘points’ or ‘coupons’ to be allocated between a group of commodities), and there is an extensive literature on the general case of nonlinear budget constraints, from both theoretical and empirical perspectives (see Hausman, 1985).

Consider first the case where only two commodities are consumed. This misses many important aspects of rationing, but allows most of the basic ideas to be introduced using a simple diagram. In Figure 1, the unconstrained optimal consumption bundle \((x_0, y_0)\) is represented by point A, the point of tangency between the budget constraint \(BC\) and the highest attainable indifference curve, \(I\). Suppose now that the consumer is faced with an additional constraint which stipulates that consumption of commodity \(y\) cannot exceed the level \(\bar{y}\). The consumer is therefore forced to adjust consumption to the point \(D\). Here, the budget constraint is still satisfied, consumption of \(y\) is constrained to equal \(\bar{y}\), and expenditure has spilled over onto the unrationed commodity \(x\), leading to a new higher consumption level \(\tilde{x}\) (where a tilde ‘\(\sim\)’ denotes a demand schedule for unrationed commodities in the presence of the ration constraint \(\bar{y}\)). The consumer is also at a lower indifference curve \(I'\), so rationing reduces real income, or increases the true cost of living, even though prices and nominal income are unchanged.

Rationing occurs whenever economic agents face quantity constraints on their demand for or supply of particular commodities. This article reviews the main results of rationing theory: a tightening of a ration constraint raises the demand for unrationed substitutes and reduces the price responsiveness of all unrationed goods (the Le Chatelier effect). It shows how the technique of virtual prices can be used to generalize these results to the case of strictly binding rations, and briefly reviews some applications, empirical and theoretical, of rationing theory to public and environmental economics, fix-price macroeconomics, and the effects of quotas on international trade.

rationing: The New Palgrave Dictionary of Economics

The case illustrated in Figure 1 is of course extremely special because the number of commodities is the same as the number of independent binding constraints, so the optimal consumption bundle is uniquely determined. In the more usual case, where there are fewer constraints than commodities, the consumer is free to allocate her uncommitted expenditure between a number of unrationed commodities, and a major focus of rationing theory has been on how this allocation, and its responsiveness to changes in exogenous variables, is affected by the presence of rationing. One important special case where rationing has very simple effects is when preferences are weakly separable between the rationed and unrationed commodities. This implies that the direct utility function \( v(x, y) \), can be written in the form \( U[f(x)], y \) where \( f \) is a scalar sub-utility function defined over a vector of unrationed commodities \( x \). Weak separability implies that the demand for each good depends only on the prices of goods within the separable group and on the expenditure allocated to it. Hence the ration constraint has an income effect only and the constrained demand functions for the unrationed goods take the special form \( \tilde{x}(\rho, 1 - q\bar{y}) \). This specification is plausible in the case of some public goods (for example, increased spending on national defence is unlikely to affect the pattern of demand for private goods). Unfortunately, it is less satisfactory in other applications. For example, if leisure is the rationed commodity, weak separability implies that all other goods must be substitutes for it, irrespective of the extent of unemployment.

When preferences are unrestricted, a useful starting point to understanding the effects of rationing is to note that an unrationed consumer would choose to consume at point \( D \) under certain circumstances. Specifically, this would occur if the consumer were faced with a relative price ratio equal to the tangent to the indifference curve \( I' \) at \( D \), and were given an adjusted level of income such that that point represented the unconstrained utility-maximizing consumption bundle. The hypothetical relative price ratio required is given by the slope of the line \( EF \). Following Rothbarth (1941) and Neary and Roberts (1980), the price of the rationed commodity underlying \( EF \) is called its virtual price: the price which would induce the consumer to purchase the ration level voluntarily. The advantage of this approach is that the effect of any exogenous shock on a rationed consumer may be decomposed into the sum of two effects on an orthodox unrationed consumer: the direct effect of the shock itself and the indirect effect arising from the induced change in the virtual price of the rationed good. (Note in passing that the terms ‘virtual price’, ‘demand price’ or, if the ration is set at a zero level, ‘reservation price’ are preferable to ‘shadow price’, since the latter risks confusion with the shadow price of the ration constraint which emerges from the consumer’s maximization problem.)

It is clear that, for non-zero virtual prices to be unique and well defined, the indifference curve at \( D \) must be convex and differentiable. (Further technical details may be found in Neary and Roberts, 1980.) Consider then the general case where unrationed commodities are represented by a vector \( x \) and their prices by a vector \( p \), while the commodity subject to a binding ration constraint is represented by a scalar \( y \) and its market price by \( q \). (The algebra that follows applies equally to the general case with more than one rationed commodity, but it is easier to give intuition for the case of a single rationed good.) It is then straightforward to relate the Hicksian or compensated demand schedules for \( x \) in the presence of rationing to the corresponding unrationed schedules, since both are evaluated at the same utility level, that corresponding to the indifference curve \( I' \):

\[
\tilde{x}^C(p, \bar{y}, u) = \tilde{x}^C(p, \tilde{y}, u).
\]

(1)
Here, a superscript 'c' denotes compensated demands. Crucially, the virtual price $\overline{q}$ is not a parameter but is defined implicitly by the condition that it equate the unconstrained demand for $y$ to the ration level $\overline{y}$:

$$\overline{y} = y^c(p, \overline{q}, u).$$

Differentiating (1) and (2) now yields two important comparative statics results. Consider first the effect of a change in the ration level $\overline{y}$ on the demand for unrationed commodities $x$:

$$\Delta x^c = x^c(\overline{y})^{-1}$$

where subscripts indicate partial derivatives (for example, $x^c_i$ is the vector whose $i$th element gives the partial derivative of the rationed compensated demand function for $x_i$ with respect to the level of the ration constraint). Since the compensated own-price derivative $\overline{y}_x$ is negative, the sign of (3) depends on the sign of $x^c_i$. Thus, a tightening of the ration constraint (a reduction in $\overline{y}$) raises the compensated demand for unrationed commodities which are net substitutes for $y$ and reduces it for commodities which are net complements for $y$.

Next, consider the effects on the demand for $x$ of changes in their own prices. Differentiating (1) and (2) and rearranging yields:

$$\Delta x^c - x^c = - x^c(\overline{y})^{-1} x^c_i.$$

Since the substitution effect $\overline{y}_x$ is negative, this equation shows that the difference between the matrices of own-price responses of the unrationed commodities with and without rationing is a positive definite matrix. For any particular unrationed commodity, this implies that rationing reduces its responsiveness to its own price. This result is often referred to as the Le Chatelier principle, and was first introduced into economics by Samuelson (1947, pp. 36–9). Strictly speaking, the principle relates only to a comparison of compensated demands (compare (10) below). Moreover, it is a local result only, since it requires that the derivatives of both rationed and unrationed demand schedules be evaluated at the same consumption bundle, point $D$ in Figure 1 (though Roberts, 1999, shows that it applies globally in an average sense). Despite these qualifications, the principle is often interpreted as implying in general that the imposition of restrictions on some aspects of behaviour makes individuals less responsive to exogenous changes in their environment.

Equations (3) and (4) are two of the most important results in rationing theory. However, their simplicity depends crucially on the fact that they refer to the properties of compensated demand schedules. There is one special case where equation (3) holds exactly for uncompensated (Marshallian) as well as compensated (Hicksian) demands, namely, where the ration 'just' binds, in the sense that the ration constraint coincides exactly with the amount of $y$ that would be demanded by an unrationed consumer (so that points $A$ and $D$ in Figure 1 coincide). This was the case for which Tobin and Houthakker (1950–1) derived their results in a classic paper. For strictly binding ration constraints, any exogenous change has additional income effects, whose implications were first derived by Neary and Roberts (1980).

To illustrate the additional income effects which strictly binding ration constraints introduce, refer again to Figure 1. The distance $OC$ measures the consumer's actual income in terms of $x, I/\pi p + (q/\pi p)\overline{y}$. However, this income would not be sufficient to induce an unrationed consumer faced with prices $p$ and $\overline{q}$ to consume voluntarily at $D$; to do this they would need an income equal (in terms of good $x$) to the distance $OF$. Simple geometry shows that this distance equals $x + (\overline{q}/\pi p)\overline{y}$ or $[1 + (\overline{q} - q)\overline{y}] / \pi p$. Hence, the uncompensated...
demands of the rationed consumer may be equated to the uncompensated demands of an unrationed consumer, provided the latter are evaluated at the virtual price \( \bar{q} \) and at a ‘virtual income’ \( l + (\bar{q} - q) \bar{y} \):

\[
\check{x}(\rho, q, \bar{y}, l) = x[\rho, \bar{q}, l + (\bar{q} - q) \bar{y}].
\]  

(5)

In addition, the virtual price and income must be such that they induce an uncompensated demand for the rationed good equal to the ration constraint, so that (2) must be replaced by:

\[
\bar{y} = y[\rho, \bar{q}, l + (\bar{q} - q) \bar{y}].
\]  

(6)

Differentiating (5) and (6) now yields the full effects of exogenous changes on the demand for unrationed commodities. Consider first the effect of a change in income:

\[
\check{x}_l = x_l - x_y^c y_l.
\]  

(7)

Thus, an increase in income affects demands for unrationed goods in two ways: first, it has a direct effect identical to the effect of an income increase in the absence of rationing (though evaluated at the virtual prices and income, of course); and second, by raising demand for the rationed good (on the assumption that \( y \) is normal so that \( y_I \) is positive), it is equivalent to a tightening of the ration constraint, and so has an indirect effect given by eq. (3). Differentiating (5) and (6) also gives the effect of a change in the ration constraint:

\[
\check{x}_y = \check{x}_y^c + \check{x}_l(\bar{q} - q).
\]  

(8)

This shows that a tightening of the ration constraint has a compensated or substitution effect given by (3) and an additional income effect, given by the last term in (8). This term vanishes if the virtual and actual prices of the rationed good coincide, which corresponds to the case where the ration constraint ‘just’ binds. In the case illustrated in Figure 1, where the consumer would like to consume more of the rationed good, \( \bar{q} \) exceeds \( q \), and so a tightening of the ration constraint, by lowering real income, tends to reduce the demand for all normal unrationed goods. (Of course, as already noted in discussing the diagram, the total effect must be an increase in spending on the unrationed goods as a group.) Finally, the effect of changes in prices may be obtained in a similar manner. First, for an increase in the prices of the unrationed goods themselves:

\[
\check{x}_p = x_p - \check{x}_y^c y_p.
\]  

(9)
This shows that an increase in the price of an unrationed good has a direct effect, equal to its effect in the absence of rationing, and an indirect effect: by changing the demand for the rationed good it is equivalent to a tightening or relaxation of the ration constraint and so has the usual effect given by (3). Equation (9) may be rewritten in a form which, by comparison with (4), shows how income effects may counteract the Le Chatelier principle:

\[ \delta p - \delta P = (\delta p - \delta P) + \delta i \]

By contrast, the effect of a change in the price of the rationed good is much simpler:

\[ \delta q = - \delta i \]

This price change has no substitution effect, which explains why \( q \) is not an argument in the compensated rationed demand schedules (1). Its only effect is to lower real income by requiring the consumer to pay more for the rationed good, and so it reduces the demand for normal unrationed goods.

Before we leave the basic comparative statics of rationing, a problem which is peculiar to this area should be mentioned. All the results which have been derived assume that the values of the exogenous variables are such that the ration constraint is a binding one. However, it is quite possible for a finite change in an exogenous variable to render the constraint non-binding. For example, in Figure 1 this would occur if the ration constraint \( y \) rose above the unconstrained demand \( y(p, q, I) \). If this happens, the ration constraint ceases to be binding and the ordinary unconstrained demand functions become applicable. Shifts of ‘regime’ such as this dictate great care in applying rationing theory in cases where large finite changes in exogenous variables occur; and in applications such as fixprice macroeconomics, where interest focuses on the interaction between constraints which impinge on different agents.

In empirical applications of rationing theory, attention has focused on deriving explicit forms for rationed demand functions which are tractable but not too restrictive. As in the case of consumer theory in the absence of rationing, progress in this direction comes most easily not by specifying functional forms for the direct utility function but by adopting a dual approach, which takes the expenditure function as its starting point. In the presence of rationing the constrained expenditure function gives the minimum cost of attaining a given utility level when consumption of the rationed commodity is predetermined:

\[ \tilde{E}(\bar{y}, p, q, u) = \min\{ p' x + q \bar{y}; v(x, y) \geq u \} = p' \tilde{\delta} \xi(p, \bar{y}, u) + q \bar{y} \]

Substituting from (1) and (2) yields, after some manipulation, the fundamental relationship between constrained and unconstrained expenditure functions:

\[ \tilde{E}(\bar{y}, p, q, u) = E(p, \bar{q}, u) + (\bar{q} - q) \bar{y} \]
In principle, this identity permits the derivation of a matched pair of rationed and unrationed demand functions, characterizing the behaviour of the same consumer in both environments. Two interesting specifications of the expenditure function which permit this are investigated in the labour supply context by Deaton and Muellbauer (1981). Unfortunately, the derivation of such matched pairs of demand functions is not possible in general. An alternative approach is to specify a general functional form for the rationed expenditure function which imposes fewer restrictions on demand responses though at the cost of an inability to write the unrationed demand functions in closed form. This approach has been pursued by Deaton (1981), who derives a system of rationed demand functions which express budget shares as a linear function of the ration level and the logarithms of prices and real expenditure on unrationed goods. He shows that treating expenditure on housing as predetermined in this framework leads to more plausible results than when it is assumed to be unconstrained. (Specifically, the rationed system goes much of the way towards avoiding the implausible rejection of homogeneity in nominal variables, which has been found in many empirical studies of demand.)

Insights derived from rationing have proved useful in many branches of economic theory other than consumer economics. In public economics and environmental economics, the study of optimal public policy has been extended to public goods and bads (the consumption of which is predetermined from an individual consumer's point of view) and nonlinear commodity taxation (of which government-imposed consumption quotas are a special but empirically important case). In macroeconomics, rationing theory has been used to model both current and expected future quantity constraints on households and firms in formalizations of Keynes's contribution as the economics of 'general disequilibrium', in which the failure of prices to adjust rapidly in the short run faces agents with quantity constraints which 'spill over' to influence their behaviour in other markets (see Neary and Stiglitz, 1983, and further references given there). In international trade theory, it has been shown that the behaviour of an economy subject to quotas (quantitative restraints on imports) can be characterized in the same way as that of a household subject to rationing, with the added benefit that the virtual prices can be interpreted as the domestic market-clearing prices (see Anderson and Neary, 1992).

Finally, within a utility-maximizing framework, it may be noted that rationing necessarily imposes a welfare loss. This consideration underlies the instinctive preference by most economists for the use of the price system as an allocation mechanism rather than direct controls, a preference which is supported by the two fundamental theorems of welfare economics. Nevertheless, in situations where the conditions for these theorems do not obtain, it may be possible to give a second-best justification for rationing. While work along these lines pertains more to public economics than to rationing theory per se, mention may be made of two especially interesting contributions. One is a paper by Weitzman (1977), who develops a model where the just distribution of a particular commodity on the basis of need alone is considered a socially desirable end in itself. He shows that rationing the commodity is preferable to allocating it via the price system if tastes are homogeneous but income is unevenly distributed. The other is a paper by Guesnerie and Roberts (1984), who show that, in a second-best world with given commodity taxes (so that consumer prices diverge from marginal social valuations), rationing is likely to be welfare improving.

Rau, Karl Heinrich (1792–1870)

H.C. Recktenwald
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

cameralism; Freiburg School; Historical School, German; public finance; Rau, K. H.; Smith, A.

Article

Rau was born in Erlangen and was a lecturer (Privatdozent) and professor (1816). In 1822 Rau was appointed to a chair of economics at the University of Freiburg. Involved in political affairs, as were many German professors in the 19th century, he was appointed a member of the upper Chamber of Baden and in 1848 was elected to the Frankfurt Assembly.

At first influenced by Cameralist ideas, Rau was one of the main mediators and defenders of Smith's 'system of natural liberty', whose central principles, abstractly exposed, he embodied in a rich supply of illustrative facts in his famous Lehrbuch (1826–37) yet without attempting to test his hypotheses empirically, that is, to use factual materials as confirmation instead of pure description. To that extent he was not an original thinker. Yet he was a great teacher. Similar to Samuelson's Economics in our time, his best-selling textbook, published in eight editions (1862–9), was an authoritative work for the majority of economists teaching at German universities for several generations. Based on classical ideas, it thus shaped the economic and political Weltbild of future civil servants and lawyers.

Rau's tripartite division of economics, which was obviously influenced by Smith, was divided into three volumes, theory (economic laws), policy (Polizeiwissenschaft) and public finance; this division became the established tradition in the teaching of political economy at German universities and is divisive up to the present day. With the rise and the establishment of the German Historical School and its stress on both the ethical aspect of economic issues, that is, of the distribution of income and property, and on the historical character of economic principles, Rau's star faded, although his work on public finance became the foundation of Wagner's famous treatise.

Viewed in a historical continuum, the Freiburg School (Eucken, Röpke, von Hayek), Erhard's liberal economic policy and, more recently, a group of German economists who are attempting to revive Smith's tripartite theory of order (ethics, economics and politics as an entity) all indirectly resume that thread of Rau's concept, although on a different analytical level (Recktenwald, 1973, 1985). In the light...
of a worldwide Smith renaissance in our epoch, Rau's editing function seems to merit secular attention.

The first American to publish a treatise on economic topics, Raymond was born in Connecticut but made his home in Baltimore, where he practised law. *Thoughts on Political Economy* (1820) was written to while away the time as the young attorney waited for clients. The book constituted a challenge to classical orthodoxy and as such was warmly received by the protectionists. To make his voice more resounding they tried (without success) to secure Raymond a professorship at the University of Maryland that they were willing to underwrite. Raymond was an original thinker, whose ideas reverberated in the later writings of Frederick List, the historical economists and the 20th-century literature on economic development.

Raymond's principal concern was national economic development and, unlike the classics, he placed the nation rather than the individual in the centre of his analysis. Following Lauderdale, he distinguished between national and individual wealth, but unlike Lauderdale, to whom usefulness was the characteristic feature of public wealth and scarcity that of private wealth, Raymond interpreted national wealth in terms of its ‘capacity’ to produce goods. This view opens up to government a central position in promoting economic development by means of tariff protection. Raymond also underlines the conflicts of interest among different groups in the economy and again calls on government for their resolution.

While Raymond's basic ideas reflect the influence of Alexander Hamilton, his distrust of paper money and bank credit echoes the related views of Jefferson. Raymond also was highly critical of corporations. These incongruities were bound to affect the impact of his work.

real balances

Don Patinkin
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

By the term ‘real balances’ is meant the real value of the money balances held by an individual or by the economy as a whole, as the case may be. The emphasis on real, as distinct from nominal, reflects the basic assumption that individuals are free of ‘money illusion’. It is a corresponding property of any well-specified demand function for money that its dependent variable is real balances. Indeed, Keynes in his *Treatise on Money* (1930, vol. 1, p. 222) designated the variation on the Cambridge equation that he had presented in his *A Tract on Monetary Reform* (1923, ch. 3: 1) as ‘The “Real-Balances” Quantity Equation’.

Implicit – and sometimes explicit – in the quantity-theory analysis of the effect of (say) an increase in the quantity of money is the assumption that the mechanism by which such an increase ultimately causes a proportionate increase in prices is through its initial effect in increasing the real value of money balances held by individuals and consequently increasing their respective demands for goods: that is, through what is now known as the ‘real-balance effect’. This effect, however, was not assigned a role in the general-equilibrium system of equations with which writers of the interwar period attempted to describe the workings of a money economy. In particular, these writers mistakenly assumed that in order for their commodity demand functions to be free of money illusion, they had to fulfil the so-called ‘homogeneity postulate’, which stated that these functions depended only on relative prices, and so were not affected by a change in the absolute price level generated by an equi-proportionate change in all money prices (Leontief, 1936, p. 192). Thus they failed to take account of the effect of such a change on the real value of money balances and hence on commodity demands. This in turn led them to contend that there existed a dichotomy of the pricing process, with equilibrium relative prices being determined in the ‘real sector’ of the economy (as represented by the excess-demand equations for commodities), while the equilibrium absolute price level was determined in the ‘monetary sector’ (as represented by the excess-demand equation for money): (Modigliani, 1944, sec. 13). This, however, is an invalid dichotomy, for it leads to contradictory implications about the determinacy or, alternatively, stability of the absolute price level (Patinkin, 1965, ch. 8).

Nor was the real-balance effect taken account of in Keynes’s *General Theory* and in the subsequent Hicks (1937)–Modigliani (1944) IS–LM exposition of this theory, which rapidly became the standard
one of macroeconomic textbooks. According to this exposition, the only way in which a decline in wages and prices can increase employment is by its effect in increasing the real value of money balances, hence reducing the rate of interest, and hence (through its stimulating effect on investment) increasing the aggregate demand for goods and hence employment. A further and basic tenet of this exposition was that there was a minimum below which the rate of interest could not fall. So if the wage decline were to bring about a lowering of the rate of interest to this minimum before full employment were reached, any further decline in the wage rate would be to no avail. In brief, the economy would then be caught in the ‘liquidity trap’. And even though Keynes had stated in the General Theory, ‘whilst this limiting case might become practically important in the future, I know of no example of it hitherto’ (p. 207), the Keynesian theory of employment was for many years interpreted in terms of this ‘trap’.

It was against this background that Pigou (1943, 1947) pointed out that the increase in the real value of money holdings generated by the wage and price decline increased the aggregate demand for goods directly, and not only indirectly through its downward effect on the rate of interest. Pigou's rationale was that individuals saved in order to accumulate a certain amount of wealth relative to their income, and that indeed the savings function depended inversely on the ratio of wealth to income. Correspondingly, as wages and prices declined, the real value of the monetary component of wealth increased and with it the ratio of wealth to income, causing a decrease in savings, which means an increase in the aggregate demand for consumption goods. Pigou's argument (which was formulated for a stationary state) thus had the far-reaching theoretical implication that even if the economy were caught in the ‘liquidity trap’, there existed a low enough wage rate that would generate a full-employment level of aggregate demand. In this way Pigou (1943, p. 351) reaffirmed the ‘essential thesis of the classicals’ that ‘if wage-earners follow a competitive wage policy, the economic system must move ultimately to a full-employment stationary state’.

In his exposition and elaboration of Pigou's argument (which inter alia brought out the significance of the argument for dynamic stability analysis), Patinkin (1948) labelled the direct effect on consumption of an increase in the real value of money balances as the ‘Pigou effect’. However, in subsequent recognition of the fact that this effect is actually an integral part of the quantity theory – as well as the fact that Pigou had been anticipated in drawing the implications of this effect for the Keynesian system by Haberler (1941, pp. 242, 389, and 403) and Scitovsky (1941, pp. 71–2) – Patinkin (1956, 1965) relabelled it the ‘real-balance effect’ and presented it as a component of the wealth effect.

In an immediate comment on Pigou's article, Kalecki (1944) pointed out that the definition of ‘money’ relevant for the real-balance effect is not the usual one of currency plus demand-deposits: for example, in the case of a price decline, the increase in the real value of the demand deposits has an offset in the corresponding increase in the real burden on borrowers of the loans they had received from the banking system. Thus (emphasized Kalecki) the monetary concept relevant for the real-balance effect in a gold-standard economy is only the gold reserve of the monetary system.

More generally, the relevant concept is ‘outside money’ (equivalent to the monetary base, sometimes also referred to as ‘high-powered money’), which is part of the net wealth of the economy, as distinct from ‘inside money’, which consists of the demand deposits created by the banking system as a result of its lending operations and which accordingly is not part of net wealth (Gurley and Shaw, 1960). This distinction was subsequently challenged by Pesek and Saving (1967), who contended that banks regard
only a small fraction of their deposits as debt, so that these deposits too should be included in net wealth. In criticism of this view, Patinkin (1969, 1972a) showed that if perfect competition prevails in the banking system, the present value of the costs of maintaining its demand deposits equals the value of these deposits, so that the latter cannot be considered as a component of net wealth. This is also the case if imperfect competition with free entry prevails in the system. On the other hand, if – because of restricted entry – the banking sector enjoys abnormal profits, then the present value of these profits should be included in net wealth for the purpose of measuring the real-balance effect.

There remains the question of whether – for the purpose of measuring the real-balance effect – one should include government interest-bearing debt, as contrasted with the non-interest-bearing debt (viz., government fiat money) which is a component of the monetary base. Clearly, in a world of infinitely lived individuals with perfect foresight, the former does not constitute net wealth and hence is not a component of the real-balance effect: for the discounted value of the tax payments which the representative individual must make in order to service and repay the debt obviously equals the discounted value of the payments on account of interest and principal that he will receive. Nor is the assumption of infinitely lived individuals an operationally meaningless one: for as Barro (1974) has elegantly shown, if in making his own consumption plans, the representative individual with perfect foresight is sufficiently concerned with the welfare of the next generation to the extent of leaving a bequest for it, he is acting as if he were infinitely lived. More specifically, Barro’s argument is as follows: assume that an individual of the present generation achieves his optimum position by consuming $C_0$ during his lifetime and leaving a positive bequest of $B_0$ for the next generation. Clearly, such an individual could have increased his consumption to $C_0 + \Delta C_0$ and reduced his bequest to $B_0 - \Delta C_0$ – but preferred not to do so. Assume now that the individual also holds government bonds payable by the next generation, and let the real value of these bonds increase as the result of a decline in the price level, expected to be permanent. The revealed preference of the present generation for the consumption-bequest combination $C_0, B_0$ implies that this increase in the real value of its holdings of government interest-bearing debt will not cause it to increase its consumption at the expense of the next generation. In brief, government debt in this case is effectively not a component of wealth and hence of the real-balance effect.

Needless to say, the absence of perfect foresight, and the fact that individuals might not leave bequests (as is indeed assumed by the life-cycle theory of consumption) means that government interest-bearing debt should to a certain extent be taken account of in measuring the real-balance effect – or what in this context is more appropriately labelled the ‘net-real-financial-asset effect’ (Patinkin, 1965, pp. 288–94). If we assume consumption to be a function of permanent income, and if we assume that the rate of interest which the individual uses to compute the permanent income flowing from his wealth is 10 per cent and the marginal propensity to consume out of permanent income before 0.80, then the marginal propensity to consume out of wealth (and out of real balances in particular) is the product of these two figures, or 0.08. However, in the case of consumers' durables (in the very broad sense that includes – besides household appliances – automobiles, housing, and the like), the operation of the acceleration principle implies an additional real-balance effect in the short run. In particular, assume that when the individual decides on the optimum composition of the portfolio of assets in which to hold his real wealth, $W$, he also considers the proportion, $q$, of these assets that he wishes to hold in the form of consumers durables, $K_d$, so that his demand for the stock of consumer-durable goods is $K_d = qW$. Assume
now that wealth increases solely as a result of an increase in real balances, \( M/p \). This leaves the representative individual with more money balances in relation to his other assets than he considers optimal. As a result he will attempt to shift out of money and into these other assets until he once again achieves an optimum portfolio. In the case of consumers' durables, this means that in addition to his preceding demand for new consumer-durable goods, he has a demand for

\[
C_d = \Delta K_d = q[\Delta (M / p)] = q[(M / p)_t - (M / p)_{t-1}]
\]

units, where \((M/p)_t\) represents real balances at time \(t\). In general, the individual will plan to spread this additional demand over a few periods. In any event, once an optimally composed portfolio is again achieved, this additional effect disappears, so that the demand for new consumers' durables (which in the case of a stationary state is solely a replacement demand) will once again depend only on the ordinary real-balance effect as described at the beginning of this paragraph (Patinkin, 1967, pp. 156–62).

It is, of course, true that the process of portfolio adjustment generated by the monetary increase will cause a reduction in the respective rates of return on the other assets in the portfolio, so that the initial wealth effect of the monetary increase will be followed by substitution effects. Now, Keynes limited his analysis in the *General Theory* to portfolios consisting only of money and securities; hence (as indicated above) an increase in the quantity of money could increase the demand for goods only indirectly through the substitution effect created by the downward pressure on the rate of interest. But once one takes account of the broader spectrum of assets held by individuals, one must also take account of the direct real-balance effect on the purchase of these other assets as well.

Various empirical studies have shown that the real-balance effect as here defined (viz., as part of the wealth effect) is statistically significant (Patinkin, 1965, note M; Tanner, 1970). Other studies have demonstrated the statistical significance of yet another definition of this effect: namely, as the effect on the demand for commodities of an excess supply of money, defined as the excess of the existing stock of money over its ‘desired’ or ‘long-run’ level (Jonson, 1976; Laidler and Bentley, 1983; cf. also Mishan, 1958). It seems to me, however, that such a demand function is improperly specified: for though (as indicated above) the excess supply of money has a role to play in the consumption function (and particularly in that for consumers' durables), the complete exclusion of the real-balance effect *cum* wealth effect from the aforementioned demand function implies that in equilibrium there is no real-balance effect – an implication that is contradicted by the form of demand functions as derived from utility maximization subject to the budget constraint (Patinkin, 1965, pp. 433–8, 457–60; Fischer, 1981).

Granted the statistical significance of the real-balance effect, the question remains as to whether it is strong enough to offset the adverse expectations generated by a price decline – including those generated by the wave of bankruptcies that might well be caused by a severe decline. In brief, the question remains as to whether the real-balance effect is strong enough to assure the stability of the system: to assure that automatic market forces will restore the economy to a full-employment equilibrium position after an initial shock of a decrease in aggregate demand (Patinkin, 1948, part II; 1965, ch. 14: 1). On the assumption of adaptive expectations, Tobin (1975) has presented a Keynesian model with the real-
balance effect which under certain circumstances is unstable. On the other hand, McCallum (1983) has shown that under the assumption of rational expectations, the model is generally stable. In any event, no one has ever advocated dealing with the problem of unemployment by waiting for wages and prices to decline and thereby generate a positive real-balance effect that will increase aggregate demand. In particular, Pigou himself concluded his 1947 article with the statement that such a proposal had ‘very little chance of ever being posed on the chequer board of actual life’. Thus the significance of the real-balance effect is in the realm of macroeconomic theory and not policy.

Correspondingly, recognition of the real-balance effect in no way controverts the central message of Keynes's General Theory. For this message – as expressed in the climax of that book, Chapter 19 – is that the only way a general decline in money wages can increase employment is through its effect in increasing the real quantity of money, hence reducing the rate of interest, and hence stimulating investment expenditures; but that even if wages were downwardly flexible in the face of unemployment, this effect would be largely offset by the adverse expectations and bankruptcies generated by declining money wages and prices, so that the level of aggregate expenditures and hence employment would not increase within an acceptable period of time. In Keynes's words: ‘the economic system cannot be made self-adjusting along these lines’ (ibid., p. 267). And there is no reason to believe that Keynes would have modified this conclusion if he had also taken account of the real-balance effect of a price decline (Patinkin, 1948, part III; 1976, pp. 110–11).

The above discussion has considered only the real-balance effect on the demand for goods. In principle, this effect also operates on the supply of labour: for the greater the real balances and hence wealth of the individual, the greater his demand for leisure as well, which means the smaller his supply of labour. This influence, however, has received relatively little attention in the literature (but see Patinkin, 1965, p. 204; Phelps, 1972; Barro and Grossman, 1976, pp. 14–16).

Another limitation of the discussion is that it deals only with a closed economy. In the analysis of an open economy, the real-balance effect plays an important role in some of the formulations of the monetary approach to the balance of payments.

real balances: The New Palgrave Dictionary of Economics

The real bills doctrine and the quantity theory of money represent distinct theoretical models of price-level determination and consequently imply different prescriptions for the conduct of monetary policy. The real bills doctrine takes the price level as exogenous and recommends money supply movements that passively respond to the economy. In sharp contrast, the quantity theory insists that the only way to ensure price level stability is by constraining the money supply and not allowing the money supply to move passively in response to economic conditions.

Article

Drawing on two very different hypotheses about the link between nominal money and economic activity, the real bills doctrine and the quantity theory of money represent sharply divergent advice on the conduct of monetary policy. The quantity theory has many prominent advocates, but the real bills doctrine has had a dominant influence in the history and practice of central banking. Further, the real bills doctrine was at the core of the Congressional act creating the US Federal Reserve System so that its importance echoes down to the current day.

The real bills doctrine views money as playing a decidedly passive role, calling for monetary expansion in line with economic activity. According to this view, economic activity is linked to business trade credit and the issuance of short-term debt instruments. Banks should freely purchase these ‘real bills’ with banknote issue, where the modifier ‘real’ refers to short-term debt instruments used to finance...
productive activity as opposed to speculation. The doctrine dates to at least 1705 with the publication of *Money and Trade Considered* by John Law, who suggested that banknote issue should be secured by and thus linked to the nominal value of land. The most famous statement of the doctrine is by Adam Smith, whose linkage of note issue to bills of exchange gave the doctrine its name:

When a bank discounts to a merchant a real bill of exchange drawn by a real creditor upon a real debtor, and which, as soon as it becomes due, is really paid by that debtor; it only advances to him a part of the value which he would otherwise be obliged to keep by him unemployed, and in ready money for answering occasional demands. The payment of the bill, when it becomes due, replaces to the bank the value of what it had advanced, together with the interest. The coffers of the bank, so far as its dealings are confined to such customers, resemble a water pond, from which, though a stream is continually running out, yet another is continually running in, fully equal to that which runs out; so that, without any further care or attention, the pond keeps equally, or very nearly full. (1776, p. 304)

Smith's water-pond metaphor illustrates the real-bills view that note issue would be self-regulating when tied to economic activity, that is, money issue could never be excessive when issued against short-term commercial bills.

The fundamental criticism of the real bills doctrine is that the value of commercial bills (or, in Law's case, the value of land) is tied proportionately to the price level. A commercial bill necessarily includes the dollar value of the goods or services to which it is linked. Thus, under the real bills doctrine, nominal note issue is tied to the nominal price level. If the price level is influenced by the money supply, then we have a circularity problem: nominal prices determine note issue, and note issue affects prices. Henry Thornton first noted the danger of this inflationary circle in his 1802 *An Enquiry into the Nature and Effects of the Paper Credit of Great Britain*. (David Ricardo was also a prominent opponent of the doctrine.) The thrust of Thornton's criticism was that the real bills doctrine provided no limit on banknote issue. Smith seems to have avoided Thornton's criticism because in Smith's system the gold standard provided an overall restraint on note issue. An excessive banknote issue would result in a bank losing its gold holdings, and see a drain on its ‘coffers’. (See Laidler, 1981; 1984, for a defence of Smith.) But in a world with an inconvertible paper currency Thornton's inflationary critique is devastating.

Humphrey (2001) provides an algebraic description of the real bills doctrine. Suppose that the needs for trade credit are proportional to nominal production, \(PY\), where \(P\) denotes the price level and \(Y\) denotes real production. The real bills doctrine would imply that banknote issue and thus the money supply \((M)\) should be proportionally linked to the needs of trade credit so that we have:

\[
M = kPY
\]

where \(k\) is the constant of proportionality between trade credit and nominal production. The Thornton...
inflationary critique is now obvious: even with an exogenous level of output \((Y)\), there is no way of determining the two endogenous variables, the money supply \((M)\) and price level \((P)\). A real bills counter-argument would be that the price level is exogenous to money, that is, the money supply has no direct effect on prices. As discussed below, the quantity theory makes the exact opposite claim.

**The real bills doctrine and the Great Depression**

Remarkably, the real bills doctrine survived Thornton and Ricardo's withering 19th century criticism to find a central place in 20th century US monetary history. In a fascinating account, Meltzer (2003) and Humphrey (2001) trace the flowering of the real bills doctrine into the US Federal Reserve Act of 1913. US Federal Reserve Banks existed for the purpose of ‘accommodating commerce and business’ and were supposed to discount only ‘eligible paper’, which the Act defined as ‘notes, drafts, and bills of exchange arising out of actual commercial transactions’. Although, like Adam Smith, the Act presumed the existence of the gold standard, the real bills doctrine was deemed sufficient even in the absence of a specie constraint. For example, in the *Tenth Annual Report* (1924) of the Board of Governors of the Federal Reserve System, it is noted that ‘there is little danger that the credit created and distributed by the Federal Reserve Banks will be in excessive volume if restricted to productive issues’ (1924, p. 28). The Report further suggested no link between money and prices: ‘The interrelationship of prices and credit is too complex to admit of any simple statement’ (1924, p. 32). Adolph Miller, a founding member of the Federal Reserve Board and co-author of the Report, rejected the notion that ‘changes in the level of prices are caused by changes in the volume of credit and currency…or that changes in the volume of credit and currency are caused by Federal Reserve policy’ (quoted in Meltzer, 2003, pp. 187–8).

Meltzer (2003) convincingly argues that it was this belief in the self-regulating nature of the real bills doctrine that led the Federal Reserve to stand idly by as the US economy spiralled into the Great Depression in the early 1930s. From a real-bills perspective, monetary policy was very loose during these years because Reserve Banks stood ready to discount bills at historically low nominal rates of interest. Meltzer (2003, p. 321) concludes that

> the real bills doctrine implied that the correct policy was a passive one. Most [Federal Reserve] governors had always held these views … The economies of the United States and much of the rest of the world became victims of the Federal Reserve's adherence to an inappropriate theory and the absence of basic economic understanding such as that developed by [Henry] Thornton and [Irving] Fisher.

**The quantity theory**

In sharp contrast to the real bills doctrine, the quantity theory held as its fundamental principle that the quantity of nominal money \((M)\) is largely exogenous and is the principal force determining the endogenous price level \((P)\). This argument was first articulated by David Hume (1752). An immediate corollary is that changes in the price level, that is, inflation, are primarily determined by movements in
real bills doctrine versus the quantity theory: The New Palgrave Dictionary of Economics

the supply of money. In the words of the celebrated quantity theorist Milton Friedman (1956, pp. 20–1):

> there is perhaps no other empirical relation in economics that has been observed to recur so uniformly under so wide a variety of circumstances as the relation between substantial changes over short periods in the stock of money and in prices; the one is invariably linked with the other and is in the same direction; this uniformity is, I suspect, of the same order as many of the uniformities that form the basis of the physical sciences.

The quantity theory’s causal link between $M$ and $P$ included the concept of long-run monetary neutrality: exogenous changes in $M$ would eventually be exactly matched by proportional changes in $P$. This inference is grounded on the stability of real money demand. In the words of Friedman: ‘The quantity theory is in the first instance a theory of the demand for money’ (1956, p. 4); ‘The quantity theorist accepts the empirical hypothesis that the demand for money is highly stable – more stable than functions such as the consumption function that are offered as alternative key relations’ (1956, p. 16). If we let $L(R, Y)$ denote real money demand as a function of the nominal interest rate ($R$) and the level of real production ($Y$), we have a money market equilibrium condition given by:

$$L(R, Y) = \frac{M}{P}.$$  

The proportionality hypothesis is then quite clear: for a stable level of $L$, exogenous changes in $M$ must be matched by changes in $P$ of the exact same magnitude.

The quantity theory also included the concept of short-run non-neutrality. In the words of Hume (1752, p. 38):

> When any quantity of money is imported into a nation, it is not at first disposed into many hands but is confined to the coffers of a few persons, who immediately seek to employ it to advantage … It is easy to trace the money in its progress through the whole commonwealth, where we shall find that it must first quicken the diligence of every individual before it increase the price of labour.

‘There is always an interval before matters be adjusted to their new situation’ (1752, p. 40). Quantity theorists would argue that increases in $M$ are initially met by increases in production ($Y$) and declines in interest rates ($R$), but that in the long run $R$ and $Y$ would return to their original levels and that $P$ would thus fully reflect the new higher level of $M$.

The quantity theory is closely associated with the quantity equation which can be derived as follows. The previous money demand relationship can be re-written as

$$L(R, Y) = \frac{M}{P}.$$
If we define the velocity of money as

\[ V = \frac{Y}{L(R, \gamma)} \]

then we can write this relationship as the celebrated quantity equation:

\[ MV = PY. \]

This is Pigou's (1927) variant of Irving Fisher's (1922) classic equation of exchange. The quantity equation is a useful device for expositing the two central tenets of the quantity theory of money: (a) in the long run, output \((Y)\) and velocity \((V)\) are exogenous to money, so that exogenous movements in the money supply \((M)\) are met by proportional movements in prices \((P)\), and (b) in the short run, movements in the money supply are met by some combination of movements in velocity, prices and output, so that changes in \(M\) have non-neutral effects on output. The quantity equation can also be used to illustrate Thornton's inflationary critique of the real bills doctrine. For a given level of the nominal rate and an exogenous level of production, velocity is determined by the money demand function, but there is no restriction on the size of \(M\) or the size of \(P\).

The contemporary policy debate

From the vantage point of the outset of the 21st century, there is a sense in which the quantity theory has won numerous intellectual battles but lost the war. Most economists subscribe to the principles of long-run monetary neutrality and short-run non-neutrality. Most would also agree that the quantity equation can be a useful intellectual organizing device. Finally, a standard result in any monetary theory course is the nominal indeterminacy that arises under an exogenous interest-rate operating procedure (for example, Sargent, 1987, ch. 4). This result is just the modern statement of Thornton's 1802 criticism of the real bills doctrine. Hence, it would appear that the quantity theory is in the ascendant. But remnants of the real bills doctrine are pervasive in both monetary policy implementation and theoretical work. In terms of policy, essentially all central banks in the industrialized world typically ignore or downplay movements in monetary aggregates and instead conduct monetary policy according to an interest rate operating procedure, a close descendant of a real-bills policy. The rationale for such a policy choice is the assertion that the demand for money and thus velocity are unstable. Such a policy
implies seasonal movements in monetary aggregates to accommodate movements in real activity, a
passive money supply movement that is directly out of a real-bills playbook.
From a theoretical perspective, there have been two prominent recent contributions in favour of interest
rate policy. First, Sargent and Wallace (1982) provide something of a rehabilitation of the real bills
doctrine by developing a model in which fluctuating nominal interest rates are harmful, and in which a
policy of pegging the nominal interest rate at zero is Pareto efficient. Second, Woodford (2003) has
pioneered an effort to conduct monetary policy analysis in ‘cashless’ models – models in which the price
level is well defined even though there is no money in the model and the central bank follows an interest-
rate operating procedure. We review each of these contributions in turn.
Sargent and Wallace (1982) consider a two-period-lived overlapping-generations model in which fiat
money is held even though nominal interest rates are positive because of a legal restriction on private
real lending. There are three types of agents: poor savers, rich savers, and borrowers. Using their
logarithmic preference specification, the two classes of savers have a constant desired level of savings,
say, $S^P$ for the poor and $S^R \gg S^F$ for the rich. The borrowers have a demand for loans given by

$$D^L = \frac{D}{1 + r}$$

where $r$ is the real interest rate, and $D > S^R$. (Sargent and Wallace, 1982, consider the case in which the
demand for loans fluctuates deterministically, but this is unimportant for their basic result.) The legal
restriction is that borrowers cannot issue small-denomination notes. Hence, poor savers cannot lend
directly to the borrowers, but can only save by accumulating fiat money. The equilibrium conditions for
the money and credit markets are given by:

**Money market:** $S^P = \frac{M_t}{P_t}$

**Credit market:** $S^R = \frac{D}{1 + r_t}$

where $M_t$ and $P_t$ denote the time-$t$ money supply and price level, and $r_t$ is the real rate of interest. Under
what Sargent–Wallace call a ‘quantity-theory’ regime, the central bank keeps the money supply fixed at
some $M_t = M$. In this case, the price level and the real interest rate are constant and calculated from the above equilibrium conditions. This equilibrium is clearly not Pareto optimal as agents do not face the same inter-temporal rate of return – that is, rich savers earn a return of $r > 0$, while poor savers earn a zero real return on currency holdings.

Under a ‘real-bills’ regime the central bank stands ready to lend cash at a zero nominal rate of interest so that

$$\left(1 + r_t\right) = \frac{p_t}{p_{t+1}}.$$  

In particular, the central bank purchases the ‘real bills’ issued by the borrowers. To finance these purchases the central bank creates the new fiat money denoted by $N_t$. The borrowers can then use this cash to purchase goods from the poor savers. By purchasing the borrowers' bonds with fiat money, the central bank is effectively opening up an avenue by which poor savers can lend to borrowers. Without this central bank intervention, the positive nominal rates in the credit market are symptoms of a problem – the inability of a fixed money stock to promote proper credit allocation. The real bills equilibrium conditions are given by:

Money market: $S^P = \frac{M_t + N_t}{p_t}$

Credit market: $\frac{N_t}{p_t} + S^R = \frac{D}{\left(p_t / p_{t+1}\right)}$.

Combining, we have that an equilibrium under the real-bills regime is defined by a price sequence that satisfies:

$$S^P + S^R = \frac{M_t}{p_t} + \frac{D}{\left(p_t / p_{t+1}\right)}.$$
Solving, we have:

\[ p_t = \left( \frac{D}{S^P + S^R} \right) p_{t+1} + \left( \frac{1}{S^P + S^R} \right) m_t. \]

Assuming \( D < (S^P + S^R) \), the set of stationary equilibria are given by

\[ p_t = \left( \frac{1}{S^P + S^R} \right) \sum_{j=0}^{\infty} \left( \frac{D}{S^P + S^R} \right)^j M_{t+j}. \]

where the path of the money supply is free. In the special case in which the money supply grows at a constant rate \( g \) we have

\[ p_t = \left( \frac{1}{S^P + S^R - D(1 + g)} \right) M_t. \]

Note that, if \( g \) becomes large enough, the monetary equilibrium disappears.

Sargent and Wallace restrict the analysis to a particular equilibrium in which the beginning-of-period money supply is held fixed, \( m_t = M \) for \( t = 0, 1, 2, \ldots \). However, the money supply grows and contracts within each period as the central bank accommodates the supply of one-period bonds issued by the borrowers ('real bills') with the passive expansion of \( N_t \). In this equilibrium the price level is constant and the real return on savings is zero. This equilibrium is Pareto efficient, in contrast to the Pareto inefficiency of the quantity-theory regime. This is an argument in favour of the real bills doctrine and represents Sargent and Wallace's rehabilitation of the doctrine.

There are difficulties with this conclusion. First, the real-bills equilibrium selected by Sargent and Wallace does not Pareto-dominate the quantity-theory regime (rich savers are worse off under the real-bills regime). Second, there is an infinite number of other real-bills equilibria, all defined by the behaviour of the money stock, and not all of these are Pareto efficient. For example, if the money supply grows at a constant rate \( g > 0 \) the real-bills equilibrium is not Pareto efficient. Finally, Thornton's inflationary critique of the real-bills regime endures: since the money supply is entirely free, there are no restrictions on the short-term and long-term price level.
The second body of recent theoretical work that has a real-bills flavour is provided by Woodford (2003). The title of Woodford's treatise is *Interest and Prices*, a title that makes clear a principal assertion in the work: the money supply is largely irrelevant to price-level determination. The key relationship in the work is the Fisher equation linking nominal rates \((i_t)\) to inflation rates and real rates \((r_t)\):

\[
i_t = r_t + p_{t+1} - p_t
\]

where \(p_t\) is the log of the price level. For simplicity let us suppose that the real rate is exogenous. If the central bank conducts policy according to an exogenous nominal interest rate policy, then the Fisher equation uniquely determines the growth rate of prices (the inflation rate), but not the level of prices. This is, again, the Thornton critique of the real bills doctrine. But Woodford assumes that the central bank follows an endogenous interest rate policy in which the nominal rate responds to movements in prices:

\[
i_t = \alpha p_t.
\]

Assuming that \(\alpha > 0\), the unique stationary equilibrium is given by:

\[
p_t = \sum_{j=0}^{\infty} \left( \frac{1}{1 + \alpha} \right)^{j+1} r_{t+j}.
\]

From a quantity-theory perspective this is a remarkable conclusion: the price level is determined without any mention being made of the money supply. Where is the money demand curve? Either it does not matter (as the money supply moves passively to hit the interest rate target) or it does not even exist (a ‘cashless’ world). Woodford's (2003) analysis thus rejects the quantity theory as a useful guide for policy, and at the same time provides a 21st-century response to Thornton's 19th-century critique of the real bills doctrine: the money supply should be adjusted passively to hit the interest-rate target (as under a real-bills policy), but the interest-rate target should be moved endogenously to ensure price-level stability.

In the intellectual clash of ideas there are typically no clear winners or losers, but instead a synthesis of the combatants. This is surely true of the debate between the real-bills doctrine and the quantity theory of money. Current monetary policy practice and theory has a notable real-bills flavour in the near-universal use of interest rates as the operating target. To repeat, the advantage of such a policy is that it
allows the money supply to respond automatically to and thus accommodate natural movements in real economic activity. But Thornton and the quantity theorists provide a cautionary critique: under an exogenous interest rate policy, there is no way of limiting the inflationary circle between note issue and the price level. To respond to this quantity-theory critique, Woodford (2003) and others have proposed an endogenous interest-rate policy of the form outlined above. This is just one manifestation of the synthesis of the two combatants in this intellectual debate.

The ‘real bills doctrine’ has its origin in banking developments of the 17th and 18th centuries. It received its first authoritative exposition in Adam Smith's *Wealth of Nations*, was then repudiated by Thornton and Ricardo in the famous Bullionist Controversy, and was finally rehabilitated as the ‘law of reflux’ by Tooke and Fullarton in the currency–banking debate of the mid-19th century. Even now, echoes of the real bills doctrine reverberate in modern monetary theory.

The central proposition is that bank notes which are lent in exchange for ‘real bills’, that is, titles to real value or value in the process of creation, cannot be issued in excess; and that, since the requirements of the non-bank public are given and finite, any superfluous notes would return automatically to the issuer, at least in the long run. The grounds for rejecting the real bills doctrine have been many and varied. The main counter-argument is that overissue is not merely possible but inevitable in the absence of any external principle of limitation; in this view, commercial wants are insatiable and excess notes would not return to the issuer but undergo depreciation in the exact proportion to their excess.

By the time the real bills doctrine appeared in the economic literature, fractional reserve banking was already well established, releasing unproductive hoards for trade and investment. This did not satisfy John Law, that ‘reckless, and unbalanced but most fascinating genius’ (Marshall, 1923, p. 41n.). He outlined a primitive real bills doctrine in the course of his proposal for a land bank, which would issue paper money on ‘good security’. He imagined, however, that the need for a metallic reserve was superseded by the abolition of legal convertibility, and that economic convertibility would always be maintained by conformity with the real bills doctrine (Law, 1705, p. 89).
The problem was that, as a mercantilist, Law identified money with capital; he believed that creating paper money was equivalent to increasing wealth. It was his attempt to ‘break through’ the metallic barrier that gave him ‘the pleasant character mixture of swindler and prophet’ (Marx, 1894, p. 441). The spectacular collapse of Law's ‘System’ set off a negative reaction against financial innovation, which was reflected in Cantillon's ‘anti-System’ (Rist, 1940, p. 73) and in Hume's opposition to what he called 'counterfeit money' (1752, p. 168). A more positive effect was a shift in the focus of political economy itself to the production process. This shift was led by the Physiocrats and by Adam Smith, whose 'original and profound' (Marx, 1859, p. 168) analysis of money and banking was developed in the context of classical value theory.

A decade before the Wealth of Nations, Sir James Steuart had attempted to revive Law's ideas from a 'neo-mercantilist' viewpoint (1767, book IV, pt. 2). For Smith, by contrast, the role of bank credit was to increase not the quantity of capital but its turnover (1776, pp. 245–6; also Ricardo, Works, III, pp. 286–7). Output was fixed by the level of accumulation, which for all the classical economists included the speed of its turnover. Credit had the effect both of reducing the magnitude of reserve funds which economic agents needed to hold and of allowing the money material itself – treated as an element of circulating capital and an unproductive portion of the social wealth – to be displaced by paper, thus providing ‘a sort of wagon-way through the air’.

Smith followed Law and Steuart, however, in arguing that an overissue of bank notes could not take place if they were advanced upon ‘real’ bills of exchange, that is, those ‘drawn by a real creditor upon a real debtor’, as opposed to ‘fictitious’ bills, that is, those ‘for which there was properly no real creditor but the bank which discounted it, nor any real debtor but the projector who made use of the money’ (1776, p. 239; also p. 231). When a banker discounted fictitious bills, the borrowers were clearly ‘trading, not with any capital of their own, but with the capital which he advances to them’. When, on the other hand, real bills were discounted, bank notes were merely substituted for a substantial proportion of the gold and silver which would otherwise have been idle, and therefore available for circulation (p. 231). The quantity of notes was thus equivalent to the maximum value of the monetary metals that would circulate in their absence at a given level of economic activity (p. 227).

This development of the classical law of circulation applied to credit and fiduciary money alike, with the difference that in the latter case overissue in the ‘short run’ might result in a permanent depreciation of the paper. By contrast, credit-money, that is, banknotes which were exchanged for real bills, could never be in long-run excess:

> The coffers of the bank … resemble a water-pond, from which, though a stream is continually running out, yet another is continually running in, fully equal to that which runs out; so that, without any further care or attention, the pond keeps always equally, or very near equally full. (p. 231)

Only what Smith called ‘over-trading’ would upset this balance, by promoting excessive credit expansion and an accompanying drain of bullion. Although the real bills doctrine was accepted by the Bank of England Directors as a guide to monetary management, it was challenged in the bullion controversy following the suspension of cash payments in 1797 as ‘the source of all the errors of these practical men’ (Ricardo, Works, III, p. 362; also Thornton,
real bills doctrine: The New Palgrave Dictionary of Economics

1802, p. 244 and passim). In the view of the ‘bullionists’,

The refusal to discount any bills but those for bona fide transactions would be as little effectual in limiting the circulation; because, though the Directors should have the means of distinguishing such bills, which can by no means be allowed, a greater proportion of paper currency might be called into circulation, not than the wants of commerce could employ but greater than what could remain in the channel of currency without depreciation. (Ricardo, Works, III, p. 219)

Indeed, there was no other limit to the depreciation, and corresponding rise in the price level, ‘than the will of the issuers’ (Works, III, p. 226).

Nevertheless, the bullionist argument itself was open to challenge, because it confused money with credit. The inconvertible paper of the Bank Restriction was issued not as forced currency but on loan; it was therefore responsible not for increasing the money supply but simply altering its composition, by substituting one financial asset for another in the hands of the public. Only when cash payments were restored, however, was any further attempt made to rehabilitate the real bills doctrine, this time as the ‘law of reflux’: provided notes were lent on sufficient security, ‘the reflux and the issue will, in the long run, always balance each other’ (Fullarton, 1844, p. 64; Tooke, 1844, p. 60). The ‘Banking School’ called this law ‘the great regulating principle of the internal currency’ (Fullarton, 1844, p. 68). Their opponents, the ‘Currency School’ orthodoxy, ‘never achieved better than this average measure of security’; and, after all, the average ‘is not to be despised’ (Marx, 1973, p. 131). The real bills doctrine made its next appearance in the Federal Reserve Act of 1913. In banking at least, discretion has always been the better part of valour.

**Real Business Cycles**

Ellen R. McGrattan  
Edited by Steven N. Durlauf and Lawrence E. Blume

**Abstract**

Real business cycles are recurrent fluctuations in an economy's incomes, products, and factor inputs – especially labour – that are due to non-monetary sources. These sources include changes in technology, tax rates and government spending, tastes, government regulation, terms of trade and energy prices.

Most real business cycle (RBC) models are variants or extensions of a neoclassical growth model. One such prototype is introduced. It is then shown how RBC theorists, applying the methodology of Kydland and Prescott (*Econometrica* 1982), use theory to make predictions about actual time series. Extensions of the prototype model, current issues and open questions are also discussed.

**Article**

*Real business cycles* are recurrent fluctuations in an economy's incomes, products, and factor inputs – especially labour – that are due to non-monetary sources. Long and Plosser (1983) coined the term 'real business cycles' and used it to describe cycles generated by random changes in technology. Other real sources of fluctuations that have been studied include changes in tax rates and government spending, tastes, government regulation, terms of trade, and energy prices.

Kydland and Prescott (1982), who studied the *quantitative* predictions of a stochastic growth model with shocks to technology, found that covariances between model series and autocorrelations of model output were consistent with corresponding statistics for US data. These findings were viewed as surprising, for
two reasons. First, the findings ran counter to the idea that monetary shocks are the driving force behind business cycle fluctuations. Second, the policy implication for Kydland and Prescott’s model was that stabilization policies are counterproductive. Fluctuations arise when households optimally respond to changes in technology.

The methodology that Kydland and Prescott (1982) used in their study of business cycles transformed the way in which applied research in macroeconomics is done. For this reason, the term ‘real business cycles’ is often associated with a methodology rather than Kydland and Prescott’s original findings. Indeed, the methods of their 1982 paper have been used to study many different sources of business cycles, including monetary shocks.

Most real business cycle (RBC) models are variants or extensions of a neoclassical growth model. One such prototype is introduced. It is then shown how RBC theorists, following Kydland and Prescott (1982), use theory to make predictions about actual time series. Extensions of the prototype model are discussed. Current issues and open questions follow.

Prototype real business cycle model

Households choose sequences of consumption and leisure to maximize expected discounted utility. When aggregated, preferences are defined for a stand-in household that maximizes the expected value of

$$\sum \beta^t u(c_t, 1-h_t)N_t,$$

(1)

where $u$ is the utility function, $c_t$ is per capita consumption at date $t$, $1-h_t$ is per capita leisure at date $t$, $N_t$ is the population at date $t$ which grows at rate $\eta$, and $\beta$ is a discount factor.

The technology available in period $t$ is $z_tF_t(K_t, H_t)$, where $z_tF_t$ is the output produced at date $t$ with $K_t$ units of capital and $H_t$ hours. The function $F_t$ has constant returns to scale so that doubling the inputs doubles the output. The variable $z_t$ is a stochastic technology shock assumed to follow a Markov process. The variation in $z$ modelled here is variation in the effectiveness of factor inputs, capital and labour, to produce final goods and services or total factor productivity (TFP). Fluctuations in TFP arise from many possible sources. For example, improvements in TFP can arise from new inventions or innovations in existing production processes. Reductions in TFP can arise from increased regulation on producers.

Households are endowed with time each period, normalized without loss of generality to 1, which they can allocate to work or to leisure. They can invest $x_t$ (per capita) in new capital goods. Doing so yields

$$N_{t+1}k_{t+1} = N_t[(1-\delta)k_t + x_t],$$

(2)
where \( k_t \) is per capita beginning-of-period \( t \) capital, \( k_{t+1} \) is per capita end-of-period \( t \) capital, and \( \delta \) is the rate of per period depreciation.

Households face taxes on purchases of consumption and investment and on incomes to capital and labour. With taxation, the household budget constraint in period \( t \) is

\[
(1 + \tau_{ct})c_t + (1 + \tau_{xt})x_t = r_t k_t - \tau_{kt}(r_t - \delta)k_t + (1 - \tau_{ht})w_t h_t + \psi_t.
\]

Variables \( r_t \) and \( w_t \) are pre-tax payments to capital and labour, respectively. Variables \( \tau_{ct}, \tau_{xt}, \tau_{kt}, \) and \( \tau_{ht} \) are tax rates on consumption, investment, capital, and labour, respectively. These tax rates are assumed to be stochastic and follow a Markov process. Variable \( \psi_t \) is the per capita transfer payment at date \( t \) made by the government to each household. Total transfer payments are equal to tax revenues less total spending by the government. The per capita spending of the government at date \( t \) is \( g_t \).

To derive explicit predictions about the behaviour of these households, it is necessary to first define and then compute an equilibrium for the economy. In doing so, it is convenient to de-trend any variables that grow over time and deal only with stationary processes. To be precise, assume that there is a constant rate of improvement in production processes over time so that \( F_t(K_t, H_t) \equiv F(K_t, (1 + \gamma)^t H_t) \) with \( F \) homogeneous of degree 1. If the per capita capital stock grows at rate \( \gamma \) and \( z_t \) and \( h_t \) are stationary, then output grows at rate \( \gamma \). Certain assumptions on utility and the process for government spending also ensure that components of output grow at rate \( \gamma \). Denote by \( \hat{V}_t \) the de-trended level of variable \( v_t \), that is, \( \hat{V}_t = v_t / (1 + \gamma)^t \).

A competitive equilibrium is defined as household policy functions for consumption \( c(\hat{K}, \hat{K}, s) \), investment \( x(\hat{K}, \hat{K}, s) \), and hours \( h(\hat{K}, \hat{K}, s) \), where \( \hat{K} \) is the (de-trended) stock of capital for the household, \( \hat{K} \) is the (de-trended) aggregate stock of capital, and \( s = (\log z, \tau_c, \tau_x, \tau_k, \tau_h, \log g) \); pricing functions \( w(\hat{K}, s) \) and \( r(\hat{K}, s) \); a function governing the evolution of the aggregate capital stock \( \hat{K}' = \Psi(\hat{K}, s) \) that maps the current state into the capital stock next period \( (\hat{K}') \), and a function \( \Phi(s', s) \) governing the transition of the stochastic shocks from \( s \) to \( s' \) such that \((a)\) households maximize the expected value of (1) subject to (2) and (3) with the initial capital stock \( \hat{K} \) and functions for prices, aggregate capital, and the transition of \( s \) taken as given; \((b)\) productive factors are paid their marginal products; \((c)\) expectations are rational so that \( \hat{K} = \hat{K} \) and

\[
\Psi(\hat{K}, s) = [(1 - \delta)\hat{K} + x(\hat{K}, s)] / [(1 + \eta)(1 + \gamma)];
\]
and (d) markets clear:

\[ \zeta(\ddot{K}, \dot{K}, s) + x(\ddot{K}, \dot{K}, s) + g(s) = z(s)F(\ddot{K}, h). \]

Note that, in forming expectations about the future, households take processes for prices, tax rates and transfers as given. If households behave competitively, they assume that their own choice of capital next period does not affect the economy-wide level of capital. Therefore, in computing optimal decision functions for the household, it is necessary to distinguish the household's holdings of capital and the aggregate holdings of capital.

**Comparing model predictions with data**

Given equilibrium functions, properties of the model time series can be compared with data in a straightforward way. Starting with initial conditions on the state, the evolution of the state is determined by functions \( \Psi \) and \( \Phi \), resulting in sequences \( \{\ddot{K}, \dot{K}, s\}_{t=0}^{\infty} \) for the state. Equilibrium price and decision functions are then used with these sequences for the state to determine sequences of all prices and allocations.

A standard assumption for the transition \( \Phi (s', s) \) is the vector autoregression

\[ s_{t+1} = P_0 + Ps_t + Q\epsilon_{t+1}, \]

where each element of \( \epsilon_t \) is a normally distributed random variable, independent of the other elements of \( \epsilon \) and across time, with mean equal to zero and variance equal to 1. Allowing non-zero off-diagonals in the matrices \( P \) and \( Q \) allows for correlations in the elements of the vector \( s \). For example, a standard assumption is that tax rates and spending are positively correlated.

If the elements of the matrix \( QQ' \) are not large, the equilibrium evolution of the capital stock is well approximated by the following function:

\[ \log \ddot{K}_{t+1} = A_0 + A_k \log \ddot{K}_t + B_k s_t, \]

which is linear in the log of the de-trended, per capita capital stock and the stochastic states. Similarly, the logarithms of consumption, investment, output and hours of work can be well approximated as linear.
functions of $\log k_t$ and $s_t$. (See Marimon and Scott, 1999, for an introduction to log-linear methods and nonlinear methods.) Stacking the results in matrix form yields a system of equations

$$X_{t+1} = AX_t + B\epsilon_{t+1}$$

$$Y_t = CX_t + \omega_t$$

where $X$ contains all variables of interest, some of which may not be observable, and $Y$ is a vector of observables. This system can be easily simulated and lends itself nicely to standard methods of estimating model parameters. (See Anderson et al., 1996.)

An important feature of the analysis in Kydland and Prescott (1982) was the construction of the same statistics for the model and for the US data. Employing this methodology requires two necessary steps. The first concerns measurement: data series must be consistent with model series. For example, consumer durable expenditures are investments much like expenditures on new housing. National accountants treat expenditures on durables and housing differently, but the prototype model does not. Thus, revising the national accounts to include services, rents and depreciation of durables is necessary for data and model series to be consistent. The second step of Kydland and Prescott’s (1982) methodology concerns reporting: the same statistics should be computed for the model and the revised data. Such comparisons are useful in highlighting similarities and deviations, which are both necessary ingredients to further the development of good theory.

Applying the two methodological tenets to the prototype model and US data yields a number of interesting results. Both the theory and the US data display pro-cyclical movements in consumption and investment, with the movements in investment being far greater in percentage terms. With tax rates and government spending fixed at mean US levels, the theory predicts fluctuations in per capita hours that are too smooth relative to US hours, and a correlation between hours worked and productivity that is too high relative to the correlation in US data. When fiscal shocks consistent with US policy are introduced, the theory predicts movements in per capita hours and a correlation between hours worked and productivity that are in line with the data.

**Extensions of the prototype**

During the 1980s and 1990s, business cycle research was exploratory but methodologically rooted. Researchers investigated the effects of many different shocks, the mechanisms that propagate them, and the welfare implications – in a consistent way that made clear what factors were important and why. A
brief history is provided here, but interested readers are referred to the volume edited by Cooley (1995) and to a summary of more recent work in King and Rebelo (1999) and Rebelo (2005). Kydland and Prescott (1982) and Long and Plosser (1983) emphasize technology shocks as an important source of fluctuations. Greenwood, Hercowitz and Huffman (1988) also explore the role of technology shocks for the business cycle but restrict attention to technological changes affecting the productivity of new capital goods and allow for accelerated depreciation of old capital. Mendoza (1995) includes shocks to the terms of trade in an international business cycle model and shows that responses of real exchange rates to productivity shocks and terms-of-trade shocks are quite different, both qualitatively and quantitatively. Braun (1994), Christiano and Eichenbaum (1992), and McGrattan (1994) add fiscal shocks which are important for movement in hours and labour productivity, as noted above. Kim and Loungani (1992) add shocks to energy prices and show that the addition has only a modest impact on the variability of output and hours. Cooley and Hansen (1989) include monetary shocks and a cash-in-advance constraint and show that these additions have negligible effects on business cycle predictions. The original technology-driven business cycle models under-predicted fluctuations in observed hours and over-predicted the correlation between hours and productivity, leading to further investigations of the model of the labour market and alternative mechanisms for propagating shocks. High – possibly infinite – elasticities were required in the original RBC models to generate fluctuations in aggregate hours comparable to the data. Rogerson (1988) motivates an infinite aggregate elasticity of labour supply in a world with variation in the fraction of people working: individuals work a standard workweek or not at all. This idea is implemented in an RBC model by Hansen (1985), who finds a significant increase in hours fluctuations relative to Kydland and Prescott (1982).

Another factor affecting the labour market is explored by Benhabib, Rogerson and Wright (1991) and Greenwood and Hercowitz (1991) who introduce home production. These researchers show that business cycle predictions depend crucially on the willingness and opportunity of households to substitute time in home work and market work. Under plausible parameterizations, the models do in fact generate greater variability of hours and lower correlations between hours and productivity. The empirical performance of the RBC model is also improved when labour-market search frictions are introduced, as in Andolfatto (1996) and Merz (1995). Labour-market search models have also been used to study movements in unemployment and vacancies.

Current research and open questions

RBC research has evolved beyond the study of business cycles. The methodology that Kydland and Prescott (1982) introduced is now being applied to central questions in labour, finance, public finance, history, industrial organization, international macroeconomics and trade. Within business cycle research, some open questions remain. What is the source of large cyclical movements in TFP? This question is especially interesting in the case of the US Great Depression, when TFP declined significantly (Cole and Ohanian, 2004). Are movements in TFP primarily due to new inventions and processes that are, by the nature of research and development, stochastically discovered? Or are movements in TFP primarily due to changing government regulations that may alter the efficiency of production? Are they due to unmeasured investments that fluctuate over time? The answers
matter for policymakers, and they matter for economists who calculate the welfare costs or gains of changing policies.

real cost doctrine

J. Maloney
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

alternative cost doctrine; Austrian economics; Edgeworth, F. Y.; Jevons, W. S.; labour supply; marginal utility theory; Marshall, A.; real cost doctrine; subjective theory of value

Article

Real cost doctrine is the doctrine that the supply price of a good is the price required to overcome the disutility involved in producing it. The worker, in other words, produces output up to the point at which his (decreasing) marginal utility of income equals his (increasing) marginal disutility of labour. The real cost doctrine can be seen as a half-way house inhabited by economists who had adopted a subjective theory of value but stopped short of the 'alternative cost' doctrine whereby the supply price of a resource is equal to its potential earning in its next most productive use. Much of the discussion which took place between English and Austrian economists concerned whether, and to what extent, the two doctrines logically came to the same thing. Jevons (1871) formulated the real cost doctrine in terms of the diagram in Figure 1. Jevons assumes here (no such assumption is strictly necessary) that the worker at the start of the day not only enjoys his work but that, for a while, his enjoyment increases as he warms up to it. But, as the hours pass, the fatigue and boredom come to predominate over pleasure at an ever-increasing rate. The worker will maximize his surplus of utility over disutility by stopping at point X (ab=bc.)

Figure 1
The idea that subjective disutility of labour is central in determining output and price is, perhaps, Jevons’s most unquestionably original idea. Not only is it absent from the work of Walras and Menger, but its prefigurations in the classical period are rare and rudimentary when compared with the pre-1871 analyses of marginal utility theory. (Jennings, 1855, points out that marginal disutility of labour increases as the working day progresses but fails to build anything upon it.)

Marshall’s theory of price determination, unveiled in his *Principles of Economics* (1890), differs little from Jevons’s. Yet what looked radical in Jevons appears almost backward-looking in Marshall. This has something to do with the extension and dissemination of neoclassical principles in the intervening 20 years. But it also stems from a difference of presentation grounded in the contrast between Jevons’s impatience with and Marshall’s deference towards the Ricardian tradition. Much of Marshall’s frequent praise for the English classical economists deftly sidesteps the question of how far they had actually been right. In the *Principles*, however, not only are cost and utility considerations given equal importance when determining price, but the fact that Marshall’s conception of cost is ultimately a Jevonian ‘subjective disutility’ one is played down. It receives the strongest emphasis when Marshall argues that the capitalist as well as the worker undergoes real costs in the productive process, the capitalist’s cost being that of ‘waiting’ rather than consuming his wealth immediately. (Nassau Senior had invoked Marx’s sarcasm by speaking of capitalist ‘abstinence’ in the same context: Marshall tried both to circumvent the ridicule by renaming abstinence ‘waiting’ and to defend Senior from a neoclassical perspective, pointing out that at the margin of aggregate saving, considerable immediate sacrifice was undoubtedly involved.)

The rival doctrine, that of alternative cost, was espoused principally by the Austrians Wieser and Böhm-Bawerk and advertised in Britain by Wicksteed. All three denied the existence of any such thing as a supply curve, ‘supply’ simply being reverse demand. Böhm-Bawerk cited a horse fair: the buyer’s utility from acquiring a horse and the seller’s utility from keeping his horse played not just an equal but an identical role in determining price. Hence only a demand curve need be drawn; at the equilibrium price, it crosses the vertical line
representing the fixed stock of horses. Both Marshallian and Austrian analysis predict the same price. But, of course, the fixed stock of horses makes this a very simple case: we are ignoring the cost of producing them. Such considerations, however, were no problem to the Austrians, who proclaimed that the costs of factors of production and raw materials ultimately depended on utilities from alternative uses forgone. Thus, as regards the labour market, the wage in a particular industry was governed by the demand for labour in other industries. Each worker had to be paid enough to keep him out of his next best paid available job. The Jevonian notion of disutility of labour dropped out of the picture, Böhm-Bawerk (1894) arguing against it on the empirical ground that few workers had the chance to make fine adjustments to the length of their working day. To this Edgeworth retorted that the Austrian doctrine implied that individuals made the choice to work or not to work once and for all at the beginning of their careers – it could not handle variations in labour supply due to variations in the wage rate. The debate as a whole seemed to imply that the choice between real cost and alternative cost depended on whether flexible labour supply at the individual level (assumed by Jevons) or inflexible labour supply at the aggregate level (implied by the Austrians) was the more objectionable violation of reality. Yet logically the two theories come to exactly the same thing, and are seen to do so as long as the two ‘sides’ make one clarification apiece.

Austrians must make it clear that ‘forgone utility’ includes not only forgone income but also forgone leisure (when you work at all) and forgone non-pecuniary benefits (when you choose a less pleasant but better-paid job in preference to a more pleasant but worse-paid one). Böhm-Bawerk (1894) did spell this out. Real cost theorists must make it clear that when a baker ponders whether to work another hour, what matters is not the disutility of the work as compared with doing nothing, but the disutility of work as compared with what he would choose to do (it might still be nothing!) if he were not baking. Equally it is not the ‘gross’ marginal utility of income which matters but the marginal utility of the additional income gained from spending another hour at the bakery rather than doing something else (other paid work, some leisure activity, or nothing). Edgeworth (1894) failed to spell this out; had he done so, a number of economists might have realized sooner than they actually did that both theories ultimately come to the same thing. (See Hobson, 1926, for an example of confusion persisting well into the 20th century.)

real exchange rates

Menzie D. Chinn
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The real exchange rate plays a central role in the open economy. This article describes the various ways in which the real exchange rate has been defined in the literature. It also examines the theoretical and empirical determinants of this variable.

Keywords

exchange rate dynamics; nominal exchange rates; productivity; purchasing power parity; real exchange rates; sticky prices; terms of trade; tradable and non-tradable goods; unit roots

Article

The real exchange rate plays a crucial role in models of the open economy. How the real exchange rate should be defined, how it behaves over time, and what determines it at various time horizons are all questions that have been posed over the years. They have taken on heightened importance in recent years, as the scope of international transactions has expanded and more and more economic activity is either directly or indirectly affected by economic activity in other countries.

The most common definition of the real rate is the nominal exchange rate adjusted by price levels,

\[ q_t = s_t - p_t + p^*_t \]  

where \( s \) is the log exchange rate defined in units of home currency per unit of foreign, and \( p \) and \( p^* \) are log price levels. If purchasing power parity (PPP) holds, then \( q \) is always unity (or a constant if price
indices are used). One should expect PPP to hold in a world where transportation and transactions costs were negligible, consumption baskets were identical, and no arbitrage profits existed. Absent these conditions, the real exchange rate will vary.

One way of thinking about the determinants of movements in the real exchange rate is to appeal to a decomposition. Suppose the price index is a geometric average of traded and non-traded good prices:

\[ p_t = \alpha p_t^N + (1 - \alpha) p_t^T \]  
\( (2) \)

where the lower-case letters denote logged values. Then substituting (2) into (1) yields:

\[ q_t \equiv (s_t - p_t^T + p_t^T*) + [ - \alpha (p_t^N - p_t^T) + \alpha^* (p_t^N^* - p_t^T^*) ] \]
\( (3) \)

Equation (3) indicates that the real exchange rate can be expressed as the sum of two components: (i) the relative price of tradables \( q^T \), (ii) the intercountry relative price of non-tradables in terms of tradables in the home country \( \omega^t \).

The determinants of the real exchange rate

If PPP holds only for tradable goods, then only the second term in eq. \( (3') \) can be non-zero, and the relative tradables–non-tradables price is the determining factor in the value of the real exchange rate. Another possibility is that all goods are tradable but not perfectly substitutable; then the imperfect substitutes model results, and \( q^T \) is equivalent to \( q \). More generally, both terms on the right hand side of eq. \( (3') \) can take on non-zero values. In either of these cases, there are a large number of variables that could influence each relative price. And of course, there is nothing to rule out both relative price channels as being operative. In popular discussion, all three definitions of ‘the real exchange rate’ are used, sometimes leading to considerable confusion.
Most models of the real exchange rate can be categorized according to which specific relative price serves as the object of focus. If the relative price of non-tradables is key, then the resulting models – in a small country context – have been termed ‘dependent economy’ (Salter, 1959; Swan, 1960) or ‘Scandinavian’ model. In the former case, demand-side factors drive shifts in the relative price of non-tradables. In the latter, productivity levels and the nominal exchange rate determine the nominal wage rate and hence the price level, and hence the relative price of non-tradables. In this latter context, the real exchange rate is a function of productivity (Krueger, 1983, p. 157). Consequently, the two sets of models both focus on the relative non-tradables price but differ in their focus on the source of shifts in this relative price. Since the home economy is small relative to the world economy (hence, one is working with a one-country model), the tradable price is pinned down by the rest-of-the-world supply of traded goods. Hence, the ‘real exchange rate’ in this case is \( p^N - p^T \).

The relative price of tradables definition is most appropriate when considering the relative price that achieves external balance in trade in goods and services. This variable is also what macroeconomic policymakers refer to as ‘price competitiveness’; hence, anything that affects the markup of price over cost – including both the level of demand, input costs, and market structure – can determine the real exchange rate.

Notice the dichotomy between the relative price of tradables and the relative price of non-tradables breaks down when countries specialize in the production of goods. Then the real exchange rate is the same as the terms of trade; purchasing power parity would occur only if the two goods were perfect substitutes (see Lucas, 1982; Stockman, 1980).

### Empirical modelling and results

#### Real exchange rate dynamics

In one special case, there is no need to model the real exchange rate. If relative PPP is assumed to hold, then \( q \) is a constant. Empirically, this is clearly not true in the short run but could be in the long run. Consequently, tremendous effort has been invested in investigating whether \( q \) is trend stationary, even though trend stationarity is not the same as purchasing power parity holding (the stronger condition of mean stationarity is required). Numerous studies have evaluated the trend stationarity of \( q \) directly by application of unit root tests, or indirectly by assessing whether the component series of \( q \) exhibit common long-term trends. Broadly speaking, the conclusions in this literature are mixed. Generally, panel methods, long time samples, and the use of producer or wholesale price indices provide more evidence in favour of a trend stationarity \( q \) than do pure time series methods, short samples, and the use of consumer price indices (see Rogoff, 1996; Taylor and Taylor, 2004). These results leave open the possibility that economic variables affect the movement of exchange rates over the short as well as the long run.

#### Modelling real exchange rate movements as a function of economic variables

The modelling of the real exchange rate determinants can be divided into two main categories. The first category includes models of the nominal exchange rate which, by virtue of the assumption of sticky
prices, become models of the real exchange rate. First and foremost among these are sticky price monetary models that incorporate exchange rate overshooting, such as Dornbusch (1976) and Frankel (1979). In the long run, purchasing power parity holds, so that these models are only short-run models. The second category includes models that focus on the determinants of the long-run real exchange rate. By far dominant in this category are those that centre on the relative price of non-tradables. These include the specifications based on the approaches of Balassa (1964) and Samuelson (1964) that model the relative price of non-tradables as a function of sectoral productivity differentials, including Hsieh (1982), Canzoneri, Cumby and Diba (1999) and Chinn (1999; 2000). They also include those models that search more broadly and include demand-side determinants of the relative price, such as DeGregorio and Wolf (1994). Engel (1999) has cast doubt upon the relevance of the relative non-tradables price. He demonstrates that for the G-7 economies, the variability of $q^T$ as proxied by the tradable components of the CPI is comparable to the variability of $\omega$ even at horizons of 15 years. More recently, some version of the portfolio balance model has been resurrected. Lane and Milesi-Ferretti (2002) have forwarded a model wherein the real rate depends upon net foreign assets. Early panel evidence in favour of the importance of this factor is to be found in Gagnon (1996). Some methodological approaches do not fall neatly into one or the other category. The analysis by Mark and Choi (1997) is one instance. They compare the usefulness of monetary and real factors in predicting exchange rate changes over long horizons, and find – surprisingly – that monetary factors have persistent effects on the real exchange rate. Using a different methodology, namely, a structural vector autoregression, Clarida and Gali (1995) find that monetary and demand-side factors dominate in the determination of exchange rates. Also relying upon a structural (permanent-transitory) decomposition involving the real exchange rate and the current account, Lee and Chinn (2006) find that positive permanent shocks (interpreted as productivity innovations) tend to appreciate the currency and (at least for the United States) have an impact comparable in magnitude to those of temporary shocks.

real rigidities

David Romer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Real rigidities are forces that reduce the responsiveness of firms' profit-maximizing prices to variations in aggregate output resulting from variations in aggregate demand. Real rigidities make firms less inclined to take actions that dampen movements in aggregate output, and so increase the responsiveness of output to disturbances. They appear essential to any successful explanation of short-run macroeconomic fluctuations. As a result, various forms of real rigidity pervade modern models of business cycles.

Keywords

adjustment costs; aggregate demand; business cycles; capital-market imperfections; cyclical markups; efficiency wages; elasticity of substitution; imperfect competition; input–output analysis; labour mobility; labour supply; menu costs; nominal rigidities; real business cycles; real rigidities; staggered price setting; sticky prices; strategic complementarity

Article

‘Real rigidities’ is the name given to a large class of business cycle propagation mechanisms. Real rigidities appear essential to any successful explanation of business cycles.

The definition of real rigidities

Although the term ‘real rigidities’ appears vague, it in fact refers to a precise concept. Consider an economy of symmetric price-setting firms that is at its flexible-price equilibrium, and suppose that the money supply increases with prices unchanged, so that aggregate output increases. Now ask by how much a representative firm would want to increase its price if it faced no barriers to nominal price adjustment. By definition, the smaller the amount the firm would want to increase its price in response to
a given increase in aggregate output, the greater the degree of real rigidity.

One can see the meaning of ‘real rigidity’ more formally by observing that, in the experiment described above, the profits of the firm that is considering changing its price, neglecting any costs of price adjustment, typically can be written in the form $V(p_i - p, y)$, where $p_i$ is the firm's price, $p$ is the aggregate price level, and $y$ is the departure of output from its flexible-price level (all in logs). In most models of this type, $V(\cdot)$ is a smooth function. The first-order condition for the profit-maximizing price is $V(p_i^* - p, y) = 0$ (subscripts denote partial derivatives). At the flexible-price equilibrium, $p_i^* = p$ and $y = 0$. Starting from that equilibrium, the derivative of the representative firm's desired relative price, $p_i^* - p$, with respect to $y$ is thus

$$\frac{d(p_i^* - p)}{dy} \bigg|_{p_i^* - p = 0, y = 0} = \frac{V_{12}(0, 0)}{-V_{11}(0, 0)} \equiv \varphi.$$

For the flexible-price equilibrium to be stable, $\varphi$ must be positive. By definition, a lower value of $\varphi$ corresponds to greater real rigidity. Note that real rigidity is defined entirely in terms of relations among real variables: it refers to the (lack of) responsiveness of desired real prices to aggregate real output. The definition of real rigidity in models without symmetric price-setting firms is analogous: any force that reduces the amount that price setters would change their relative prices in response to movements in aggregate output that are the result of changes in aggregate demand is a real rigidity.

**Real rigidities and business cycles**

Real rigidities are crucial to business cycles. At a general level, real rigidities make firms less inclined to take actions that dampen movements in aggregate output. As a result, they increase the responsiveness of output to disturbances.

The importance of real rigidities is easiest to see in a static model where firms face fixed costs of changing prices. Consider the model sketched above, with two extensions. First, replace the profit function with a second-order approximation around the flexible-price equilibrium. This implies that the representative firm's loss in profits from failing to charge its profit-maximizing price (neglecting costs of price adjustment) is $\kappa(p_i - p_i^*)^2$, where $\kappa \equiv -V_{11}$. It also implies that the representative firm's profit-maximizing price is given by $p_i^* - p = \varphi y$, where $\varphi$ is as defined before. Second, assume that each firm faces a fixed cost $Z > 0$ of changing its nominal price.

The economy begins at its flexible-price equilibrium. We want to know by how much output can change in response to a change in aggregate demand before firms change their prices. Non-adjustment is an equilibrium as long as the representative firm's losses from failing to adjust are less than $Z$. Prior to the shock, the representative firm's price equals the aggregate price level, $p$. If the firm adjusts its price, it sets it to the new profit-maximizing level, $p + \varphi y$. Thus the condition for nonadjustment to be an
equilibrium is $K[p - (p + \varphi y)]^2 < Z$, or $|\gamma| < 1 / (\varphi \sqrt{Z / K})$. Thus, when $\varphi$ is lower – that is, when real rigidity is greater – the range over which aggregate demand shocks affect real activity is greater. Real rigidities are not just important to models with nominal rigidity, however. Consider, for example, the following minimalist real business cycle model. The markets for labour and goods are perfectly competitive, and the representative firm's production function is $y_i = a + n_i$ ($y$ is output, $a$ is productivity, and $n$ is labour input, again all in logs).Labour supply is $n = \gamma w$, $\gamma > 0$, where $w$ is the (log) real wage. In this model, the elasticity of profit-maximizing relative prices to demand-driven output fluctuations (that is, to variations in $y$ with $a$ fixed, which must come from variations in $n$) equals the elasticity of the real wage with respect to $y$, which is $1/\gamma$. Thus a larger value of $\gamma$ corresponds to greater real rigidity. The production function implies that labour demand is perfectly elastic at $w = a$. Labour-market equilibrium therefore requires that $n = \gamma a$. A larger value of $\gamma$ therefore implies that productivity shocks have a larger impact on employment, and thus that the output effects of the shocks are magnified to a greater extent. Thus, even in this purely Walrasian model of fluctuations, real rigidity acts as a propagation mechanism.

Real rigidities also act as amplification mechanisms in dynamic models of price adjustment. Consider an economy with barriers to price adjustment where output is above its flexible-price level, and suppose that some firms have an opportunity to change their prices, and that their new prices will be in effect for more than one period. Greater real rigidity increases the persistence of the departure of output from its flexible-price level, for three reasons. First, as in the static model of price adjustment, it reduces the benefits of price adjustment, and so makes firms more inclined not to adjust at all. Second, the fact that only some firms have the opportunity to adjust means that output will continue to be above its flexible-price level. Greater real rigidity then implies that the firms that adjust will respond by less, thus drawing out the period of above-normal output. Third, the fact that other firms will be in the same situation when they adjust their prices means that they will adjust by less, which in turn dampens the adjustments of the firms that adjust immediately.

There is a close link between real rigidity and strategic complementarity in profit-maximizing prices. If we assume the stylized aggregate demand curve $Y = m - P$ (where $m$ reflects factors that shift aggregate demand), then the expression for the representative firm's profit-maximizing relative price, $P_i^* - P = \varphi Y$, implies $P_i^* = \varphi m + (1 - \varphi) P$. Thus greater real rigidity corresponds to greater strategic complementarity in desired prices: when $\varphi$ is lower, each firm wants its price to move more closely with other prices.

Real rigidity and strategic complementarity in desired prices are not identical, however. To see this, suppose the aggregate demand equation is instead $Y = \beta(m - P)$, $\beta > 0$. Then $P_i^* = \varphi \beta m + (1 - \varphi \beta) P$. Thus $\beta$ affects strategic complementarity but not real rigidity. And it is real rigidity that is key to cyclical fluctuations. Nonetheless, because of the close link between the two concepts, and because many business cycle models assume $Y = m - P$, the terms real rigidity and strategic complementarity in prices are often used interchangeably.

Types of real rigidities

Since any force that reduces the responsiveness of profit-maximizing relative prices to demand-driven fluctuations...
output fluctuations is a real rigidity, there are many possible real rigidities. Some might not be commonly thought of as ‘rigidities’. For example, as the simple real business cycle model shows, more elastic labour supply is a type of real rigidity. Such neoclassical sources of real rigidity, however, are almost surely not strong enough to generate output fluctuations of the size and nature that we observe. In Walrasian models, the real wage is likely to rise sharply with the quantity of labour. For this not to occur, either the long-run elasticity of labour supply must be high or the intertemporal elasticity of substitution in labour supply must be high and short-run aggregate fluctuations must have a large transitory component. Neither of these conditions appears to hold in practice. In models of nominal disturbances and barriers to nominal price adjustment, the result is large incentives for price changes, and thus little nominal rigidity. In productivity-driven real business cycle models, the result is small movements in labour input, so that the dynamics of aggregate output largely mimic the dynamics of the underlying productivity shocks. Researchers have therefore turned their attention to non-Walrasian sources of real rigidity.

It appears difficult to understand substantial employment fluctuations without non-Walrasian real rigidities in the labour market. At a general level, what is needed is for some force causing workers to be off their labour supply curves, at least in the short run, so that the cyclical behaviour of the real wage is not governed by the elasticity of labour supply. For example, if there is equilibrium unemployment because of efficiency wages, the cyclical behaviour of the real wage depends on how the efficiency wage varies with aggregate output. As a result, the real wage can be (though it need not be) less procyclical than in a Walrasian labour market, with the result that fluctuations in employment and output are greater.

A more subtle real rigidity in the labour market arises if labour is imperfectly mobile in the short run (because of search frictions, for example), so that each firm faces an upward-sloping labour supply curve rather than perfectly elastic supply at the economy-wide wage. Consider, for example, a firm contemplating cutting its price and increasing production in a recession. With imperfectly mobile labour, this requires paying a higher real wage. Thus the amount the firm wants to reduce its price is smaller – that is, real rigidity is greater.

There can also be important real rigidities in other markets. In the goods market, forces making desired markups countercyclical act as real rigidities. When desired markups are more countercyclical, then, for a given degree of procyclicality of real marginal costs, desired movements in relative prices are smaller. Countercyclical desired markups can stem from a variety of sources. One simple but potentially important possibility is that, when economic activity is greater, firms’ incentives to disseminate information and consumers’ incentives to acquire it are greater, and so demand is more elastic. Another feature of goods markets that can act as a real rigidity is input-output links among firms. If the prices charged by intermediate suppliers are sticky, the costs that firms face for intermediate inputs tend to rise by less than the suppliers' costs in a boom, thereby reducing the amount that firms would raise their prices if they were free to do so.

Capital-market imperfections can also create real rigidities. Capital-market imperfections can cause financing costs to be countercyclical, as higher output increases cash flow (and hence firms' ability to use internal finance) and raises asset values (and hence increases collateral and reduces the cost of external finance). With one component of costs countercyclical, desired prices are less procyclical. To give another example, financial difficulties in recessions can increase the importance of short-term profits to firms relative to expanding their customer base, and so can make desired markups

There is an important distinction between two broad categories of real rigidities. One category consists of forces, such as limited short-run labour mobility among firms, that increase real rigidity by affecting what happens when one firm changes its prices and others do not. The other consists of forces, such as factors that reduce the procyclicality of the real wage, that increase real rigidity by affecting what happens when all firms' output moves together. In terms of the definition of real rigidity as $V_{12}(0,0)/-[V_{11}(0,0)]$, the first category consists of forces raising $-V_{11}(0,0)$, and the second consists of forces reducing $V_{12}(0,0)$.

The distinction between these two categories is important for two reasons. First, real rigidities that result from forces that affect what happens when one firm changes its price with other firms' prices fixed are not relevant to the properties of business cycle models with identical firms and fully flexible prices. Second, the two types of real rigidities have different microeconomic implications. Most importantly, factors that increase real rigidity by affecting what happens when one firm changes its price and others do not increase the costs of departures from the profit-maximizing price; as a result, they typically predict smaller movements in firms' relative prices in response to many types of shocks.

Selected literature

Ball and Romer (1990) establish that in a static setting, imperfect competition and barriers to nominal adjustment alone are unlikely to generate substantial nominal rigidity. They show the general importance of real rigidities to static menu-cost models and stress that forces making desired real wages relatively unresponsive to output fluctuations are likely to be essential to generating substantial nominal rigidity (see also Blanchard and Fischer, 1989, ch. 8). Earlier work by Akerlof and Yellen (1985) incorporates substantial real rigidity in a model of price stickiness, although it does not explicitly analyse the importance of real rigidity to the results. Haltiwanger and Waldman (1989) show that strategic complementarity magnifies the impact of non-responders on equilibrium outcomes, a result that is closely related to the finding that real rigidities magnify the effects of barriers to price adjustment. Kimball (1995) establishes the central role of real rigidities to the persistence of output fluctuations in models of staggered price adjustment, and stresses the importance of the distinction between forces that affect what happens when all firms' outputs move together and forces that affect what happens when one firm changes its price with other firms' prices fixed (see also Blanchard, 1987). Klenow and Willis (2006) show the differing microeconomic implications of the two categories of real rigidities. Romer (2006, ch. 6) provides a general discussion of the importance of real rigidities to static and dynamic models of nominal rigidity, catalogues many specific real rigidities and provides numerous references. Real rigidities pervade modern business cycle models. In real business cycle models, for example, such common features as indivisible labour supply, variable capital utilization and labour hoarding, and learning-by-doing (see, for example, Rogerson, 1988; Burnside and Eichenbaum, 1996; and Chang, Gomes and Schorfheide, 2002) magnify the effects of disturbances precisely because they are real rigidities. In models with price stickiness, some important recent analyses where real rigidities play a central role include Mankiw and Reis (2002), Gertler and Leahy (2006) and Carvalho (2006).

real wage rates (historical trends)

Robert C. Allen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Historical studies of the real wage allow us to track the divergence in the world of economics since the Middle Ages and changes in the distribution of income during the Industrial Revolution. Before the 19th century, the real wage moved inversely to the population. Since then it has increased dramatically.

Keywords

Article

The real wage indicates the purchasing power of a worker's income. The real wage is the ratio of the nominal wage (what someone is actually paid) to a price or price index. Sometimes that price is the price of the product of a competitive firm, in which case the real wage is the marginal product of labour and has a productivity interpretation. In the more common case, however, and the one this article deals with, the price deflator is a consumer price index. In this case, the real wage measures the standard of living of the worker. Since that bears on central questions of economic growth and distribution, real wages have been an important tool for measuring and interpreting economic growth and stagnation over the last millennium.

Measuring real wages raises practical problems that are particularly acute in historical investigations. First, one needs information about wages, prices and spending shares to perform any calculations. Data sources for these have to be developed, which ultimately involves extensive archival work. There are conceptual problems as well since many people in the past received some income in kind as well as cash and many were also employed on piece rates that must be converted to earnings before an assessment of their purchasing power can be made. Second, an index number must be chosen to compute the consumer price index. While theorists have advanced many useful arguments about why some formulae are better than others, data limitations often force compromises. One of the most extreme was the once common practice of deflating wages by the price of grain. Other products were ignored, as well as the inconvenient fact that most people in the West ate bread, not grain. Most recent studies have avoided this practice. Third, new products and improvements in the quality of old products bedevil historical studies as they do modern ones. Although product innovation was less common in the past, the creation of the global economy led to the introduction into Europe or mass availability of maize, potatoes, tomatoes, chilli peppers, sugar, tobacco, cotton cloth, tea, coffee and porcelain. Also, comparisons of real wages between continents with radically different diets raise the question of new products in a cross-sectional context. How do you compare the standard of living of an English worker eating bread, beef and beer with a Chinese worker eating fish and rice?

Real wages and economic growth in developed countries

Economic theorists have divided the history of the world into two phases. Before the onset of modern economic growth around 1800, income per head grew very slowly, if at all.
Increases in productivity simply resulted in more people. The real wage moved inversely with the population and remained constant in the long run. This was the Malthusian phase of history.

The second phase began in about 1800. Technology improved steadily raising income per head. Population growth was restrained, so an increase in the labour force did not swamp the increase in labour demand. Consequently, the real wage rose in step with productivity. This has been called the Solow phase in view of Solow's (1956) growth model. While these models can be nuanced, as we will see, they provide a starting point for real wage history: is it consistent with these models?

We can measure the real wage over the past 800 years thanks to the accumulated research of historians who have written ‘price histories’ of cities since the mid-19th century. The price historian finds an institution like a college or hospital that has existed for centuries and examines its accounts to abstract the prices of the things it bought and the wages it paid. Oxford and Cambridge colleges were the first to be studied (Rogers, 1866–92) and since then many European cities have been investigated. Phelps-Brown and Hopkins (1955; 1956) were the first to take advantage of this material and construct a real wage index for English building workers from 1264 to 1954. More recently, Allen (2001) and Clark (2005) have reworked this material and added new evidence to compute new real wage series. While there are differences among these authors on issues like real wage change in the Industrial Revolution, the broad outlines of the real wage story are the same (Figure 1).

Figure 1
The Malthusian and Solow phases stand out in this figure. Before the 19th century, England followed the Malthusian pattern. There was no long-run trend in the real wage, although there were fluctuations. These coincided with population swings; in particular, the real wage rose after the Black Death in 1348–9, which killed about one-third of the population, and fell in the 16th century as the population started to rebound. Real wages only rose above the pre-industrial peak once the Industrial Revolution was well under way or completed. The rise since then has been spectacular by comparison, and today the real wage is ten times its level in the pre-industrial world. This is the Solow phase of economic history.

The period of the Industrial Revolution, roughly 1770–1860, is something of a problem. Were real wages rising then or falling? The classical economists, who were writing in the early 19th century, were pessimistic about the prospects of workers. While they agreed that capitalism was likely to cause output per capita to rise, they also believed that real wages would remain constant at ‘subsistence’. For Malthus, Ricardo and other mainstream economists, the reason was demographic: wages were the income of the bulk of the population, and a higher wage would lead them to have more children and live longer. The result would be an increase in the workforce that would push wages back to subsistence. While radicals like Marx and Engels rejected the demographic model, they agreed that wages would not rise under capitalism. Their explanation, however, turned on the demand for labour rather than its supply. Marx and Engels believed that technological progress would be so rapid and so labour-saving that the demand for labour would always fall short of the supply – again forcing wages back to subsistence. Only collective action or state interference would prevent this. None of the classical economists, in other words, expected the ‘Malthusian economy’ to transmute into the ‘Solow economy’.

By the 20th century, it was clear that these arguments were wrong, for living standards were far higher than they had been 100 years before, as Figure 1 shows. Kuznets (1955) raised the possibility that inequality went through an ‘invented U’ patterned during economic development. In his model, this worked through the wage structure itself. At the outset, workers were in low-productivity, low-wage sectors. As the modern sector grew, it attracted workers by offering higher wages. Inequality increased as workers moved to that sector since those employed there were earning more than their counterparts in agriculture. Inequality in wages declined as the process of labour reallocation was completed, for all workers were then earning the higher wage paid in the modern sector.

The problem of economic development in poor countries provoked Lewis (1954) to propose a model of growth and distribution that was more classical in spirit and that emphasized the differential movements of output per head and the real wage. Lewis divided the economy into two sectors. In the traditional sector, consisting of peasant agriculture and the urban ‘informal’ economy, the main inputs were land and labour, and the latter was in surplus. In the modern, industrial sector, output was produced with capital and labour, and the former was scarce. Growth occurred as capital was accumulated and the modern sector expanded. Its labour force was drawn from the traditional sector. Surplus labour in that sector meant that the marginal product of labour was low, perhaps even zero, and income was shared and at a subsistence level. An elastic supply of labour kept the real wage in the modern sector at subsistence even though output per worker was rising. This process of rising inequality would continue, in Lewis’s view, until the modern sector had expanded to absorb all the surplus labour. Only then would the real wage rise in step with output per worker.

How well do these theories fare in practice? The question has been extensively researched and vigorously debated in the case of the British Industrial Revolution. Lindert and Williamson (1983) were the first to apply modern economic methods to the question. They computed economy-wide average earnings and a consumer price index founded on budget surveys and corresponding prices. Their conclusion was guardedly ‘optimistic’ in that they found the average real wage rose sharply after 1815. This conclusion was not universally accepted. Feinstein (1998) computed an alternative price index that significantly reduced the rate of real wage growth leading to his title ‘pessimism perpetuated’. Clark (2005), on the other hand, proposed yet another price index that tilted the conclusions back in a Lindert–Williamson direction. Most recently, Allen (2007a) has plumped for ‘pessimism preserved’.

These disagreements reflect the limitations of the data, which are only a poor reflection of the ideal information discussed above. There were no comprehensive and representative samples of consumer spending, and even the annual series of individual prices are problematic. Quality change, in particular the growing use of cotton rather than wool in clothing, is only imperfectly grasped with the available information. There is considerable scope for contradictory – yet plausible – readings of the evidence.

The impact of economic development on wage rates has been pursued for many other countries with mixed results. Over the long term, real wage change in Western Europe has followed a pattern like that for England shown in Figure 1 (Scholliers and Zamagni, 1995). The United States has been repeatedly studied, and revisions to price and wage indices have been as thoroughgoing for the USA, as they have been for Britain. For instance, Douglas’s (1930) conclusion that real wages only rose by eight per cent during the boom from 1890 to 1914 was overturned by Rees (1961), who found that real wages increased by 40 per cent. Over the long term, of course, real wages have risen dramatically in America, but the real wage lagged behind GDP per head during early industrialization, according to Margo’s (2000) study of the period 1800–60.

Outside the advanced Organisation for Economic Co-operation and Development (OECD) countries, the link between economic growth and real wage advance is much weaker. The economic boom experience by Tsarist Russia, for instance, was not reflected in urban or rural real wages (Allen, 2003a). Latin America enjoyed a substantial rise in GDP per head in the 20th century, with only an elusive impact on real wages. In Mexico, which has been studied more than most countries, there were periods when real wages surged and others when real wages collapsed. The declines look about as big as the gains, but the uncertainty arising from the introduction of new goods makes definitive conclusions hazardous (Bortz and Aguila, 2006).

Real wages and the great divergence
The difference in real wages can be computed between two places as well as between two times, and the geographical dimension has allowed real wages to play an important role in the ‘great divergence’ debate. Since 1800, incomes have grown most rapidly in the most prosperous countries, so their lead over the poor countries has increased. Charting this divergence is the first step in explaining it. Real GDP per head may be the best indicator, and economists have tried to extrapolate it far into the past. Errors, however, accumulate, and the estimates become increasingly problematic the further back one goes. Real wages provide an alternative, and simpler, approach to the problem. The real wage is individual in its focus – what could a particular worker buy with his or her income? – and so avoids the economy-wide assumptions of national income accounting. The real wage also requires fewer data, and it can be computed directly for dates in the past without the need to extrapolate backwards.

Indeed, the classical economists, who established a long-standing view on the subject, expressed Europe's lead in terms of real wages. Adam Smith (1776, pp. 74–5, 91, 187, 206) saw the world in terms of a wage ladder: workers in England and the Netherlands had a higher standard of living than workers in France or elsewhere on the European continent. Workers in Asia lagged behind Europeans. ‘The real price of labour, the real quantity of the necessaries of life which is given to the labourer…is lower both in China and Indostand than it is through the greater part of Europe.’

This view has recently been challenged by scholars of Asia who have argued that Asia was as prosperous as Europe at the time Smith wrote. According to Pomeranz (2000, p. 49), ‘It seems likely that average incomes in Japan, China, and parts of South-East Asia were comparable to (or higher than) those in western Europe even in the late eighteenth century.’

How does Smith's wage ladder stand up in terms of modern evidence? The price histories of European cities provide a start, for they allow us to compute real wage differences across Europe from the late Middle Ages to the 19th century (van Zanden, 1999; Allen, 2001). While today real wages are similar across Western Europe, the calculations show that the last time this was even approximately true was in the late 15th century. Between 1500 and 1750, real wages in Amsterdam and London, the booming maritime cities of north-western Europe, were trendless, while they fell sharply in other parts of Europe under the impact of population growth not offset by economic expansion (Allen, 2003b). Incomes had diverged in Europe, in the manner described by Smith, before the Industrial Revolution. Indeed, it was decades, if not a century, before modern economic growth was perceptible in the real wage data. So far as Europe was concerned, the great divergence preceded the Industrial Revolution rather than being its sequel.

What about Europe and Asia? It is only very recently that comparisons have been made across the continents. Parthasarathi’s (1998) study of England and India supported the revision view, but a broader collection of data supports Smith's assessment (Allen, 2007b). Comparisons with Japan and China also show that real wages there were like those of the backward parts of Europe. Even the Yangtze Delta, the most advanced region in China, had real wages on a par with those in Milan, not London or Amsterdam (Allen et al., 2007). While the Ottoman Empire has not received as much attention as east Asia in the revisionist historiography, Özmcucur and Pamuk (2002) have shown that the real wage in Istanbul was also like that in Italy.

The worldwide conclusions require comparisons across regions with radically different diets. The comparisons are made by computing the cost of Smith’s ‘quantity of necessaries of life which is given to the labourer’. Figure 2 shows full-time, full-year earnings for a labourer deflated by the cost of maintaining a family on a mainly carbohydrate diet yielding 1,920 calories per adult male equivalent. In each region, the cheapest available carbohydrate is used for the calculation. A value of 1 indicates that the labourer's wage equalled this ‘bare bones’ subsistence, and, indeed, that was the case in the 18th century in much of Europe and Asia. Living standards were higher, however, in Amsterdam and London.

**Figure 2**

The history of the global economy has attracted attention and real wages have played an important role in exposing its properties. Research on the 19th and 20th centuries has aimed to establish trends in real wages across countries as well as over time (Allen, 1994; Williamson, 1995). O'Rourke and Williamson (1999) argued that international trade and migration tightly bound economies and determined their relative factor prices. Trends in real wages, in other words, were determined by the evolution of the global economy rather than by the internal forces of capital accumulation and technical change that most previous theories have emphasized. In a study of the British economy, O'Rourke and Williamson (2005) argued that international factors determined factor prices from 1850 onwards and perhaps from as early as 1750. The relative importance of internal and external factors in determining the
real wage is a lively area of current research.

realized volatility

Torben G. Andersen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Realized volatility is a fully nonparametric approach to \textit{ex post} measurement of the actual realized return variation over a specific trading period. It encompasses specific empirical procedures and an associated continuous-record asymptotic theory for arbitrage-free jump diffusions. It provides the ideal model-free benchmark for volatility model performance evaluation, and it has numerous natural areas of application within financial economics.

Keywords

affine models of the term structure; conditional return variance; derivative prices; econophysics; forecasting; historical volatility; integrated variance; jumps; martingales; microstructure noise; parametric time series models; realized volatility; return volatility; stochastic volatility models; yield curve

Article

Return volatility is critical for a range of issues in financial economics. In theory, an asset price reflects its return covariation with economy-wide risk factors, often captured through its covariance with returns of factor-replicating financial portfolios, including the broad (stock) market. Hence, assessments of asset pricing, fund performance and portfolio allocation are all directly linked to expectations of the future volatility and covariability of financial assets. Likewise, individual asset volatilities are key inputs to derivatives pricing and risk management. Finally, in recent years volatility \textit{realizations} have become the object of direct contracting as the payoff on so-called volatility swaps is determined by the future value attained by a specified measure of return volatility over the contract horizon.

As a consequence, return volatility has been studied extensively in the literature. Until recently, there were two dominant paradigms. One uses parametric time series models within the GARCH (Engle, 1982; Bollerslev, 1986) or (genuine) stochastic volatility (Shephard, 2005) class to obtain conditional
realized volatility: The New Palgrave Dictionary of Economics

return variance estimates and forecasts. A second exploits market prices of volatility sensitive contracts, such as options, to back out the (implied) expected future volatility. Although the latter approach also conditions on a specific pricing model, it embodies a wider information set as market prices reflect the views of market participants, not just historical returns. However, derivative prices carry premiums for bearing volatility risk and thus provide a less direct measure of expected (physical) volatility. Hence, these measures are complementary and each likely provides independent information. More importantly in this context, they both focus on an a priori concept of return volatility, largely synonymous with the conditional variance. This is appropriate for many purposes as financial decisions are made subject only to current expectations regarding the future market environment. However, such measures are identified only through specific parametric representations. Moreover, the ex ante expectations differ from the subsequent (random) volatility realizations. The latter may be assessed only from ex post model-free measurements of the actual return variation. Such measures are obviously useful for assessing (volatility) model performance. In addition, if accurate measures of realized volatility are available it is natural to exploit these directly for modelling and forecasting. With increasing availability of intra-day tick-by-tick trade and quote data, this perspective has gained in popularity and a voluminous literature is evolving on the approach. This article presents a brief overview of these developments and associated empirical applications.

Historical volatility

The concept of realized volatility refines and extends the historical volatility measure which has a fairly long precedent in the literature. To make the argument transparent, we initially consider an extremely simplified environment. Assume we are given the daily closing logarithmic asset price, denoted $p_t$. The associated daily continuously compounded return is then $r_t = \ln(p_t) - \ln(p_{t-1})$. Moreover, assume the returns are conditionally mean zero with i.i.d. standardized residuals, that is,

$$r_t = \sigma_t \cdot z_t, \text{ with } z_t \sim \mathcal{N}(0, 1) \text{ and } \text{Var}(z_t^2) = \omega. \quad (1)$$

The goal of realized volatility measurement is to provide a model-free estimator for the return variation or volatility, $\sigma_t^2$, given only the concurrent return observations. Obviously, if volatility is time-varying, this is problematic. We have, at the daily level, conditional on current volatility,

$$E[r_t^2] = \text{Var}(r_t) = \sigma_t^2, \quad \text{Var}(r_t^2) = \omega \cdot \sigma_t^4, \quad \text{and} \quad E[r_t^2] / [\text{Var}(r_t^2)]^{1/2} = \omega^{-1/2}. \quad (2)$$
Hence, the concurrent squared return is an unbiased estimator of the underlying return variance. Unfortunately, it is extraordinarily noisy. The signal-to-noise ratio, defined as the mean of the estimator relative to the standard deviation, equals $\omega^{-\frac{1}{2}}$. Invariably, $\omega > 1$ at daily (and lower) frequencies, so the standard deviation of (estimated) realized volatility exceeds the expected value. Matters improve if we assume constant volatility, at $\sigma_t^2$, over the month representing, say, $K$ daily returns. Letting $r_{t:K} = r_t + \ldots + r_{t+K}$ denote the monthly return, we may exploit the historical volatility indicator, $[r_t^2 + \ldots + (r_{t+K})^2]$ rather than simply $(r_{t:K})^2$. We then have,

$$\text{Var}(r_{t:K}) = E[r_t^2 + \ldots + (r_{t+K})^2] = K \cdot \sigma_t^2, \text{ and } \text{Var}[(r_t^2 + \ldots + (r_{t+K})^2] = K \cdot \omega \cdot \sigma_t^4. \quad (3)$$

The signal-to-noise ratio for the monthly realized volatility is $(K/\omega)^{1/2}$ or a factor $K^{1/2}$ larger than for eq. (2). Equation (3) may also readily be converted into an estimator for daily volatility based on the sample mean of the daily squared return over the month. This estimator is consistent with convergence rate $K^{1/2}$. However, given the simplifying assumptions, this measure is best viewed as an informal gauge of the underlying level of volatility. It was applied for computation of annual realized volatility from monthly data by Officer (1973) and monthly volatility series from daily data by, amongst others, Merton (1980), and French, Schwert and Stambaugh (1987).

The two equivalent interpretations of eq. (3) have distinct properties within a more realistic time-varying volatility setting. Since it is untenable to assume constant volatility for a month, or even one day, estimation of daily volatility from a surrounding set of daily returns covering, say, one month is inherently problematic. Nonetheless, the monthly realized volatility measure is robust to variation in volatility as explained more formally below. Of course, given the rapidly evolving markets, we would often need to assess the time variation in realized volatility at a daily level. The above reasoning suggests this will require access to high-frequency intra-day data. This is the starting point for the modern realized volatility literature.

**Realized volatility as an ex post return variability measure**

Given the round-the-clock activity on financial markets, volatility is naturally seen as evolving stochastically in continuous time. A complete characterization of the volatility realization then consists of a full specification of the actual sample path. However, at most one price is observed at each point in time so *instantaneous* volatility cannot be assessed without relying on adjacent observations, which is justified only under auxiliary assumptions – just as daily volatility cannot be estimated from a single return. In contrast, realized volatility seeks to measure the temporally cumulated (instantaneous) volatility so the target is the (average) realization of volatility over a non-negligible interval, allowing for a feasible and robust estimator with desirable properties.
As a benchmark for analysis, let the logarithmic asset price, $p(t)$, be a continuous time stochastic process observed in a frictionless market. For brevity and clarity, the formal exposition is cast in a univariate setting, but all results for realized volatility generalize readily to the multivariate case. To avoid arbitrage, and subject only to weak auxiliary conditions, the price process constitutes a (special) semi-martingale (Harrison and Kreps, 1978; Back, 1991). The price process may then quite generally be represented as follows,

$$dp(t) = \mu(t) \, dt + \sigma(t) \, dB(t) + j(t) \, dJ(t), \quad t \in [0, T], \tag{4}$$

where $\mu(t)$ is a predictable, continuous process with bounded variation, the volatility process $\sigma(t)$ is strictly positive, $B(t)$ denotes a standard Brownian motion, $J(t)$ is a jump indicator taking the values zero (no jump) or unity (jump) and, finally, the $j(t)$ indicates the jump in the return process if a jump occurs at time $t$ and $j(t) \equiv 0$ otherwise. We assume the jump intensity, denoted $\lambda(t)$, to be bounded so there is a finite number of jump in the price path per time period. This is standard in the asset pricing literature although it does rule out some valid Lévy representations. Equation (4) implies an instantaneous expected return of $\{\mu(t) + \lambda(t) \mathbb{E}[j(t)]\} \, dt$, which is an order smaller than the instantaneous innovation, $\sigma(t)(dt)^{1/2} + j(t)$ namely order $dt$ versus $dt^{1/2}$. Hence, for short horizons, the return variability is dominated by the unpredictable martingale component and the mean return is negligible. These features are captured formally by the notion of return quadratic variation defined below.

We denote the discretely observed continuously compounded return at time $t$, based on price observations at times $t$ and $t-h$, for $h>0$, by $r(t, h) = p(t) - p(t-h)$. From equation (4), the $h$-period return then has the representation,

$$r(t, h) = p(t) - p(t-h) = \int_{t-h}^{t} \mu(\tau) \, d\tau + \int_{t-h}^{t} \sigma(\tau) \, dB(\tau) + \sum_{t-h \leq \tau < t} j(\tau). \tag{5}$$

Formally, the sample path variation of the return process over $[t-h, t]$ is given by the quadratic variation of the logarithmic price process,

$$QV(t, h) = \int_{t-h}^{t} \sigma^2(s) \, ds + \sum_{t-h < s \leq t} j^2(s) \equiv IV(t, h) + \sum_{t-h < s \leq t} j^2(s). \tag{6}$$
Equation (6) attributes the return variation to the diffusive volatility and the cumulative squared jumps. The first term is denoted the *integrated variance*. This quantity is often the focus of the broader realized volatility literature as many studies ignore jumps. The integrated variance is also of direct relevance for option pricing under stochastic volatility (Hull and White, 1987). This is in part due to the following result for the special case with neither jumps nor correlation between the return and volatility processes, that is, $B(t)$ is independent of $\sigma(s)$ for all $0 \leq s, t \leq T$. Conditional on the mean component and integrated variance, we then have,

$$r(t, h) / \{\mu(t, h), IV(t, h)\} \sim N(\mu(t, h), IV(t, h)), \tag{7}$$

where $\mu(t, h) = \int_{t-h}^{t} \mu(\tau) d\tau$. Since (innovations to) the mean component is of smaller order than the integrated variance for low values of $h$, the dominant feature is the time-varying second moment given by the realizations of integrated variance. Hence, the return distribution is a normal mixture governed by the integrated variance process. If return and volatility innovations are correlated, the distribution is no longer mixed normal, but the interpretation of the integrated variance as a return variability measure is maintained.

Of course, short of having a continuum of price observations available, the relevant quantities in eqs (6) or (7) are not directly observable. However, in theory, the quadratic variation can be approximated closely by the corresponding cumulative squared return process, motivating the following definition. Let $[t-h, t]$ be split into $M=h/\Delta$ sub-intervals of length $\Delta$, with $0 < \Delta \ll h$, and define the *realized volatility* constructed from the equally spaced $\Delta$-period returns as

$$RV(t, h; \Delta) = \sum_{m=1}^{M} r^2(t - h + m \cdot \Delta, \Delta). \tag{8}$$

The basic theory for semi-martingales ensures that realized volatility is consistent for quadratic variation in the sense that, for finer and finer sampling of intra-day returns, eq. (8) will, in the limit, provide a perfect measure of the realizations of the latent quadratic variation, that is,

$$RV(t, h; \Delta) \to QV(t, h), \text{ as } \Delta \to 0 (\text{and } M = h/\Delta \to \infty). \tag{9}$$
This provides a formal basis for *ex post* measurement of realized volatility without parametric assumptions. It is a model-free measure of actual realizations while standard approaches provide parametric model forecasts of future volatility. We have the following approximate relationship between parametric forecasts and realized volatility, for small $h$,

$$
\text{Var}[r(t, h)|\mathcal{F}_{t-h}; \theta] \approx E[RV(t, h; \Delta)|\mathcal{F}_{t-h}] \approx E[QV(t, h)|\mathcal{F}_{t-h}],
$$

where the left most expression denotes the conditional variance over $[t-h, t]$ conditional on the available information at time $t-h$, $\mathcal{F}_{t-h}$, and the (true) model parameter vector, $\theta$. Andersen, Bollerslev and Diebold (ABD) (2008) provide an in-depth discussion of the approximation behind eq. (10). The relation shows that realized volatility is the natural benchmark for assessing volatility forecast performance. Realized volatility can in principle be used to estimate the instantaneous volatility of a pure diffusion consistently. Ruling out jumps in the price process, but allowing volatility to be càglàd (left-continuous, right limit sample path) and thus having potential discontinuities, we have

$$
QV(t, h) \rightarrow \sigma^2(t), \text{ as } h \rightarrow 0.
$$

This insight is certainly not new. Merton (1976; 1980) discusses the result explicitly, and Foster and Nelson (1996) develop asymptotic results. However, this limiting operation is impractical. Equation (10) merely requires that $M=h/\Delta \rightarrow \infty$. For eq. (11) to hold, with quadratic variation replaced by a feasible realized volatility estimator, $\Delta$ must converge to zero at a faster rate than $h$. This requires a double limiting procedure with ever more data sampled within an ever shrinking neighbourhood of $t$. Intensive sampling over short intervals magnifies the microstructure effects stemming from price discreteness, bid-ask bounce, temporary order-driven dependencies and other institutional features affecting returns at the highest frequencies. The issue of how to deal with such complications has inspired an extensive literature, summarized succinctly in Hansen and Lunde (2006). The practical complications induced by microstructure noise can be illustrated through the asymptotic theory for the realized volatility estimator. For a purely diffusive price process, it follows from Jacod and Protter (1998) and Barndorff-Nielsen and Shephard (BNS) (2002a; 2002b; 2004a), that asymptotically, as $\Delta \rightarrow 0$, 

http://www.dictionaryofeconomics.com.proxy.library.csio.edu/article?id=pde2008_R000264&goto=B&result_number=1430
so the ratio of the integrated quarticity, \( IQ(t, h) = \int_{t-h}^{t} \sigma^4(s) ds \), to the number of intra-day returns, \( M = h/\Delta \), determines the precision of the realized volatility estimator, generalizing and improving the result discussed below eq. (3). A simple way to convey the implications of microstructure noise is to impose an exogenous bound, say \( \Delta^* \), below which no useful information from sampling is available as the semi-martingale assumption is blatantly violated at the highest frequencies. Hence, over an interval of length \( h \), only \( M^* = h/\Delta^* \) observations can be exploited for inference, and \( h \) must be of a certain size for realized volatility measures to possess meaningful precision. Equation (11) requires \( \Delta \) to vanish at a rapid rate, so the bound \( \Delta^* \) is quickly binding. If only a handful of returns is available within a few minutes of \( t \), the sampling scheme behind eq. (11) breaks down. In contrast, for \( \Delta^* \) fixed at one or five minutes, it is feasible to estimate the quadratic variation with reasonable accuracy for \( h \) equal to one trading day.

Alternative return variation measures

For a pure diffusion in a frictionless market, the basic realized volatility estimator exploiting all available observations is optimal for the quadratic variation. However, once price jumps and microstructure noise are introduced, matters become more complex. A number of issues may be addressed through alternative return variation measures, including the ability to disentangle the effect of jumps from the diffusive volatility, to estimate quantities needed for feasible inference about realized volatility, and to develop more robust-to-noise measures of integrated variance.

First, absent jumps and under appropriate regularity, one may extend the theory for the integrated variance to include the integrated variation of arbitrary powers, that is, for \( \Delta \to 0 \) the realized power variation of order \( p \) consistently estimates the \( p \)'th order integrated power variation (\( p \leq 1 / 2 \)),

\[
(\mathbb{E} Z)^p - 1 (h / \Delta)^{1 - p / 2} \sum_{m=1}^{M} |r(t - h + m \cdot \Delta, \Delta)|^p \to \int_{t-h}^{t} \sigma^p(s) ds
\]

(13)

where \( Z \) denotes a standard normal variable. For \( p=4 \), this result provides a simple estimator for the integrated quarticity which may be plugged into eq. (12) to yield a feasible distribution theory for realized volatility. An asymptotic distribution theory akin to eq. (12) is available for realized power variation (see Barndorff-Nielsen et al., 2006b). Another extension, the realized k-skip bipower variation, is also consistent for the integrated variance,
For $k=1$, $BV(t,h;1,\Delta)$ is termed the realized bipower variation. These measures have convenient robustness properties. First, eq. (14) remains valid even if the return process follows a jump-diffusion. Hence, the bipower measures annihilate the jumps asymptotically and thus provide simple consistent estimators for the integrated variance. This allows for separation of the jump and diffusive contributions to the realized return variation, as

\[
RV(t,h;\Delta) - BV(t,h;\Delta) = QV(t,h) - IV(t,h) = \sum_{t-h<s<0} j^2(s), \text{ as } \Delta \to 0.
\]

Combined with the asymptotic theory for realized power and bipower variation, the result renders formal statistical tests for the presence and impact of jumps feasible. This is applied for separate analysis of the diffusive and jump components (see BNS, 2004b; 2006; Huang and Tauchen, 2005; ABD, 2007).

Alternative jump tests have recently been developed by Jiang and Oomen (2005), Andersen, Bollerslev and Dobrev (2007), and Lee and Mykland (2006).

The bipower variation measures also display robustness against microstructure noise. To first order, when not sampling at the very highest frequencies, the impact of noise may be mimicked by adding an i.i.d. process to the ‘efficient’ prices to generate noisy observations. This noise component induces negative return correlation which inflates the realized volatility estimator, resulting in a potentially strong upward bias. This may be alleviated by sampling more sparsely although this uses less data and reduces efficiency, pointing towards a bias-variance trade-off: one should sample sparsely enough to avoid a significant bias but frequently enough that efficiency is not compromised. An informal bias diagnostic is to apply the realized volatility estimator for different underlying frequencies over the full sample, that is, $h$ is on the order of years or a decade. The long horizon minimizes sampling variability so that, absent the microstructure bias, all the measures should centre closely on the sample realized return volatility. A volatility signature plot depicts those realized volatility measures against the underlying sampling frequency with $\Delta$ ranging from seconds to a full day. For liquid financial markets, signature plots typically indicate inflated values at the highest frequencies which then decay quite smoothly to a stable level for sampling between 5 and 40 minutes. Andersen, Bollerslev, Diebold and Labys (ABDL) (2000a) suggest that the shortest sampling intervals not displaying a significant bias may be desirable choices. Of course, this criterion rewards unbiasedness over efficiency. Bandi and Russell
realized volatility: The New Palgrave Dictionary of Economics

(2005a) explicitly trade off the microstructure bias with the efficiency gains from more data. An alternative is to apply skip-$k$ bipower variation measures. Huang and Tauchen (2005) document that these tend to work well when applied to noisy observations from jump diffusions. Andersen, Bollerslev, Frederiksen and Nielsen (ABFN) (2006a) extend the volatility signature plots to include both power variation and skip-$k$ bipower variation measures. Such generalized plots provide insights into the robustness of the realized quarticity and other quantities used for jump tests and may guide the choice of an adequate sampling frequency for analysis of a range of different issues in the presence of market frictions.

Finally, procedures have been developed to correct for microstructure bias while utilizing more of the available data. The proposals include the subsampling idea alluded to in Zhou (1996), and extended and formalized by Zhang, Mykland and Aït-Sahalia (2005) and Aït-Sahalia, Mykland and Zhang (2006) as well as the kernel based methods of Barndorff-Nielsen, Hansen, Lunde and Shephard (2006), and numerous filtering approaches discussed in Hansen and Lunde (2006).

Empirical applications

Hsieh (1991) is perhaps the first to apply intra-day returns for historical volatility measurement of the daily return variation. Closely related work appears in publications by the Olsen & Associates group. This is surveyed in Dacorogna et al. (2001). Zhou (1996) offers the first systematic study of the realized volatility estimator combining theoretical and empirical issues. Interestingly, he discusses contamination by market microstructure noise as well as ideas for a variety of feasible corrections. Comte and Renault (1998) also comment on estimating diffusive spot volatility through the empirical counterpart to quadratic variation.

In parallel work, Andersen and Bollerslev (AB) (1997; 1998b) explore the dynamics of high-frequency return volatility, documenting the striking effectiveness of cumulative absolute and squared returns as daily volatility measures. These findings inspired theoretical inquiries and are followed by the statement of consistency of realized volatility for the quadratic variation for a general multivariate jump-diffusion setting in ABDL (2001). In concurrent work, BNS (2001; 2002a) and Meddahi (2002) provide initial asymptotic theory for the realized volatility estimator, with the diffusive multivariate case treated in BNS (2004a).

Empirical work almost invariably operates with $h$ equal to one trading day (or more). This is due to the pronounced intra-day volatility pattern which induces systematic shifts in the quadratic return variation over different segments of the trading day. As noted in AB (1997; 1998b) this type of largely deterministic effects are alleviated at the daily frequency, rendering this the natural basis for analysis.

The list of empirical applications is growing rapidly. A brief overview of the topics explored along with selective, but not exhaustive, references are provided below.

The most common use of realized volatility is as a basis for volatility forecasting and evaluation. AB (1998a) document the potential of realized volatility for assessment of standard volatility forecasts, a theme further explored in Andersen, Bollerslev and Lange (1999) and rationalized more formally in Andersen, Bollerslev and Meddahi (2004) using powerful analytical techniques developed in Meddahi

The evidence for long-range persistence in volatility is particularly striking when analysed via realized volatility rather than via daily return observations. AB (1998a) demonstrate that return series spanning only a couple of years are sufficient to identify a distinct hyperbolic decay in the realized power variation series. Moreover, the implied degree of fractional integration appears to be stable across subsamples, at around 0.35–0.45, implying a stationary volatility series. This finding is confirmed by virtually all subsequent studies of realized volatility exploring the issue, including ABDL (2001, 2003), Areal and Taylor (2002), Martens (2002), Zumbach (2004), Deo, Hsieh and Hurvich (2005), and Deo, Hurvich and Lu (2006). Moreover, related early work by the Olsen & Associates group also note the presence of scaling laws in volatility measures obtained from high frequency returns, see, for example, Müller et al. (1990) and the review in Dacorogna et al. (2001). This inspired an extensive amount of empirical work in the ‘econophysics’ area on volatility scaling laws which is summarized in Mantegna and Stanley (2000). These robust empirical results suggest that the long-memory property is not driven by occasional structural breaks but is present in the data generating process at high frequencies. As such, it sheds new light on a contentious issue which is not readily resolved without an effective volatility measure that improves the signal-to-noise ratio, allowing for more effective inference. Explicit estimation of the long memory features may be circumvented through a model with multiple volatility components, each governed by an autoregressive process, as such structures approximate the long-memory dependencies very well. This approach has been applied for realized volatility series by ABD (2007), BNS (2001), and Corsi (2003), among others.

The no-arbitrage implications for the return dynamics expressed in eqs (4) and (5), are necessarily quite weak and general, but do nonetheless have distributional implications which are potentially testable. As highlighted by eq. (7), auxiliary assumptions produce a mixture of normals result akin to the mixture-of-distributions theory, originating from work by Clark (1973) and Tauchen and Pitts (1983). The novelty of eq. (7) is the potential ex post observability of the mixing variable, the integrated variance, which enables direct inference regarding the distributional implications without any parametric assumptions. In
practice there will be some discretization error and microstructure distortions, but the properties of the realized volatility estimator should facilitate powerful tests. ABDL (2000b) confirm that returns standardized by realized volatility are much closer to normal than the standardized residuals from the usual volatility models based on daily data, even if the normality is not exact. Thomakos and Wang (2003) reach the identical conclusion for a different set of assets. Of course, eq. (7) is not valid in the presence of price jumps or dependence between the volatility and return innovation processes. The former issue may be addressed through jump identification procedures which seek to annihilate the impact of the jumps. The latter issue is accommodated by sampling the return process in ‘financial time’, consisting of calendar periods representing equal increments to the integrated variance process, as noted by Peters and de Vilder (2006) for a diffusive return process. This approach is extended to a jump-diffusive setting by Andersen, Bollerslev and Dobrev (2007) who also explore practical implementation issues for the associated distributional tests in detail. More extensive data sets and alternative jump identification techniques are considered in ABFN (2006b). They quite generally obtain jump-adjusted, financial-time sampled returns that are indistinguishable from i.i.d. standard Gaussian variates through realized volatility based empirical procedures. In sum, the results corroborate the general framework, and the tools developed for jump identification and measurement of the quadratic variation deliver empirically meaningful series of jumps and quadratic variation which are fully consistent with the theoretical underpinnings. In the process, direct evidence of the importance of jumps and the asymmetric return-volatility relationship is provided. Jumps are present for all asset classes and constitute a non-negligible fraction of overall return variation. For equities, negative returns tend to induce higher volatility than corresponding positive returns, a feature broadly recognized in the prior literature. Interestingly, there are also signs of significant asymmetric relationships for other asset classes, although both magnitude and sign may change over time. Similar issues are studied by Fleming and Paye (2006) and closely related topics are explored by Maheu and McCurdy (2002).

Multivariate applications of the realized volatility estimator are in principle straightforward. They are used to study the broad correlation patterns among individual stocks in ABDE (2001), for volatility timing in portfolio allocation in Fleming, Kirby and Ostdiek (2003), for estimation of systematic market risk exposure (time-varying market betas) in Andersen et al. (2005), for assessment of a broader set of risk loading coefficients in Bollerslev and Zhang (2003), and for dynamic portfolio choice in Bandi, Russell and Zhou (2008). In spite of these initial explorations, it is clear that the multivariate setting introduces additional practical complications as there is evidence of significant delays in the reaction of one security price to movements in another related asset. Sheppard (2006) explores these issues in some depth even if general prescriptions for practice do not directly follow. The favoured approach in current work is to include temporal cross-correlation patterns through measurement of the relations between the return of one asset with lead and lag returns for the other asset – in the spirit of the corrections for non-trading effects in the estimation of betas from daily data in Scholes and Williams (1977). Hayashi and Yoshida (2005; 2006) and Griffin and Oomen (2006) study such realized covariance and correlation estimators. Bandi and Russell (2005b) and Zhang (2006) seek to trade off bias and efficiency optimally. An alternative approach is proposed in Bauer and Vorkink (2006).

A natural comparison for realized volatility based forecasts is with forecasts implied by traded financial contracts such as options. In fact, an intriguing parallel exists between expected future realized volatility
and the pricing of volatility swaps, with the latter reflecting the expected future integrated variance under the risk-neutral (pricing) measure if jumps in the price path are absent. Hence, systematic differences between realized volatility and implied volatility measures reflect the market prices of volatility risk (see, for example, Britten-Jones and Neuberger, 2000; Carr and Madan, 1998; Carr and Wu, 2005). Moreover, Bondarenko (2004) shows that the implied volatility result remains approximately valid for jump diffusions and returns sampled at discrete intervals only. Recent empirical papers on the performance of realized volatility forecasts versus implied volatility measures include, for example, Andersen, Frederiksen and Staal (2006), Bollerslev, Gibson and Zhou (2005), Bollerslev and Zhou (2006), Busch, Christensen and Nielsen (2006), Chan, Kalimipulli and Sivakumar (2006) and Pong et al. (2004). The findings confirm that realized volatility forecasts contain information for future return variability over-and-beyond implied volatility forecasts, while standard volatility forecasts obtained from models utilizing only daily data are fully encompassed by the market based measures.

**Future directions for research**

Most of the empirical work associated with the realized volatility concept has focused directly on the measurement precision and forecast performance. In order for the approach to enter routinely in more mainstream applications within asset pricing, risk management and portfolio allocation the empirical studies must broaden in scope. As reviewed above, this has begun to happen, but much work remains. One recent example of using the concept for model specification testing is Andersen and Benzoni (2005). The study documents a serious deficiency in the ability of affine term structure models to accommodate the observed dynamics of realized yield volatility for the US Treasury market. Theoretically, the concurrent yield curve should span yield volatility, both ex post and ex ante, but this property is systematically violated as the yield variation at every maturity displays genuine stochastic features not associated with simultaneous directional shifts in the yield curve. The result extends earlier findings based on ex ante volatility measures at the monthly frequency. For generalizations of term structure models operating within the popular and tractable affine setting, the realized volatility measures promise to be valuable diagnostic tools.

The applications of realized volatility measures will surely continue to grow and broaden as the advantages of the enhanced precision in the measurement of the return variability are much too large to be ignored and many important questions await thorough analysis from this perspective. Of particular interest is the development of practical approaches to generate reliable measures for the high-dimensional case involving a large set of assets. On the theoretical front, work remains in terms of understanding the relative advantages of the different robust alternatives to the basic realized volatility measure. One potentially promising avenue is to further develop the locally constant volatility technique developed by Mykland (2006), seeking to provide a formal, yet simple and powerful, tool for asymptotic theory while allowing for time-varying price dynamics.

reciprocity and collective action

Rajiv Sethi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A collective action problem arises when the private incentives faced by individual members of a group are not properly aligned with their shared goals. Such problems can be overcome if opportunistic behaviour is restrained by explicit sanctions or internalized social norms. In particular, collective action is facilitated by norms of reciprocity that induce individuals to undertake pro-social actions whenever they expect others to do the same. From this perspective, collective action requires coordinated expectations and effective communication. Experimental evidence suggests that reciprocity norms are widespread in human populations, and evolutionary mechanisms that can account for their prevalence have been identified.

Article

Advancing the common interest of a group sometimes requires its members to sacrifice their private interests. Such situations, in which individual incentives are not properly aligned with shared goals, are called collective action problems. They arise frequently in economic and social life, for instance in the context of political mobilization, electoral turnout, pollution abatement, common property management and the provision of public goods. They can involve relatively small groups such as families, teams, or business partnerships, or very large groups that cut across national boundaries.

In his classic work on collective action, Mancur Olson (1965) conjectured that individuals would be unable to overcome such problems unless their behaviour was constrained by rules that were externally imposed and enforced. Along similar lines, Garret Hardin (1968) argued in an influential paper that, left
to their own devices, individuals would face a ‘tragedy of the commons’ which could be overcome only by ‘mutual coercion, mutually agreed upon’. This view continues to have considerable currency in economics in the form of the free-rider hypothesis, which maintains that voluntary contributions that are socially beneficial but privately costly will not generally be observed (Bergstrom, Blume and Varian, 1986).

Despite the compelling logic underlying the free-rider hypothesis, there are numerous instances of groups having overcome collective action problems without external pressure, sometimes by designing and abiding by their own set of rules, and sometimes on the basis of less formal arrangements codified in social norms. The success of OPEC in constraining production to maintain price levels is based on a mutually beneficial agreement among member countries that has been sustained despite strong incentives for some producers to free-ride on the restraint practised by others. On a smaller scale, many examples of successful collective action in the management of local fisheries, forests, and other renewable resources have been documented (Bromley, 1992; Ostrom, 1990). Such resources are often held as common property, and the maintenance of sustainable stocks requires restraint in individual extraction levels. Restraint is typically enforced by formal or informal sanctions, and participation in such punishment mechanisms is itself a form of collective action. There also exist examples of collective action in the absence of any sanctioning mechanism. For instance, voter turnout is often substantial in large elections, contrary to the predictions of the free-rider hypothesis.

It has been argued that many instances of successful collective action arise in small and stable groups whose members interact with each other repeatedly. Under such circumstances, pro-social behaviour can be fully consistent with the standard economic hypotheses of rationality and self-interest. When interactions are repeated, self-interested cooperation can arise if one believes that non-cooperative actions will be punished in future periods. Moreover, such threats of punishment can be credible if abstaining from punishment is itself punished. Formally, cooperative behaviour can be sustained in subgame perfect equilibrium if interactions are infinitely (or indefinitely) repeated (Fudenberg and Maskin, 1986). Hence the tension between individual and common interest is less severe and collective action more likely to arise in small and stable groups.

While the threat of future punishment or the promise of future reward might motivate collective action in some instances, there are many situations in which individual actions are unobservable or repetition too infrequent for such considerations to be decisive. Voter turnout, for instance, or private donations to charity are not easily explained as self-interested responses to material incentives. Similarly, sacrifices involving risks to life and limb, as in the case of battlefield heroism or spontaneous collective violence, are unlikely to be driven by a calculated response to future costs and benefits. What, then, could account for such phenomena?

There is now a considerable body of experimental evidence to suggest that many individuals are willing to take actions that further the common interest provided that they are reasonably sure that other group members will also take such actions. Furthermore, they are willing to sanction the opportunistic behaviour of others even at some cost to themselves (Fehr and Gächter, 2000). The widespread prevalence of such preferences for reciprocity suggests that collective action can sometimes be viewed as a coordination problem: if the members of a group confidently expect others to further the common good, such expectations can be self-fulfilling. On the other hand, expectations of widespread free-riding can also be self-fulfilling, so building confidence in the behaviour of others is a critical ingredient of
successful collective action. Communication among group members can help coordinate expectations, and it is therefore not surprising that allowing for communication among experimental subjects can result in dramatically increased levels of cooperation. This is the case even if communication takes the form of ‘cheap talk’, with neither threats nor promises being enforceable (Ostrom, Walker and Gardner, 1992).

If preferences for reciprocity are indeed part of the explanation for successful collective action, this raises the question of how such preferences have come to be widespread in human populations in the first place. The existence of a willingness to sacrifice one's own material interest for the common good poses an evolutionary puzzle. In order to survive and spread in human populations, the possession of such preferences must confer on an individual some advantage relative to those who are entirely self-interested. One intriguing possibility is that, despite being disadvantageous to individuals within groups, traits that are advantageous for the group itself may survive because of competition among groups:

There can be no doubt that a tribe including many members who, from possessing in a high degree the spirit of patriotism, fidelity, obedience, courage, and sympathy, were always ready to give aid to each other and to sacrifice themselves for the common good, would be victorious over other tribes; and this would be natural selection. (Darwin, 1871, p. 166)

In order to be effective, however, this mechanism requires variability across groups to be sustained while variability within groups is suppressed (Sober and Wilson, 1998). Whether or not the conditions for this are empirically plausible remains an open question.

There exist other channels through which a preference for reciprocity can be materially advantageous to individuals. One is assortative interaction: if individuals with preferences for reciprocity are more likely to interact with each other than with opportunists, the former can end up with higher material payoffs than the latter. Such assortation arises naturally in structured populations with local interaction. Even in unstructured populations with random matching, a propensity to reciprocate or to sanction opportunistic behaviour can confer an advantage provided that such preferences are observable to others. The visible possession of such propensities can alter the behaviour of those with whom one is interacting in such a manner as to be materially rewarding. Even opportunistic individuals might be induced to behave cooperatively in interactions with those who have a credible reputation for reciprocity. Such considerations can provide the basis for an evolutionary theory of reciprocity (Sethi and Somanathan, 2001).

Reciprocity is a key feature of successful collective action, both in repeated interactions and in more spontaneous settings. The willingness to further the common good even at considerable personal cost is widespread in human populations, but is often contingent on the willingness of others to do the same. This perspective suggests that collective action problems are not insurmountable, but that communication and coordination are critical in overcoming them.

recursive competitive equilibrium

Rajnish Mehra
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In this article we define a recursive competitive equilibrium, provide an example and review the related literature.

Keywords

Arrow–Debreu model of general equilibrium; Bellman's principle of optimality; business cycles; dynamic decentralization; Markov processes; neoclassical stochastic growth model; optimality; recursive competitive equilibrium; time-invariant equilibrium decision rules; total factor productivity; valuation equilibrium

Article

The underlying structure of most dynamic business-cycle and consumption-based asset-pricing models is a variant of the neoclassical stochastic growth model. Such models have been analysed by, among others, Cass (1965), Brock and Mirman (1972), and Donaldson and Mehra (1983). They focus on how an omniscient central planner seeking to maximize the present value of expected utility of a representative agent optimally allocates resources over the infinite time horizon.

Production is limited by an aggregate production function subject to technological (total factor productivity) shocks. The solution to the planning problem is characterized by time-invariant decision rules, which determine optimal consumption and investment each period. These decision rules have as arguments the economy's period aggregate capital stock and the shock to technology.

Business cycles, however, are not predicated on the actions of a central planner, but arise from interactions among economic agents in competitive markets. Given the desirable features of the stochastic growth paradigm – the solution methods are well known and the model generates well-defined proxies for all the major macro aggregates: consumption, investment, output, and so on – it is natural to ask if the allocations arising in that model can be viewed as competitive equilibria. That is, do price sequences exist such that economic agents, optimizing at these prices and interacting through competitive markets, achieve the allocations in question as competitive equilibria? This is the essential question of dynamic-decentralization theory.

Alternative approaches to dynamic decentralization: valuation equilibrium

One way of modelling uncertain dynamic economic phenomena is to use Arrow–Debreu general equilibrium structures and to search for optimal actions conditional on the sequence of realizations of all past and present random variables or shocks. The commodities traded are contingent claim contracts. These contracts deliver goods (for example, consumption and capital goods) at a future date, contingent on a particular sequential realization of uncertainty. Markets are assumed
to be complete, so that, for any possible future realization of uncertainty (sequence of technology shocks) up to and including some future period, a market exists for contracts that will deliver each good at that date contingent on that realization (event). This requires a very rich set of markets. All trading occurs in the first period: consumers contract to receive consumption and investment goods and to deliver capital goods in all future periods contingent on future states so as to maximize the expected present value of their utility of consumption over their infinite lifetimes. Firms choose their production plans so as to maximize the present value of discounted profits. Given current prices, they contract to deliver consumption and investment goods to, and to receive capital goods from, the consumer-investors. Under standard preference structures, these contingent choices never need to be revised. That is, if markets reopen, no new trades will occur.

In its most general formulation, a valuation equilibrium is characterized simply as a continuous linear functional that assigns a value to each bundle of contingent commodities. Only under more restrictive assumptions can this function be represented as a price sequence (Bewley, 1972; Prescott and Lucas, 1972; Mehra, 1988). The basic result is that for any solution to the planner's problem – that is, sequences of consumption, investment and capital goods – a set of state-contingent prices exists such that these sequences coincide with the contracted quantities in the valuation equilibrium. This decentralization concept is quite broad and applies to central-planning formulations much more general than the neoclassical growth paradigm. It reminds us that the financial structure underlying the stochastic growth paradigm is fundamentally one of complete contingent commodity markets. Nevertheless, it is a somewhat unnatural perspective for macroeconomists (all macro policies must be announced at time zero), and it presumes a set of markets much richer than any observed. These shortcomings led to the development of the concept of a recursive competitive equilibrium.

**Recursive competitive theory**

An alternative approach that has proved very useful in developing testable theories is to replace the attempt to locate equilibrium sequences of contingent functions with the search for time-invariant equilibrium decision rules. These decision rules specify current actions as a function of a limited number of ‘state variables’ which fully summarize the effects of past decisions and current information. Knowledge of these state variables provides the economic agents with a full description of the economy's current state. Their actions, together with the realization of the exogenous uncertainty, determines the values of the state variables in the next sequential time period. This is what is meant by a recursive structure. In order to apply standard time-series methods to any testable implications, these equilibrium decision rules must be time-invariant.

Recursive competitive theory was first developed by Mehra and Prescott (1977) and further refined in Prescott and Mehra (1980). These papers also establish the existence of a recursive competitive equilibrium and the supportability of the Pareto optimal through the recursive price functions. Excellent textbook treatments are contained in Harris (1987), Stokey, Lucas and Prescott (1989) and Ljungqvist and Sargent (2004). Since its introduction, it has been widely used in exploring a wide variety of economic issues including business-cycle fluctuations, monetary and fiscal policy, trade-related phenomena, and regularities in asset price co-movements. (See, for example, Kydland and Prescott, 1982; Long and Plosser, 1983; Mehra and Prescott, 1985.)

The recursive equilibrium abstraction postulates a continuum of identical economic agents indexed on the unit interval (again with preferences identical to those of the representative agent in the planning formulation), and a finite number of firms. As in the valuation equilibrium approach, consumers undertake all consumption and saving decisions. Firms, which have equal access to a single constant-returns-to-scale technology, maximize their profits each period, and are assumed to produce two goods: a consumption good and a capital good. Unlike in the valuation equilibrium approach, trading between agents and firms occurs every period. (This is in contrast to markets in an Arrow–Debreu setting where, as mentioned earlier, no trade would occur if markets were to reopen.) At the start of each period, firms observe the technological shock to productivity and purchase capital and labor services, which are supplied inelastically at competitive prices. The capital and labour are used to produce the capital and consumption goods. At the close of the period, individuals, acting competitively, use their wages and the proceeds from the sale of capital to buy the consumption and capital goods produced by the firms. Consumers then retain the capital good into the next period, when it again becomes available to firms and the process repeats itself. Note that firms are liquidated at the end of each period.
recursive competitive equilibrium: The New Palgrave Dictionary of Economics

(retaining no capital assets while technology is freely available), and that no trades between firms and consumer-investors extend over more than one time period. Capital goods carried over from one period to the next are the only link between periods, and period prices depend only on the state variables in that period.

Formally, a **recursive competitive equilibrium** (RCE) is characterized by time invariant functions of a limited number of 'state variables', which summarize the effects of past decisions and current information. These functions (decision rules) include (a) a pricing function, (b) a value function, (c) a period allocation policy specifying the individual's decision, (d) a period allocation policy specifying the decision of each firm and (e) a function specifying the law of motion of the capital stock.

While the restrictive structure of markets and trades makes this concept less general than the valuation equilibrium approach, it provides an interpretation of decentralization that is better suited to macro-analysis. More recently, the recursive equilibrium concept has been generalized to admit an infinitely lived firm which maximizes its value. When an RCE is Pareto optimal, its allocation coincides with that of the associated planning problem. The solution to the central-planning stochastic-growth problem may then be regarded as the aggregate investment and consumption functions that would arise from a decentralized, recursive homogeneous consumer economy. We illustrate this with the help of an example below, which considers an economy with a single capital good. The reader is referred to Prescott and Mehra (1980) for the more general case with multiple capital types.

**An example**

Consider the simplest central planning stochastic growth paradigm

\[
W(k_0, \lambda_0) = \max \left\{ \sum_{t=0}^{\infty} \beta^t u(c_t) \right\}
\]

(P1)

subject to

\[
c_t + k_{t+1} \leq \lambda_t f(k_t, l_t), \lambda_0, k_0 \text{ given}, \quad l_t = 1 \quad \forall t.
\]

In this formulation, \(u(\cdot)\) is the period utility function of a representative consumer defined over his period \(t\) consumption \(c_t\); \(k_t\) denotes capital available for production in period \(t\) and \(l_t\) denotes period \(t\) labour supply which is inelastically supplied by the consumer-investor at \(l_t = 1\), for all \(t\). The expression \(f(k_t, l_t)\) represents the period technology (production function) which is shocked by the bounded stationary stochastic factor \(\lambda_t\). (It is assumed that \(\lambda_t\) is subject to a stationary Markov process with a bounded ergodic set.) \(E\) denotes the expectations operator and the central planner is assumed to have rational expectations; that is, he uses all available information to rationally anticipate future variables. In particular he knows the conditional distribution of future technology shocks \(E(\lambda_{t+1}; \lambda_t)\). For the purposes of this example we restrict preferences to be logarithmic and assume a Cobb–Douglas technology (to the best of my knowledge, this parameterization is the simplest example known to result in closed form solutions): \(u(c_t) = \ln c_t\) and \(f(k_t, l_t) = k_t^{\alpha}l_t^{1-\alpha}\). We also assume that \(\alpha, \beta < 1\) and that capital fully depreciates each period.

These conditions are sufficient to guarantee a closed form solution to the planning problem:
where we identify as investment, $i_t$, the capital stock held over for production in period $t+1$. These allocations are Pareto optimal.

We will show that the investment and consumption policy functions arising as a solution to this problem may be regarded as the aggregate investment and consumption functions arising from a decentralized homogenous consumer economy. We first qualitatively describe the RCE underlying this model, and then demonstrate the relevant equilibrium price and quantity functions explicitly. The one capital good is assumed to produce two goods – a consumer good and an investment (capital) good. At the beginning of each period, firms observe the shock to productivity ($\lambda_t$) and purchase capital and labour from individuals at competitively determined rates. Both capital and labour are used to produce the two output goods. Individuals use their proceeds from the sale of capital and labour services to buy the consumption good ($c_t$) and the investment good ($i_t$) at the end of the period. This investment good is used as capital ($k_{t+1}$) available for sale to the firm next period and the process continues recursively.

To cast this problem formally as a recursive competitive equilibrium, we introduce some additional notation. Let $k_t$ denote the capital holdings of a particular (measure zero) individual at time $t$, and $k_t$ the distribution of capital amongst other individuals in the economy. This latter distinction allows us to make formal the competitive assumption: all the economic participants will assume that $k_t$ is exogenous to them and that the price functions depend solely on this aggregate (in addition to the technology shock). Clearly, in equilibrium, $k_t = k_t$ for our homogeneous consumer economy. In addition, let $p_t$, $p_c$ and $p_k$ be the price of the investment, consumption and capital goods respectively and $p_l$ be the wage rate. These prices are presumed to be functions of the economy-wide state variables exclusively and all participants take these prices as given for their own decision making purposes. The ‘state variables’ characterizing the economy are $(k, \lambda)$ and the individual are $(k_t, k_t, \lambda_t)$.

We use the symbols $(c, i, k, l)$ to denote points in the ‘commodity space’ for the firm and the consumer. The $c$ in the commodity point of the firm is a function specifying the consumption good supplied by the firm and is written as $c^s(k_t, \lambda_t)$. Similarly, the $c$ in the commodity point of the individual is the amount of the consumption good demanded by the individual and is written as $c^d(k_t, k_t, \lambda_t)$. In equilibrium (as mentioned earlier, in equilibrium $k_t = k_t$), since the market clears, of course $c^s = c^d$. The same comments apply to the other elements of the commodity point.

In the decentralized version of this economy, the problem facing a typical household is

$$v(k_0, k_0, \lambda_0) = \max E \left\{ \sum_{t=0}^{\infty} \beta^t H_t \cdot c^d(k_t, k_t, \lambda_t) \right\}$$

subject to
\[ p_c(k_t, \lambda_t) i^d(k_t, k_t, \lambda_t) + p_i(k_t, \lambda_t) i^s(k_t, k_t, \lambda_t) \leq p_k(k_t, \lambda_t) k^s(k_t, k_t, \lambda_t) + p_l(k_t, \lambda_t) l^s(k_t, k_t, \lambda_t) \]

\[ k_{t+1} = k^s(k_{t+1}, k_{t+1}, \lambda_{t+1}) = i^d(k_t, k_t, \lambda_t), i^s(k_t, k_t, \lambda_t) \leq 1 \text{ and } k_{t+1} = \psi(k_t, \lambda_t) \]

is the law of motion of the aggregate capital stock.

With capital and labour priced competitively each period, the firm's objective function is especially simple – maximize period profits. The firm's problem then is

\[
\max \left\{ p_c(k_t, \lambda_t) c^s(k_t, \lambda_t) + p_i(k_t, \lambda_t) i^s(k_t, \lambda_t) - p_k(k_t, \lambda_t) k^d(k_t, \lambda_t) - p_l(k_t, \lambda_t) l^d(k_t, \lambda_t) \right\}
\]

subject to

\[ c_t^s + i_t^s \leq \lambda_t(k_t^d, l_t^d) \alpha (l_t^d)^{1-\alpha}. \]

Via Bellman's principle of optimality, the recursive representation of the individual's problem P2 is

\[
\nu(k_t, k_t, \lambda_t) = \max \left\{ c^d, i^d, i^s, k^d \right\} \left\{ \ln \left( c^d(k_t, k_t, \lambda_t) \right) + \beta \int \nu(i^d(k_t, k_t, \lambda_t), \psi(k_t, \lambda_t), \lambda_{t+1}) \, d\lambda_t \right\}
\]

subject to

\[ p_c(k_t, \lambda_t) c^d(k_t, k_t, \lambda_t) + p_i(k_t, \lambda_t) i^d(k_t, k_t, \lambda_t) \leq p_k(k_t, \lambda_t) k^s(k_t, k_t, \lambda_t) + p_l(k_t, \lambda_t) l^s(k_t, k_t, \lambda_t) \]

\[ k_{t+1} = k^s(k_{t+1}, k_{t+1}, \lambda_{t+1}) = i^d(k_t, k_t, \lambda_t), i^s(k_t, k_t, \lambda_t) \leq 1 \text{ and } k_{t+1} = \psi(k_t, \lambda_t) \]
is the law of motion of the aggregate capital stock.
The firm of course, simply maximizes its period profits and hence does not have a multiperiod problem.
The following functions that are a solution to the individual and firm maximization problem above satisfy the definition of recursive competitive equilibrium:

1. A value function
\[
V(k_0, k_0, \lambda_0) = \mathbb{E} \left\{ \sum_{t=0}^{\infty} \beta^t \ln \left[ (1 - \alpha \beta) \lambda_t k_t^{\alpha-1} \left\{ \alpha (k_t - k_t) + k_t \right\} \right] \right\}
\]
It can be shown that
\[
V(k_0, k_0, \lambda_0) = A + Bk_0^\alpha + Ck_0^\beta \lambda
\]
where \(A, B\) and \(C\) are constants which are functions of the preference and technology parameters.

2. A continuous pricing function \(p(k_t, \lambda_t) = \{ p_c(k_t, \lambda_t), p_i(k_t, \lambda_t), p_k(k_t, \lambda_t), p_l(k_t, \lambda_t) \} \) that has the same dimensionality as the commodity point, where
\[
p_c(k_t, \lambda_t) = p_i(k_t, \lambda_t) = 1
\]
(We have chosen the consumption good to be the numeraire.)

\[
p_k(k_t, \lambda_t) = \alpha \lambda_t k_t^{\alpha-1}
\]
\[
p_l(k_t, \lambda_t) = (1 - \alpha) \lambda_t k_t^{\alpha-1}.
\]

3. Consumption and investment functions for the individual that are a function of the current state of the individual \((k, \lambda)\)
\[
\ell^d(k_t, k_t, \lambda_t) = (1 - \alpha \beta) \lambda_t k_t^{\alpha-1} \left\{ \alpha (k_t - k_t) + k_t \right\}
\]
\[
\ell^s(k_t, k_t, \lambda_t) = 1
\]

4. Decision rules for the firm that are contingent on the state of the economy \((k_t, \lambda_t)\)

\[ i^d(k_t, k_t, \lambda_t) = \alpha \beta \lambda_t k_t^{\alpha - 1} \{ \alpha (k_t - k_t) + k_t \} \]

\[ k^s(k_{t+1}, k_{t+1}, \lambda_{t+1}) = i^d(k_t, k_t, \lambda_t). \]

5. The law of motion for the capital stock specifying the next period capital stock as a function of the current state of the economy \((k_t, \lambda_t)\)

\[ i^d(k_t, \lambda_t) = 1, \]

\[ i^s(k_t, \lambda_t) = \alpha \beta \lambda_t k_t^{\alpha}, \]

\[ k^d(k_{t+1}, \lambda_{t+1}) = i^s(k_t, \lambda_t). \]

6. The consumption and investment decisions of the individual \(c^s(k, k, \lambda), i^s(k, k, \lambda)\) and \(i^s(k, k, \lambda)\) maximize the expected utility subject to the budget constraint. So that
\[ v(k_t, k_{t+1}, \lambda_t) = \ln \left( (1 - \alpha \beta) \lambda_t k_t^{\alpha - 1} (\alpha (k_t - k_{t+1}) + k_{t+1}) \right) + \beta \int v(\alpha \beta \lambda_t k_t^{\alpha - 1} (\alpha (k_t - k_{t+1}) + k_{t+1}), \lambda_{t+1}) dF(\lambda_{t+1} | \lambda_t). \]

7. The decision rules of the firm \( r^d(k_t, \lambda_t), l^d(k_t, \lambda_t), i^d(k_t, \lambda_t) \) maximize firm profit.

Demand equals supply

\[ r^d(k_{t+1}, k_{t+1}, \lambda_{t+1}) = r^s(k_t, \lambda_t), \quad l^d(k_{t+1}, k_{t+1}, \lambda_{t+1}) = l^s(k_t, \lambda_t), \quad i^d(k_{t+1}, k_{t+1}, \lambda_{t+1}) = i^s(k_t, \lambda_t). \]

The law of motion of the representative consumers capital stock is consistent with the maximizing behaviour of agents \( \psi(k_t, \lambda_t) = i^d(k_t, k_{t+1}, \lambda_t) \). It is readily demonstrated that since \( v(k_0, k_0, \lambda_0) = w(k_0, \lambda_0) \), the competitive allocation is Pareto optimal. See eqs (P1) and (P2).

Having formulated expressions for the prices of the various assets and their laws of motion, it is a relatively simple matter to calculate rates of return (price ratios) and study their dynamics. For an application to risk premia, see Donaldson and Mehra (1984).

Some researchers have formulated models that can be cast in this same recursive setting, yet whose equilibria are not Pareto-optimal. As a consequence, the model's equilibrium can no longer be obtained as the solution to a central-planning-optimum formulation. These models incorporate various features of monetary phenomena, distortionary taxes, non-competitive labour market arrangements, externalities, or borrowing-lending constraints. Besides increasing general model realism, such features enable the models not only to better replicate the stylized facts of the business cycle, but also to provide a rationale for interventionist government policies. Monetary models of this class include those of Lucas and Stokey (1987, a monetary exchange model) and Coleman (1996, a monetary production model). Bizer and Judd (1989) and Coleman (1991) present models in which non-optimality is induced by tax distortions, while Danthine and Donaldson (1990) present a model in which non-optimality results from efficiency-wage considerations. In these models, equilibrium is characterized as an aggregate-consumption and an aggregate-investment function which jointly solves a system of first-order optimality equations on which market-clearing conditions have been imposed. Coleman (1991) provides a widely applicable set of conditions under which these suboptimal equilibrium functions exist. As already noted, however, these optimality conditions cannot, in general, characterize the solution to an optimum problem.

recursive contracts

Albert Marcet
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A number of dynamic models in economics are formulated with forward-looking elements in the constraints – for example, models of risk-sharing with participation constraints and models of optimal policy. Here, standard dynamic programming does not apply. Recent contributions show how to reformulate these models by either rewriting the forward-looking constraints (promised utility approach) or by using a Lagrangean formulation (recursive Lagrangean). Both make it possible to obtain a recursive formulation that allows for easier computation and analytical results. A number of applications can be found to optimal fiscal or monetary policy, risk sharing or investment with various financial constraints, and employment decisions.

Article

In contract theory it is standard to introduce a participation constraint (PC) insuring that the contract offered to the agent delivers a utility higher than the best outside option. In a dynamic set-up agents may abandon the contract at any point in time, even after the contract has been in place for a while. For example, workers can leave a labour contract at almost no cost, or a borrower can stop repaying the loan if he or she declares bankruptcy. The possibility that the agent does not continue with the plan of the contract is usually called ‘default’. Hence, in a dynamic context, it is natural to require that the PC is satisfied in all periods, in order to avoid default.
It turns out that, if a PC in all periods and realizations is introduced in the design of the optimal contract, standard dynamic programming does not apply, the Bellman equation does not hold, and the solution is not guaranteed to be a time-invariant function of the usual state variables. This complicates enormously the solution of these models.

To discuss this in a simple risk-sharing model, consider two agents \(i=1,2\) with utility function \(E_0 \sum_{t=0}^{\infty} \beta^t u(c^i_t)\), where \(\beta \in (0,1)\) is the discount factor and \(u\) the instantaneous utility. Each agent receives a stochastic endowment \(w^i_t\) and the realization of endowments is known both to the agents and the principal. The principal has full commitment, and will stick to his announced plan. Endowments provide the only supply of consumption good so that the following feasibility condition holds

\[c^1_t + c^2_t = w^1_t + w^2_t\]  

(1)

A Pareto-optimal risk-sharing contract (implemented by a competitive equilibrium under complete markets) would set \(u'(c^1_t)\) and \(u'(c^2_t)\) constant for all periods, so that agents would share all idiosyncratic risks. This allocation would be chosen as the optimal contract if agents would commit to never leave the risk-sharing arrangement. We refer to this allocation as the first best. The optimum satisfies the usual recursive structure in dynamic models, namely, that \(c_t = F(w_t)\) where \(F\) is a time-invariant function and \(w_t = (w^1_t, w^2_t)\).

Assume now agents cannot commit to staying in the contract for ever. An agent can leave the contract and consume for ever his individual endowment, so that a contract can only be implement if it satisfies

\[E_t \sum_{j=0}^{\infty} \beta^j u(c^i_{t+j}) \geq V^a_i(w_t)\]

at all periods and realizations, where \(V^a_i(w_t) \equiv E_t \sum_{j=0}^{\infty} \beta^j u(w^i_{t+j})\) is the utility of consuming in autarky for ever after \(t\).

It is clear that the above PC is likely to be violated by the first best allocation. In periods when \(w^i_t\) is high, the right side of the PC is high, but the agent has to surrender a large part of his endowment in the first best and the left side of the PC is too low. Therefore, PCs are often binding and they make the first best unfeasible.

A Pareto-optimal risk-sharing contract with PCs can now be found by maximizing the weighted utility
of the two agents $E_0 \sum_{t=0}^{\infty} \beta^t [\lambda u(c^1_t) + (1 - \lambda) u(c^2_t)]$ subject to the above PC for all periods and realizations and for both agents. The parameter $\lambda$ indexes all such Pareto-optimal allocations. The result is an optimal contract under full commitment by the principal and partial commitment by the agents.

The Bellman equation does not give the solution to this problem. A key feature of standard dynamic programming is that the set of feasible actions must depend only on variables that were determined last period and the current shock. But it is possible to evaluate if a certain consumption level $\bar{c}_t$ satisfies the PC at time $t$ only if future plans for consumption are known.

Intuitively, a promise of higher consumption in the future makes a lower consumption today compatible with the PC. But in order to implement this plan the principal has to ‘remember’ all the promises for higher consumption that were made in the past. Therefore, the optimal solution is unlikely to be a function of only today’s endowment, the principal also needs to recall if, say, ten periods ago, the PC of one of the agents was binding.

As argued by Kydland and Prescott (1977), the same problem arises in models of optimal policy. The future restricts today’s actions through the first order conditions of optimality of the agents, this causes the Bellman equation to fail and, in their language, the solution was time inconsistent. We find the same difficulty in contracting models of private information with incentive constraints, where some relevant piece of information is hidden from the principal, and more generally, in game theoretical models where an agent optimizes subject to the plans for the future of another agent.

If the Bellman equation fails, the solution could depend on all past shocks, and solving for the variables as a function of all past shocks would be very difficult. Too many variables would appear as arguments of the decision function. To overcome this difficulty the ‘recursive contracts’ literature provides several alternatives. The general idea is to recover a recursive formulation by adding a co-state variable.

One approach builds on the paper of Abreu, Pierce and Stachetti (1990; hereafter APS). To show how this can be applied in the above risk-sharing model with PCs, consider the case where $w_t$ is i.i.d. and has two possible realizations $\bar{w}$ and $\tilde{w}$ with probabilities $\pi$ and $(1 - \pi)$. Denote the utility of agent $i$ for the whole future at $t$ if $w_t = \bar{w}$ by $\bar{v}_t = E_t(\sum_{j=0}^{\infty} \beta^j u(c^i_{t+j}) | w_t = \bar{w})$, and let $\tilde{v}_t$ be the analogue for realization $\tilde{w}$. The above PC can be reformulated as

$$v^i_t = u(c^i_t) + \beta \left( \pi \bar{v}^i_{t+1} + (1 - \pi) \tilde{v}^i_{t+1} \right)$$

(2)

$$\bar{v}^i_{t+1} \geq v^i(\bar{w}), \quad \tilde{v}^i_{t+1} \geq v^i(\tilde{w}) \text{ for all } t > 0,$$
where $V_t^i$ is the actual realized utility. The first equation insures that $V_t^i$ is the expected discounted utility, the second guarantees that the PC holds.

We can view the planner's choice at $t$ as choosing the promised utilities $V_{t+1}^i, V_{t+1}^j$ and consumption $c_t^i$, while $V_t^i$ is given by past choices. It is clear that, in the APS approach, today's choice variables $x_t = (V_{t+1}^i, V_{t+1}^j, c_t^i)$ are restricted by yesterday's promised utilities only, and the Bellman equation delivers the optimal contract after the realized $V_t^i$ is included in the list of state variables. The promised utility $V_t^i$ plays the same role as capital in a standard growth model, and (2) plays the role of the transition equation. Therefore, the optimal solution for the choices can be described recursively by a time-invariant function $x_t = F(w_t, V_t)$ for all $t > 0$.

A crucial caveat is that (2) is not sufficient to insure that the PCs are satisfied. The principal could choose arbitrarily high consumption and have ever higher $V$s to satisfy (2), in a sort of Ponzi scheme for utility. The promised utilities have to be further restricted to belong to a feasible set. Let us call $\mathcal{S} \subset \mathcal{R}$ the feasible set of utilities such that, for each element $\nu \in \mathcal{S}$, there is a sequence of consumptions $\{c_{t+j}^i\}$ that satisfy (1) and the PCs such that $\nu_t = \mathbb{E}_t(\sum_{j=0}^{\infty} \beta^j u(c_{t+j}^i) | w_t = \bar{w})$. Results in APS insure that this set is convex. Since in this case $\mathcal{S} \subset \mathcal{R}$, this set is an interval and there exist bounds $\tilde{V}_L^i$ and $\tilde{V}_U$ such that adding the constraints

$$\tilde{V}_L^i \leq V_{t+1}^i \leq \tilde{V}_U$$

(and similarly for $\bar{V}_t$) to (2) is enough to insure feasibility. These bounds can be easily introduced in the Bellman equation and this guarantees that the chosen consumption sequences satisfies the PC. The only complication is that upper bound $\tilde{V}_U$ needs to be computed separately, as it is not a datum of the problem ($\tilde{V}_L^i$ is trivially equal to $V^1_i(\bar{w})$).

Another difference with standard dynamic programming is that the initial utility $V_0^1$ is an outcome of the solution and it is not fixed beforehand. This feature shows how time inconsistency arises in this model, since the choice for $V$ in period zero is not given, but in future periods it is given from the past. Promised utilities as co-states have been used extensively in models with incentive or participation constraints. Among others, Phelan and Townsend (1991) studied a model of risk-sharing with incentive constraints, Kocherlakota (1996) analysed the risk-sharing model with the PC described above, Hopenhayn and Nicolini (1997) a model of unemployment insurance and Alvarez and Jermann (2000) a
recursive contracts: The New Palgrave Dictionary of Economics
decentralized version of the above risk-sharing model with debt constraints. In models of Ramsey
equilibria it has been used by Golosov, Kocherlakota and Tsyvinski (2003) to study optimal taxation
under private information and Chang (1998) in a model of optimal monetary policy.
The main problem with this approach is the computation of the set of feasible utilities $\tilde{\mathbf{S}}$. In the specific
model described above this is not too costly, because it involves finding only two numbers, namely, the
upper bounds $\bar{V}_U$, $\bar{V}_U$. But the difficulties multiply when more than one co-state variable is needed. For
example, if a third agent is included in the above risk-sharing model, the co-state variables would be
$(V^1_t, V^2_t)$. Results in APS guarantee that the set of feasible utilities $\tilde{\mathbf{S}} \subset \mathbb{R}^2$ is convex, but now it is a
generic set, not an interval. Computing a set is much harder than computing two numbers. Some papers
overcome these difficulties; for example, Abraham and Pavoni (2005), who show how to find such a set
in a model of saving under private information, or the paper of Judd, Yeltekin and Conklin (2003). But
the difficulties increase very fast with the dimensionality of the promised utilities.
Furthermore, in some models, the set of feasible promised utilities changes every period. If a
‘traditional’ state variable (say, capital stock) appears in the problem, the set of feasible utilities is
different depending on the level of capital, so that the feasible set is now given by a correspondence
$\tilde{\mathbf{S}}(k)$. The researcher now needs to solve for a mapping from capital stock to sets. Phelan and Stacchetti
(2001) compute in this way the optimal fiscal policy in a model with capital.
An alternative to APS is the Lagrangean approach described in Marcet and Marimon (1998). The
Lagrangean for the optimal risk-sharing problem with PC is

$$
L = E_0 \sum_{t=0}^{\infty} \beta^t \left[ \lambda u(c^1_t) + (1 - \lambda) u(c^2_t) + \sum_{i=1,2} \gamma^i_t \left( E_t \sum_{j=0}^{\infty} \beta^j u(c^i_{t+j}) - V^a_i(w_t) \right) \right]
$$

where $\gamma^i_t \geq 0$ is the Lagrange multiplier of the PC. This can be rewritten as

$$
L = E_0 \sum_{t=0}^{\infty} \beta^t \left[ (\lambda + \mu^1_t) u(c^1_t) + (1 - \lambda + \mu^2_t) u(c^2_t) \right] s.t. \quad \mu^i_t = \mu^i_{t-1} + \gamma^i_t, \quad \gamma^i_t \geq 0, \quad \mu^i_{-1} = 0
$$

In this formulation, only current and past variables enter in the objective and in the constraints of this
Lagrangean, and a proper initial condition for $\mu$ is given. In this approach, $\mu_t$ plays the role of the co-
state variable instead of the promised utility in the APS approach. A saddle point functional equation
(analogous but not equal to the Bellman equation) is satisfied, insuring that the optimal solution satisfies
$(c_t, \gamma_t, V_t) = G(\mu_{t-1}, w_t)$ with $\mu^{i}_{-1} = 0$ for a time invariant function $G$. 

The equilibrium satisfies $\frac{u'(c^1_t)}{u'(c^2_t)} = \frac{1 - \lambda + \mu^2_t}{\lambda + \mu^1_t}$. If the PC for agent $i$ is binding, the corresponding $\gamma^i_t$ is strictly positive, the weight $\mu^i_t$ goes up and so does $c^i_t$. The increase in $\mu$ is permanent (at least until another PC is binding). In this way the principal avoids default by spreading the reward over time in order to enhance smoothing of consumption.

Note that the initial value of $\mu$ is given and equal to zero, while in future periods $\mu_{t-1}$ needs to be set according to past Lagrange multipliers. Therefore, the initial value of the co-state does not need to be found separately as in APS. It is clear that, if the principal could re-optimize ignoring past commitments at sometime $t$, he or she would ignore the past co-state and reset $\mu = 0$. This is how time inconsistency is reflected in this formulation.

In the Lagrangean approach there is no need to find the set of feasible utilities. The only constraint on the co-states is the non-negativity constraint on $\gamma$’s. Application to models with capital accumulation and several co-states is much easier; for example, Marcet and Marimon (1992) solve a risk-sharing growth model with PC as described above and capital accumulation, Aiyagari et al. (2002) in a Ramsey equilibrium for fiscal policy under incomplete markets, where debt is a state variable, Attanasio and Ríos-Rull (2000) risk-sharing in small villages, Scott (2007) a model of optimal taxes with capital, Kehoe and Perri (2002) international capital flows with capital accumulation under PC, King, Kahn and Wolman (2003) optimal monetary policy, Cooley, Marimon and Quadrini (2004) a model of investment under private information, Abraham and Carceles-Poveda (2006) discuss how to decentralize a model with participation constraints, and Ferrero and Marcet (2004) and Scholl (2004) a model of temporary exclusion in the case of default. The drawback of the Lagrangean approach is that, at this writing, the theory for the non-convex case and for the private information case is still incomplete.

Recursive preferences characterize the trade-offs between current and future consumption by summarizing the future with a single index, the certainty equivalent of next period's utility. Recursive utility functions are built from two components. A risk aggregator encodes trade-offs across the outcomes of a static gamble and, hence, defines the certainty equivalent of future utility. A time aggregator encodes trade-offs between current consumption and the certainty equivalent of future utility. We suggest functional forms for time and risk aggregators with desirable properties for applications in economics and finance, such as the standard intertemporal consumption/portfolio problem, which we solve using dynamic programming.

Article
1 Introduction

Recursive methods have become a standard tool for studying economic behaviour in dynamic stochastic environments. In this chapter, we characterize the class of preferences that is the natural complement to this framework, namely recursive preferences.

Why model preferences rather than behaviour? Preferences play two critical roles in economic models. First, preferences provide, in principle, an unchanging feature of a model in which agents can be confronted with a wide range of different environments, institutions, or policies. For each environment,
we derive behaviour (decision rules) from the same preferences. If we modelled behaviour directly, we
would also have to model how it adjusted to changing circumstances. The second role played by
preferences is to allow us to evaluate the welfare effects of changing policies or circumstances. Without
the ranking of opportunities that a model of preferences provides, it's not clear how we should
distinguish good policies from bad.

Why recursive preferences? Recursive preferences focus on the trade-off between current-period utility
and the utility to be derived from all future periods. Since an agent's actions today can affect the
evolution of opportunities in the future, summarizing the future consequences of these actions with a
single index, that is, future utility, allows multi-period decision problems to be reduced to a series of two-
period problems, and in the case of a stationary infinite-horizon problem, a single, time-invariant two-
period decision problem. As we will see, this logic applies equally well to environments in which
current actions affect the values of random events for all future periods. In this case, the two-period
trade-off is between current utility and a *certainty equivalent* of random future utility. This recursive
approach not only allows complicated dynamic optimization problems to be characterized as much
simpler and more intuitive two-period problems, it also lends itself to straightforward computational
methods. Since many computational algorithms for solving stochastic dynamic models themselves rely
on recursive methods, numerical versions of recursive utility models can be solved and simulated using
standard algorithms.

2 The stationary recursive utility function

Assume time is discrete, with dates $t=0,1,2,...$. At each $t>0$, an event $z_t$ is drawn from a finite set $\mathcal{Z}$,
following an initial event $z_0$. The $t$-period history of events is denoted by $z^t=(z_0, z_1, ..., z_t)$ and the set of
possible $t$-histories by $\mathcal{Z}^t$. Environments like this, involving time and uncertainty, are the starting point
for much of modern economics. A typical agent in such a setting has preferences over payoffs $c(z^t)$ for
each possible history. A general set of preferences might be represented by a utility function $U(\{c(z^t)\})$.
In what follows, we will think of consumption as a scalar. This is purely for exposition since the
extension to a vector of consumption at each point in time is straightforward.

Consider the structure of preferences in this dynamic stochastic environment. We define the class of
stationary recursive preferences by

$$U_t = V[Z_t, \mu_t(U_{t+1})],$$

where $U_t$ is short-hand for utility starting at some date-$t$ history $z^t$, $U_{t+1}$ refers to utilities for histories $z^{t+1}=(z^t, z_{t+1})$ stemming from $z^t$, $V$ is a time aggregator, and $\mu_t$ is a certainty-equivalent function based on
the conditional probabilities $p(z_{t+1}|z^t)$. As with other utility functions, increasing functions of $U$, with
suitable adjustment of $\mu$, imply the same preferences. This structure of preferences leads naturally to
recursive solutions of economic problems, with (1) providing the core of a Bellman equation.

In general, the properties of $U_t$ depend on both the properties of the time aggregator and the certainty equivalent. Since the certainty equivalent will be scaled such that $\mu(x) = x$ when $x$ is a perfect certainty, the time aggregator $V$ is all that matters in deterministic settings. Similarly, for a purely static problem with uncertainty, the certainty-equivalent function $\mu$ is all that matters. We consider the specification of each of these components in turn.

It is important to note that the utility functions presented in this article are not ad hoc but rather have clear axiomatic foundations, and can be derived from more primitive assumptions on preference orderings. Since utility functions are the typical starting point for applied research, we skip this step and refer the interested reader to the axiomatic characterizations of recursive preferences in the papers cited at the end of this article.

3 The time aggregator

Time preference is a natural starting point. Suppose there is no risk and $c_t$ is one-dimensional. Preferences might then be characterized by a general utility function $U(\{c_t\})$. A common measure of time preference in this setting is the marginal rate of substitution between consumption at two consecutive dates ($c_t$ and $c_{t+1}$, say) along a constant consumption path ($c_t = c$ for all $t$). If the marginal rate of substitution is

$$\text{MRS}_{t,t+1} = \frac{\partial U / \partial c_{t+1}}{\partial U / \partial c_t},$$

then time preference is captured by the discount factor

$$\beta(c) \equiv \text{MRS}_{t,t+1}(c).$$

(Picture the slope, $-1/\beta$, of an indifference curve along the '45-degree line'.) If $\beta(c)$ is less than one, the agent is said to be impatient: along a constant consumption path (that is, in the absence of diminishing marginal utility considerations), the agent requires more than one unit of consumption at $t+1$ to induce a sacrifice of one unit at $t$.

For the traditional time-additive utility function,

$$U(\{c_t\}) = \sum_{t=0}^{\infty} \beta^t u(c_t),$$
β (<i>c</i>) = β < 1 regardless of the value of <i>c</i>, so impatience is built in and constant. A popular and useful special case of this utility function implies a constant elasticity of intertemporal substitution by assuming <i>u(c) = c<p>ρ</p> / ρ</i> for ρ < 1. Note that we can define the utility function in (2) recursively:

\[ U_t = u(c_t) + \beta U_{t+1}, \]

(3)

for <i>t = 1, 2, ...</i>. The constant elasticity version can be expressed

\[ U_t = [(1 - \beta) c_t^p + \beta U_{t+1}^p]^{1/p}, \]

(4)

where ρ < 1 and σ = 1/(1 - ρ) is the intertemporal elasticity of substitution. (To put this in additive form, use the transformation \( \hat{U} = U^p / \rho \).) Note that \( U_t \) is homothetic and that the scaling we have chosen measures utility on the same scale as consumption:

\[ U(c, c, c, ...) = c. \]

More generally, impatience summarized by the discount factor, β (<i>c</i>), could vary with the level of consumption. Koopmans (1960) derives a class of stationary recursive preferences by imposing conditions on a general utility function \( U \) for a multi-dimensional consumption vector <i>c</i>. In the Koopmans class of preferences, time preference is a property of the time aggregator \( V \). Consider our measure of time preference:

\[ U_t = V(c_t, U_{t+1}) = V[c_t, V(c_{t+1}, U_{t+2})]. \]
The marginal rate of substitution between \( c_t \) and \( c_{t+1} \) is therefore

\[
\text{MRS}_{t,t+1} = \frac{V_2(c_t, U_{t+1})V_1(c_{t+1}, U_{t+2})}{V_1(c_t, U_{t+1})}.
\]

A constant consumption path at \( c \) is defined by \( U = V(c, U) \), implying \( U = g(c) = V[c, g(c)] \) for some function \( g \).

In modern applications, we typically work in reverse order: we specify a time aggregator \( V \) and use it to characterize the overall utility function \( U \). Any \( U \) constructed this way defines preferences that are stationary and dynamically consistent. In contrast to time-additive preferences, discounting depends on the level of consumption \( c \).

The most common example of Koopmans's structure in applications is a generalization of eq. (3):

\[
V(c, U) = u(c) + \beta(c) U,
\]

where there is no particular relationship between the functions \( u \) and \( \beta \). For this example, the intertemporal trade-off is given by

\[
\text{MRS}_{t,t+1} = \beta(c_t) \left[ \frac{u'(c_{t+1}) + \beta'(c_{t+1}) U_{t+2}}{u'(c_t) + \beta'(c_t) U_{t+1}} \right].
\]

When \( \beta'(c) \neq 0 \), optimal consumption plans will depend on the level of future utility. And along a constant consumption path, discounting is decreasing (increasing) in consumption when \( \beta'(c) < 0 \) (\( \beta'(c) > 0 \)). Also note that \( U_t \) in this example is not homothetic.

4 The risk aggregator

Turn now to the specification of risk preferences, which we consider initially in a static setting. Choices have risky consequences or payoffs, and agents have preferences defined over those consequences and their probabilities. To be specific, let us say that the state \( z \) is drawn with probability \( p(z) \) from the finite set \( z = \{1, 2, \ldots, Z\} \). Consequences \( (c, \text{say}) \) depend on the state and the agent's preferences are represented...
by a utility function of state-contingent consequences (‘consumption’):

\[ U(\{c(z)\}) = U[c(1), c(2), \ldots, c(Z)]. \]

At this level of generality there is no mention of probabilities, although we can well imagine that the probabilities of the various states will show up somehow in \( U \). We regard the probabilities as known, which you might think of as an assumption of ‘rational expectations’.

We prefer to work with a different (but equivalent) representation of preferences. Suppose, for the time being, that \( c \) is a scalar; very little of the theory depends on this, but it streamlines the presentation. We define the \textit{certainty equivalent} of a set of consequences as a certain consequence \( \mu \) that gives the same level of utility:

\[ U(\mu, \mu, \ldots, \mu) = U[c(1), c(2), \ldots, c(Z)]. \]

If \( U \) is increasing in all its arguments, we can solve this for the certainty-equivalent function \( \mu(\{c(z)\}) \). Clearly \( \mu \) represents the same preferences as \( U \), but we find its form particularly useful. For one thing, it expresses utility in payoff (‘consumption’) units. For another, it summarizes behaviour towards risk directly: since the certainty equivalent of a sure thing is itself, the impact of risk is simply the difference between the certainty equivalent and expected consumption.

The traditional approach to preferences in this setting is expected utility, which takes the form

\[ U(\{c(z)\}) = \sum_z p(z) u[c(z)] = E_u(c), \]

or

\[ \mu(\{c(z)\}) = u^{-1}\left(\sum_z p(z) u[c(z)]\right) = u^{-1}[E_u(c)]. \]

Preferences of this form have been used in virtually all economic theory. The utility function of Kreps and Porteus employs a general time aggregator and an expected utility certainty equivalent. Following Epstein and Zin, many recent applications, particularly in dynamic asset pricing models, use the
Recursive preferences: The New Palgrave Dictionary of Economics

Homothetic version of this utility function which combines the constant elasticity time aggregator in (4) with a linear homogeneous (constant relative risk aversion) expected utility certainty equivalent. Empirical research both in the laboratory and in the field has documented a variety of difficulties with the predictions of expected utility models. In particular, people seem more averse to bad outcomes than implied by expected utility. In response to this evidence, there is a growing body of work that looks at decision making under uncertainty outside of the traditional expected utility framework. Without surveying all of these extensions, we demonstrate the basic mechanics of recursive utility with non-expected utility certainty equivalents by studying one particular analytically convenient class of preferences in detail, the Chew–Dekel class. Notable among the alternatives to this class are recursive and dynamic extensions of the Gilboa and Schmeidler ‘max-min’ preferences.

The Chew–Dekel certainty equivalent function $\mu$ for a set of payoffs and probabilities $\{c(z), p(z)\}$ is defined implicitly by a risk aggregator $M$ satisfying

$$\mu = \sum_z p(z) M [c(z), \mu].$$  
(5)

Such preferences satisfy a weaker condition than the notorious independence axiom that underlies expected utility, yet like expected utility, they lead to first-order conditions in decision problems that are linear in probabilities, hence easily solved and amenable to econometric analysis. We assume $M$ has the following properties: (i) $M(m, m) = m$ (sure things are their own certainty equivalents), (ii) $M$ is increasing in its first argument (first-order stochastic dominance), (iii) $M$ is concave in its first argument (risk aversion), and (iv) $M(kc, km) = kM(c, m)$ for $k > 0$ (linear homogeneity). Most of the analytical convenience of the Chew–Dekel class follows from the linearity of eq. (5) in probabilities. (Note that this implies that indifference curves on the probability simplex are linear, but not necessarily parallel.) Examples of tractable members of the Chew–Dekel class include the following:

1. 1. Expected utility. A version with constant relative risk aversion (that is, linear homogeneity) is implied by

$$M(c, m) = c^\alpha m^{1-\alpha} / \alpha + m(1 - 1/\alpha).$$

If $\alpha \leq 1$, $M$ satisfies the conditions outlined above. Applying (5), we find

$$\mu = \left( \sum_z p(z) c(z)^\alpha \right)^{1/\alpha}.$$
the usual expected utility with a power utility function.

2. **Weighted utility.** A relatively easy way to generalize expected utility given (5): weight the probabilities by a function of outcomes. A constant-elasticity version follows from

\[ M(c, m) = (c/m) \gamma c^\alpha m^{1-\alpha} / \alpha + m[1 - (c/m)^\gamma / \alpha]. \]

For \( M \) to be increasing and concave in \( c \) in a neighbourhood of \( m \), the parameters must satisfy either (a) \( 0 < \gamma < 1 \) and \( \alpha + \gamma < 0 \) or (b) \( \gamma < 0 \) and \( 0 < \alpha + \gamma < 1 \). Note that (a) implies \( \alpha < 0 \), (b) implies \( \alpha > 0 \), and both imply \( \alpha + 2\gamma < 1 \). The associated certainty equivalent function is

\[ \mu^\alpha = \frac{\sum z p(z)c(z)^{\gamma+\alpha}}{\sum x p(x)c(x)^\gamma} = \sum \hat{p}(z)c(z)^\alpha, \]

where

\[ \hat{p}(z) = \frac{p(z)c(z)^\gamma}{\sum x p(x)c(x)^\gamma}. \]

This version highlights the impact of bad outcomes: they get greater weight than with expected utility if \( \gamma < 0 \), less weight otherwise.

3. **Disappointment aversion.** Another model that increases sensitivity to bad events (‘disappointments’) is defined by the risk aggregator

\[ M(c, m) = \begin{cases} c^\alpha m^{1-\alpha} / \alpha + m(1 - 1 / \alpha) & c \geq m \\ c^\alpha m^{1-\alpha} / \alpha + m(1 - 1 / \alpha) + \delta(c^\alpha m^{1-\alpha} - m) / \alpha & c < m \end{cases} \]
with $\delta \geq 0$. When $\delta = 0$ this reduces to expected utility. Otherwise, disappointment aversion places additional weight on outcomes worse than the certainty equivalent. The certainty equivalent function satisfies

$$
\mu^\alpha = \sum_z p(z) c(z)^\alpha + \delta \sum_z p(z) I[c(z) < \mu] [c(z)^\alpha - \mu^\alpha] = \sum_z \hat{p}(z) c(z)^\alpha,
$$

where $I(x)$ is an indicator function that equals one if $x$ is true and zero otherwise, and

$$
\hat{p}(z) = \left( \frac{1 + \delta I[c(z) < \mu]}{1 + \delta \sum_x p(x) I[c(x) < \mu]} \right) p(z).
$$

It differs from weighted utility in scaling up the probabilities of all bad events by the same factor, and scaling down the probabilities of good events by a complementary factor, with good and bad defined as better and worse than the certainty equivalent. (This implies a ‘kink’ in state-space indifference curves at certainty, which is referred to as ‘first-order’ risk aversion.) All three expressions highlight the recursive nature of the risk aggregator $M$: we need to know the certainty equivalent to know which states are bad so that we can compute the certainty equivalent (and so on).

5 Optimization and the Bellman equation

For an illustrative application of recursive utility, we turn to the classic Merton–Samuelson consumption/portfolio-choice problem. Consider a stationary Markov environment with states $z$ and conditional probabilities $\rho(z'|z)$. Preferences are represented by a constant-discounting/constant-elasticity aggregator and a general linear homogeneous certainty equivalent. A dynamic consumption/portfolio problem for this environment is characterized by the Bellman equation which implicitly defines the value function:

$$
J(a, z) = \max_{c, w} \left\{ (1 - \beta) c^\rho + \beta \mu [J(a', z')]^\rho \right\}^{1/\rho},
$$

subject to the wealth constraint, $a' = (a - c) \Sigma jw_i r_i(z, z') = (a - c) \Sigma jw_i r_i' = (a - c) r p$, where $a$
denotes wealth, \( r_p \) is the return on the portfolio \((w_1, w_2, \ldots, w_{N-1}, 1 - \sum_{i=1}^{N-1} w_i)\), of assets with risky returns \((r_1, r_2, \ldots, r_N)\). The budget constraint and linear homogeneity of the time and risk aggregators imply linear homogeneity of the value function: 

\[ J(a, z) = a L(z) \]

for some scaled value function \( L \). The scaled Bellman equation is

\[
L(z) = \max_{b, \omega} \left\{ (1 - \beta) b^\rho + \beta (1 - b)^\rho \mu [L(z') r_p(z, z')]^\rho \right\}^{1/\rho}, 
\]

where \( b \equiv c / a \). Note that \( L(z) \) is the marginal utility of wealth in state \( z \).

This problem divides into separate portfolio and consumption decisions. The portfolio decision solves:

choose \( \{w_i\} \) to maximize \( \mu [L(z') r_p(z, z')] \). The portfolio first-order conditions are

\[
\sum_{i} p(z' | z) M_{1} [L(z') r_p(z, z'), \mu] L(z') [r_i(z, z') - r_j(z, z')] = 0
\]

(6)

for any two assets \( i \) and \( j \).

Given a maximized \( \mu \), the consumption decision solves: choose \( b \) to maximize \( L \). The intertemporal first-order condition is

\[
(1 - \beta) b^{\rho - 1} = \beta (1 - b)^{\rho - 1} \mu^\rho.
\]

(7)

If we solve for \( \mu \) and substitute into the (scaled) Bellman equation, we find

\[
\mu = \left[ (1 - \beta) / \beta \right]^{1/\rho} \left[ b / (1 - b) \right]^{(\rho - 1)/\rho}
\]
The first-order condition (7) and value function (8) allow us to express the relation between consumption and returns in a familiar form. Since $\mu$ is linear homogeneous, the first-order condition implies $\mu(x' r_p') = 1$ for

$$x' = L' / \mu = \left[ \beta (c' / c)^{\rho - 1} (r_p')^{1-\rho} \right]^{1/\rho}.$$  

The last equality follows from $(c' / c) = (b' / b) (1 - b)r_p'$, a consequence of the budget constraint and the definition of $b$. The intertemporal first-order condition can therefore be expressed

$$\mu(x' r_p') = \mu \left( \left[ \beta (c' / c)^{\rho - 1} r_p' \right]^{1/\rho} \right) = 1, \tag{9}$$

a generalization of the tangency condition for an optimum (set the marginal rate of substitution equal to the price ratio). Similar logic leads us to express the portfolio first-order conditions (6) as

$$E \left[ M_1(x' r_p', 1) x' (r_i' - r_j') \right] = 0.$$ 

If we multiply by the portfolio weight $w_j$ and sum over $j$ we find

$$E \left[ M_1(x' r_p', 1) x' r_i' \right] = E \left[ M_1(x' r_p', 1) x' r_p' \right]. \tag{10}$$
Euler's theorem for homogeneous functions allows us to express the right side as

\[
E\left[M_1(x' r_p', 1)x' r_p'\right] = 1 - EM_2(x' r_p', 1).
\]

Whether this expression is helpful depends on the precise form of \( M \). For example, with disappointment aversion, (10) is

\[
E\left[z^{\alpha - 1}(1 + \delta l[z < 1]) \frac{r_i'}{r_p'}\right] = 1 + \delta E l[z < 1],
\]

where \( z = [\beta (c' / c)^{\rho - 1} r_p']^{1/\rho} \). This reduces to the Kreps–Porteus model when \( \delta = 0 \), and to the time-additive expected utility model when, in addition, \( \rho = \alpha \).

6 Conclusion

A recursive utility function can be constructed from two components: (a) a time aggregator that completely characterizes preferences in the absence of uncertainty and (b) a risk aggregator that defines the certainty equivalent function that characterizes preferences over static gambles and is used to aggregate the risk associated with future utility. We looked at natural candidates for each of these components and gave an example of how Bellman's equation can be used to characterize optimal plans in a dynamic stochastic environment when agents have recursive preferences.

7 Further reading

For more on this subject, see Backus, Routledge and Zin (2004) and the references cited there. Much of the material in this chapter builds from Epstein and Zin (1989), who extend the preferences in Kreps and Porteus (1978) to allow for a stationary infinite-horizon model and for non-expected utility certainty equivalents. They also derive the consumption/portfolio-choice results of Section (5). For more on time aggregators, see Koopmans (1960), Uzawa (1968), Epstein and Hynes (1983), Lucas and Stokey (1984), and Shi (1994). Common departures from expected utility are documented in Kreps (1988, ch. 14) and Starmer (2000). Epstein and Schneider (2003) and Hansen and Sargent (2004) propose different dynamic and recursive extensions of the max-min risk preference of Gilboa and Schmeidler (1993). The Chew–Dekel risk aggregator was proposed by Chew (1983; 1989) and Dekel (1986). Examples within this class: weighted utility (Chew, 1983), disappointment aversion (Gul, 1991), semi-weighted utility.
recursive preferences: The New Palgrave Dictionary of Economics

(Epstein and Zin, 2001), and generalized disappointment aversion (Routledge and Zin, 2003).

The topic of redistribution is sometimes interpreted narrowly in rather dry terms: as the description and quantification of the simple fact of change in an income or wealth distribution. This can apply both to an actual change that takes place through time and also to the apparent alteration of the distribution at a point in time by taxes and transfers, and principally involves problems of measurement that are common to other fields of applied economics. However, redistribution can also be seen as a specific goal for economic policymakers: as such it is a subject of special interest in its own right. Sections 1–4 below concentrate primarily on this second interpretation; some issues arising under the first interpretation are considered in Section 5.

1 The reason for wanting to redistribute

Perhaps the simplest and most direct reason for wishing to see a redistribution of income, consumption or wealth in the community is simple fellow feeling on the part of the citizens of the community. This can be incorporated into the utilitarian approach to welfare judgements within the tradition of Bentham and Mill, in two ways. One might suppose that judgements about distribution are made in a state of primordial ignorance about one’s own position in the distribution: social aversion to inequality is thus rationalized as individual aversion to risk (Harsanyi, 1955). Secondly, it might be supposed that the poor are made to feel worse off in their plight by the very knowledge that the well-to-do are well-to-do, and the rich are made to feel uncomfortable by the low living standards of the poor – see Hochman and Rodgers (1969). Thus the problems of inequality are rationalized within individual utilities as ‘externalities’ in a manner similar to health hazards from pollution. A weakness of this approach is that
it puts a heavy burden on the particular configuration of individual preferences that happen to be present within a given community at a given moment: should one really only redistribute if enough citizens happen to feel upset by it? And what if some citizens like knowing that the very poor are very poor? An alternative approach is to take the motivation for redistribution as a direct moral imperative – see Tawney (1965), Rawls (1971); improvement in the well-being of the disadvantaged is perceived as a social objective in its own right, along with other apparently desirable goals such as civil liberties and growth in national income.

2 The objectives of redistribution

Whatever the precise reasons for wishing to redistribute income or wealth may be, in broad terms the principal goals of redistribution policy can be stated very simply: the primary objectives are usually some goal of greater equity and of ‘social insurance’; and as a secondary, though important, desideratum, one is usually also concerned with economic efficiency.

In order to examine these objectives in more detail two concepts need to be carefully distinguished: redistribution ‘ex ante’ – the rearrangement of the structure of income-earning opportunities – and redistribution ‘ex post’ – the reallocation of income or wealth that results from the economic processes of production and exchange, whatever individual opportunities may have been. In practice the two concepts may be difficult to disentangle since a policy measure that apparently just rearranges the prizes (such as an income-tax scheme) may also have repercussions on some people’s ex ante opportunities (by, for example, affecting market wages); but both are relevant to a discussion of the relationship between equity and other goals.

In a very simplified model of the distribution of income, ‘equity’ can be expressed fairly easily: if one considers that the cake has been cut very unequally, then one sets about trying to even up the slices. But in a dynamic view of the economy where people make economic choices which affect their future incomes, the slices-of-a-fixed-size-cake analogy can be misleading, and the position may be further complicated when those choices have to be made in the face of uncertainty. Obviously the size of the national cake to be ‘shared out’ is not, in practice, fixed: individual incomes (and hence the total income in the community) are determined by the choices people make as to how much they work, save, and take entrepreneurial risks, and again the total stock of wealth obviously also depends on the rate at which people save. So the elementary equity question of who ought to get what cannot be divorced in practice from the issue of how individual incomes and wealth holdings are generated: efficiency considerations have to be taken into account in the pursuit of greater equity. There is a second, more subtle, difficulty: because of incompetence, ignorance or plain ‘bad luck’ people who may have looked alike in terms of their original economic opportunities turn out to be very dissimilar in terms of outcomes once a few rounds have been played of the great economic game that determines how much everybody actually gets. Hence there is a good case for a government concerned with distributional equity to pay attention to both the ex ante and the ex post concepts of redistribution (Hammond, 1981).

For this reason an interest in social insurance is often taken to be a natural counterpart of a concern for equity. The public provision of protection against the slings and arrows of outrageous fortune is particularly important for those events for which conventional insurance markets are likely to give inadequate coverage, such as unemployment or ill health, for example – see Atkinson (1987). By filling
such gaps social insurance may actually improve the efficient working of the economy. Besides this, social insurance can also apply to *ex post* redistribution that is intended to circumvent the otherwise unsatisfactory workings of some markets. For example, the markets for private insurance and savings might, under ideal circumstances, allow people to look after themselves effectively; but in practice problems such as imperfect information and the consequent rationing of insurance of credit to those people who are perceived to be good risks will mean that coverage is far from complete (Arrow, 1985). Hence the provision of state pensions as a means of cushioning the possibly unfortunate effects of restrictions on savings by people of modest means.

3 What should be redistributed?

Whether it is *income* (the flow of spending power during a given period) or *wealth* (the command over resources that a person may possess at a given point in time) that is to be redistributed depends to some extent on the precise definition of these terms (in particular the relevant period over which income is measured and the range of assets to be counted in as personal wealth) and also on the degree of importance that one attaches to *ex ante* or *ex post* concepts of redistribution. For example, some components of wealth (land, financial assets) may be regarded as part of the range of economic opportunities which results in the flow of spendable income. Again weekly money income might be more relevant than broader concepts of wealth or long-term income if one’s primary concern is for redistribution to alleviate short-term need rather than to alter the structure of economic opportunities (Atkinson, 1983, ch. 3).

However, the issue of what one ought to use in order to achieve the objectives of redistribution cited above raises further questions. One of the most important of these is whether one ought to redistribute income itself (which yields purchasing power over consumption goods) or rather the consumption goods directly. The standard answer provided by economists is that cash is unquestionably more effective, since it allows individuals to be the judges of what is best for their welfare and to make substitutions between different goods under varying market conditions in pursuit of that welfare: money to buy soup is supposedly more effective than the provision of soup kitchens. However, this conclusion is strictly relevant only if one imposes a number of stringent conditions, for example, the assumption that everyone has access to perfect market opportunities and accurate information on which to base his judgement in the market. It is invalid in the presence of multiple market equilibria (Foldes, 1967). It ignores pressing requirements of crises such as war and famine: extreme circumstances may require direct intervention to act more swiftly and reliably to maintain living standards than the often capricious and sluggish movements of the ‘invisible hand’.

4 The available instruments

Among the more obvious instruments available for *ex post* redistribution are taxes on income, wealth and the transfer of wealth via gifts and bequests, and transfer payments such as pensions and social-security benefits. However, it is not easy to draw a hard-and-fast line around the range of instruments that might be taken to be redistributive tools, particularly if one is concerned with description rather than prescription. There appears to be a good case in practice for including ‘indirect’ taxes (such as value
redistribution of income and wealth: The New Palgrave Dictionary of Economics

added tax), subsidies and also those benefits ‘in kind’ which are bestowed on particular households or persons, since the impact of these items on personal spending power is usually fairly clear. This may, for example, be extended to include such goods as state-provided education. However the precise distributional impact of publicly provided goods that are really consumed jointly by the community (in which category we might include items such as public sanitation, the police services, or even national defence) is less easy to determine, but should not be assumed to be negligible.

As an alternative to raising taxes and the public provision of goods and services, a government wishing to redistribute real spending power may choose to intervene directly in the market mechanism. The most obvious example of this policy is price control. This term applies not only to rationing and the regulation of prices paid by consumers for goods – which can be an effective method of intervention to achieve redistribution – in emergencies such as wartime, but also to the control of prices that individuals receive for services that they may supply (for example, minimum wage legislation) or assets that they possess (control of house rents).

The instruments available for the purposes of ex ante redistribution (that is, the means of reorganizing the opportunities for creating income and accumulating wealth) are more disparate. One has the immediate problem that the range of policies considered to be available is strongly influenced by the economic philosophy which one considers to be relevant to the analysis and by the political and social system within the community. Take a prime example of this: education. There are many opinions on the potential for using this as a redistributional tool, some of which may be crudely summarized by the following three views: (a) it is a passport to higher positions on a ladder of economic opportunity whose rungs are pretty rigidly fixed, so that greater equality can be achieved simply by changing the method of issuing the passports; (b) it forms part of a complex of personal or family investment decisions, whereby intervention in the provision of education might upset the efficient allocation of the market mechanism without doing anything to alleviate the inequality of economic opportunity; (c) even if effective redistribution could be achieved in principle, substantial reorganization of educational opportunities is bound to be limited by what are seen as fundamental freedoms of choice. Note that the divergence of view concerns both economic role of education and the extent to which one is free to use it as an instrument of public policy (Le Grand, 1982, ch. 4).

5 The effectiveness of the policy

Any attempt to quantify the effectiveness of redistribution policy has to surmount a number of extremely troublesome obstacles. In the first place one has to confront the problem of ‘unequal inequalities’, which essentially arises from an attempt to compare intrinsically complex social states. Even if one puts this in elementary terms, whereby every person's welfare is accurately measured by his or her income, a fundamental difficulty remains: apart from special circumstances – for example, a comparison involving a hypothetical state of perfect equality – the question of which of two distributions is the more unequal does not generally have a clear-cut answer. In practice, even a very successful redistribution policy will have diminished rather than completely eliminated real income differences, so that an assessment of the policy's impact necessarily involves a comparison of the apparent change in inequality that has been achieved relative to the degree of inequality that would have obtained otherwise. There is no single method for measuring such inequality changes that commands universal support, and hence no generally agreed measuring rod
to ascertain the extent of redistribution under all circumstances (Cowell, 1977; Foster, 1985). One of the practical difficulties to which this gives rise is that it is difficult to be dogmatic about labelling policy instruments in terms of degrees of ‘progressivity’ (Lambert, 1985). Moreover, in many cases redistribution may involve not just a narrowing (or indeed expansion) of income differentials, but also a re-ranking of income receivers within the pecking order so that, to quantify redistribution effectively, more is required than a simple measurement of the change in overall dispersion (Cowell, 1985).

The second problem follows directly from this: who is to say what would have happened otherwise and, therefore, what change in inequality has actually been achieved? If one is merely concerned with the documentation of trends in the perceived inequities of income distribution through time, this may not be too difficult. But if at any moment of history one attempts to draw the inference that ‘according to our chosen inequality index, the inequality of disposable income would have been 20 per cent higher than it is now but for the high marginal tax rates on upper income groups’, then one is making a much bolder assertion about how the underlying economic mechanisms are supposed to work. For the very presence of the instruments of redistribution policy will have influenced the choices people make about their jobs, business enterprises and savings, which in turn, can be expected to affect the resulting income distribution. The ‘distribution before tax’ – obtainable from a statistical office’s published figures – cannot automatically be taken to be the same thing as the distribution without the tax – the income distribution that one might expect to see if the relevant redistribution instrument were to be abolished. Some allowance for this problem is usually possible in the case of ex post redistribution instruments – for example, it is possible to estimate the likely repercussion on the supply of different types of labour that will arise because of the supplementation of some people's incomes by public transfers and the reduction in other people's incomes through taxation (Hausman, 1985; Killingsworth, 1983), or the impact on private savings of the presence of state-provided pensions and social insurance schemes (Danziger, Haveman and Plotnick, 1981; Kotlikoff, 1984). However, the allowance to be made for these feedback effects is usually quite sensitive to the particular model of household behaviour that is applied. Despite these reservations, some broad conclusions are possible. Very narrowly based measures run the danger of the ‘demarcation trap’: for example, subsidizing particular commodities or taxing only certain forms of income or wealth may present some people with an incentive to change their behaviour, or even misrepresent their true status, so as to profit by the artificial distinctions drawn by the selective tax or subsidy scheme. The effectiveness of the measure may thereby be reduced and, even if this does not happen, the discrimination of the scheme may itself create substantial inequities by treating essentially similar people in different ways. On the other hand, very broadly based measures may scatter their shot so widely that much of it misses the target: blanket allowances or exceptions within income- or wealth-tax laws, and some broadly defined educational subsidies are often found to be regressive in their actual ex post impact on income and wealth. Finally it is usually the case that taxes, taken as a whole, turn out not to be very progressive in terms of their ex post impact whereas transfers usually are.

reduced rank regression

Søren Johansen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The reduced rank regression model is a multivariate regression model with a coefficient matrix with reduced rank. The reduced rank regression algorithm is an estimation procedure which estimates the reduced rank regression model. It is related to canonical correlations and involves calculating eigenvalues and eigenvectors. We give a number of different applications to regression and time series analysis, and show how the reduced rank regression estimator can be derived as a Gaussian maximum likelihood estimator. We briefly mention asymptotic results.

Keywords

instrumental variable estimation; limited information maximum likelihood; maximum likelihood; reduced rank regression

Article

Reduced rank regression is an explicit estimation method in multivariate regression that takes into account the reduced rank restriction on the coefficient matrix.

Reduced rank regression model: We consider the multivariate regression of $Y$ on $X$ and $Z$ of dimension $p$, $q$, and $k$, respectively:

$$Y_t = \Pi X_t + \Gamma Z_t + \varepsilon_t, \quad t = 1, \ldots, T.$$

The hypothesis that $\Pi$ has reduced rank less than or equal to $r$ is expressed as $\Pi = \alpha \beta'$, where $\alpha$ is $p \times r$, and $\beta$ is $q \times r$, where $r < \min(p, q)$, and gives the reduced rank model

$$Y_t = \alpha \beta' X_t + \Gamma Z_t + \varepsilon_t, \quad t = 1, \ldots, T. \tag{1}$$

Reduced rank regression algorithm: In order to describe the algorithm, which we call $RRR(Y, X|Z)$, we introduce the notation for product moments $S_{yx} = T^{-1} \sum_{t=1}^{T} Y_t X_t'$, $S_{yx|z} = S_{yx} - S_{yz} S_{zz}^{-1} S_{zx}$, and so on. The algorithm consists of the following steps:

1. First, regress $Y$ and $X$ on $Z$ and form residuals $(\gamma|Z)_t = Y_t - S_{yz} S_{zz}^{-1} Z_t$, $(\chi|Z)_t = X_t - S_{xz} S_{zz}^{-1} Z_t$ and product moments

   $$S_{yx|z} = T^{-1} \sum_{t=1}^{T} (\gamma|Z)_t (\chi|Z)_t' = S_{yx} - S_{yz} S_{zz}^{-1} S_{zx},$$

   and so on.

2. Next, solve the eigenvalue problem

   $$\Pi = \alpha \beta' X_t + \Gamma Z_t + \varepsilon_t, \quad t = 1, \ldots, T.$$
reduced rank regression: The New Palgrave Dictionary of Economics

\[ |\lambda^2_{xx,z} - \lambda^2_{xy,z} \lambda^{-1}_{yx,z} = 0, \]

(2)

where \(|\cdot|\) denotes determinant. The ordered eigenvalues are \(\lambda = \text{diag}(\lambda_1, \ldots, \lambda_q)\) and the eigenvectors are \(V=(v_1, \ldots, v_q)\), so that

\[ S_{xx,z} V \Lambda = \lambda^{1/2} \lambda^{1/2} S_{yx,z} V, \]

and \(V\) is normalized so that \(V' S_{xx,z} V = I_p\) and \(V' S_{yx,z} \lambda^{1/2} S_{xy,z} V = \Lambda\). The singular value decomposition provides an efficient way of implementing this procedure; see Doornik and O'Brien (2002).

3. Finally, define the estimators

\[ \hat{\beta} = (v_1, \ldots, v_p) \]

with \(\hat{\alpha} = S_{yx,z} \hat{\beta}\), and \(\hat{\Omega} = S_{yy,z} - S_{yx,z} \hat{\beta} (\hat{\beta}' S_{xx,z} \hat{\beta})^{-1} \hat{\beta}' S_{xy,z}\). Equivalently, once \(\hat{\beta}\) has been determined, \(\hat{\alpha}\) and \(\hat{\Omega}\) are determined by regression.

The technique of reduced rank regression was introduced by Anderson and Rubin (1949) in connection with the analysis of limited information maximum likelihood and generalized to the reduced rank regression model (1) by Anderson (1951). An excellent source of information is the monograph by Reinsel and Velu (1998), which contains a comprehensive survey of the theory and history of reduced rank regression and its many applications.

Note the difference between the unrestricted estimate \(\hat{\Pi}_{OLS} = S_{yx,z} \lambda^{1/2}\) and the reduced rank regression estimate \(\hat{\Pi}_{RRR} = S_{yx,z} \hat{\beta} (\hat{\beta}' S_{xx,z} \hat{\beta})^{-1} \hat{\beta}' S_{xy,z}\) of the coefficient matrix to \(X\).

Applications of the reduced rank model and algorithm

The reduced rank model (1) has many interpretations depending on the context. It is obviously a way of achieving fewer parameters in the possibly large \(p \times q\) coefficient matrix \(\Pi\). Another interpretation is that, although \(X\) is needed to explain the variation of \(Y\), in practice only a few, \(r\), factors are needed as given by the linear combinations \(\beta' X\) in (1).

Restrictions on \(\Pi\): Anderson (1951) formulated the problem of estimating \(\Pi\) under \(p-r\) unknown restrictions \(\ell' \Pi = 0\). In (1) these are given by the matrix \(\ell = \alpha_1\), that is, a \(p \times (p-r)\) matrix of full rank for which \(\alpha_1' \alpha = 0\). The matrix \(\alpha_1\) is estimated by solving the dual eigenvalue problem

\[ 0_{p-r} = \lambda_{yx} S_{yy,z} S_{yx,zz}^{-1} S_{xy,z} = \hat{\alpha}_1. \]

which has eigenvalues \(\Lambda\) and eigenvectors \(W\), and the estimate is \(\hat{\alpha}_1 = (w_1, \ldots, w_{p-r})\). If \(p=q\), we can choose

\[ W = S_{yy,z} \lambda^{1/2} S_{yx,z} V \lambda^{1/2}. \]

Canonical correlations: Reduced rank regression is related to canonical correlations (Hotelling, 1936). This is most easily expressed if \(p=q\), where we find

\[ \begin{pmatrix} W & 0 \\ 0 & V \end{pmatrix} \begin{pmatrix} S_{yy,z} & S_{yx,z} \\ S_{xy,z} & S_{xx,z} \end{pmatrix} \begin{pmatrix} W & 0 \\ 0 & V \end{pmatrix} = \begin{pmatrix} I_p & \Lambda^{1/2} \\ \Lambda^{1/2} & I_q \end{pmatrix}. \]

This shows that the variables \(W'y\) and \(V'X\) are the empirical canonical variates.

Instrumental variable estimation: Let the variables \(U, V,\) and \(X\) be of dimension \(p, q,\) and \(k\) respectively with \(k \geq q\). Assume that they

are jointly Gaussian with mean zero and variance $\Sigma$, and that $E(U - Y'V)X' = 0$, so that $X$ is an instrument for estimating $Y$. This means that $\Sigma_{UX} = Y'\Sigma_X$, so that

$$E\left(\begin{pmatrix} U \\ V \end{pmatrix} | X \right) = \begin{pmatrix} Y'\Sigma_X \\ \Sigma_X \end{pmatrix}^{-1} X = \begin{pmatrix} Y' \\ \Sigma_X \end{pmatrix}^{-1} X = \alpha \beta'. $$

It follows that the $(P + Q) \times k$ coefficient matrix in a regression of $Y = (U', V')'$ on $X$ has rank $q$. Thus a reduced rank regression of $Y$ on $X$ is an algorithm for estimating the parameter of interest $Y$ using the instruments $X$. This is the idea in Anderson and Rubin (1949) for the limited information maximum likelihood estimation.

**Non-stationary time series:** The model

$\Delta Y_t = \alpha \beta' Y_{t-1} + \Gamma \Delta Y_{t-1} + \epsilon_t, \ t = 1, ..., T$

(3)

determines a multivariate times series $Y_t$, and the reduced rank of $\alpha \beta'$ implies non-stationarity of the time series. Under suitable conditions (see Johansen, 1996) $Y_t$ is non-stationary and $\Delta Y_t$ and $\beta' Y_t$ are stationary. Thus $Y_t$ is a cointegrated time series; see Engle and Granger (1987).

**Common features:** Engle and Kozicki (1993) used model (3) and assumed reduced rank of the matrix $(\alpha, \Gamma) = \xi \eta'$, so that $\Delta Y_t = \xi \eta' (Y'_{t-1} \beta, \Delta Y'_{t-1})' + \epsilon_t$. In this case $\xi' \Delta Y_t = \xi' \epsilon_t$ determines a random walk, where the common cyclic features have been eliminated.

**Prediction:** Box and Tiao (1977) analysed the model $Y_t = \Pi Y_{t-1} + \Gamma Y_{t-2} + \epsilon_t$, and asked which linear combinations of the current values, $\dot{Y}_t$, are best predicted by a linear combination of the past $(Y_{t-1}, Y_{t-2})$, and hence introduced the analysis of canonical variates in the context of prediction of times series.

**The Gaussian likelihood analysis**

If the errors $\epsilon_t$ in model (1) are i.i.d. Gaussian $N_p(0, \Omega)$, and independent of $\{X_s, Z_s, s \leq t\}$, the (conditional or partial) Gaussian likelihood is

$$-\frac{T}{2} \log |\Omega| - \frac{1}{2} \sum_{t=1}^{T} (Y_t - \alpha \beta' X_t - \Gamma Z_t)' \Omega^{-1} (Y_t - \alpha \beta' X_t - \Gamma Z_t).$$

Anderson (1951) introduced the $RRR$ algorithm as a calculation of the maximum likelihood estimator of $\alpha \beta'$. The Frisch–Waugh theorem shows that one can partial out the parameter $\Gamma$ by regression, as in the first step of the algorithm. We next regress $(Y|Z)$ on $(\beta' X|Z)$ and find estimates of $\alpha$ and $\Omega$, and the maximized likelihood function as functions of $\beta$:

$$\hat{\alpha}(\beta) = S_{YX, Z} \beta (S'_{XZ, Z} \beta)^{-1},$$

(4)
\[ \hat{\Omega}(\beta) = S_{yy,z} - S_{yx,z}\beta (\beta' S_{xx,z}\beta)^{-1} \beta' S_{xy,z}. \]

\[ \frac{-2}{T} \ln \hat{\Omega}(\beta) = \ln \hat{\Omega}(\beta). \]

The identity

\[
\begin{pmatrix}
S_{yy,z} & S_{yx,z} \\
\beta' S_{xy,z} & \beta' S_{xx,z}
\end{pmatrix}
= |S_{yy,z}| |\beta' (S_{xx,z} - S_{xy,z} S_{yy,z}^{-1} S_{xy,z})\beta| / |\beta' S_{xx,z}\beta|
\]

shows that \( \frac{-2}{T} \ln \hat{\Omega}(\beta) = |S_{yy,z}| |\beta' (S_{xx,z} - S_{xy,z} S_{yy,z}^{-1} S_{xy,z})\beta| / |\beta' S_{xx,z}\beta| \) so that \( \beta \) has to be chosen to minimize this.

Differentiating with respect to \( \beta \) we find that \( \beta \) has to satisfy the relation \( S_{xx,z}\beta = S_{xy,z} S_{yy,z}^{-1} S_{xy,z} \beta \xi \) for some \( r \times r \) matrix \( \xi \). This shows (see Johansen, 1996) that the space spanned by the columns of \( \beta \), is spanned by \( r \) of the eigenvectors of (2), and hence, that choosing the largest \( \lambda_i \) gives the smallest value of \( \frac{-1}{T} \ln \hat{\Omega}(\beta) \), so that

\[ \hat{\beta} = (\nu_1, ..., \nu_r), \frac{-2}{T} \ln \hat{\Omega}(\hat{\beta}) = |S_{yy,z}| \prod_{i=1}^{r} (1 - \lambda_i). \]

Hypothesis testing: The test statistic for rank of \( \Pi \) can be calculated from the eigenvalues because the eigenvalue problem solves the maximization of the likelihood for all values of \( r \) simultaneously. The likelihood ratio test statistic for the hypothesis \( \text{rank}(\Pi) \leq r \), as derived by Anderson (1951), is

\[ -2 \log LR(\text{rank}(\Pi) \leq r) = \sum_{i=r+1}^{\min(p,q)} \log (1 - \lambda_i). \]

(5)

Bartlett (1938) suggested using this statistic to test that \( r \) canonical correlations between \( Y \) and \( X \) were zero and hence that \( \Pi \) had reduced rank.

The simplest hypothesis to test on \( \beta \) is \( \beta = H\phi \). We can estimate \( \beta \) under this restriction by \( \text{RRR}(Y, H' X|Z) \) and therefore calculate the likelihood ratio statistic using reduced rank regression. If, on the other hand, we have restrictions on the individual vectors...
reduced rank regression: The New Palgrave Dictionary of Economics

β = (H₁φ₁, ..., Hₚφᵩ), then reduced rank regression does not provide a maximum likelihood estimator, but we can switch between reduced rank regressions as follows. For fixed β₁, ..., βᵢ₋₁, βᵢ₊₁, ..., βᵩ, we can find an estimator for \( φ_i \) and hence \( β_i = H_iφ_i \) by

\[
\text{RRR}(Y, H_i, X; (β₁, ..., βᵢ₋₁, βᵢ₊₁, ..., βᵩ)'X).
\]

By switching between the vectors in \( β \), we have an algorithm which is useful in practice and which maximizes the likelihood in each step.

A switching algorithm: Another algorithm, that is useful for this model, is to consider the first order condition for \( β \), when \( Γ \) has been eliminated, which has solution

\[
\hat{β}(α, Ω) = S_{xx, z}^{-1}S_{xy, z}Ω^{-1}α(α'Ω^{-1}α)^{-1}.
\]

Combining this with (4) suggests a switching algorithm, as follows.

First choose some initial estimator \( \hat{β}_0 \), then switch between estimating \( α \) and \( Ω \) for fixed \( β \) by least squares, and estimating \( β \) for fixed \( α \) and \( Ω \) by generalized least squares.

This switching algorithm maximizes the likelihood function in each step and any limit point will be a stationary point. It seems to work well in practice. There are natural hypotheses one can test in the reduced rank model, like general linear restrictions on \( β \), which are not solved by the reduced rank regression algorithm, whereas the above algorithm can be modified to give a solution.

Asymptotic distributions in the stationary case: The asymptotic distributions of the estimators and test statistics can be described under the assumption that the process \( (Y_t, X_t, Z_t) \) is stationary with finite second moments. It can be shown that estimators are asymptotically Gaussian and test statistics for hypotheses both for rank and for \( β \) are asymptotically \( χ^2 \); see Robinson (1973).

Asymptotic distributions in the non-stationary case: If the processes are non-stationary a different type of asymptotics is needed. As an example consider model (3) for \( I(1) \) variables. When discussing the asymptotic distribution of the estimators, the normalization by \( \hat{β}'S_{xx, z}\hat{β} = I_r \) is not convenient, and it is necessary to identify the vectors differently.

One can then prove (see Johansen, 1996), that the estimates of \( α \), \( Γ \) and \( Ω \) are asymptotically Gaussian and have the same limit distribution as if \( β \) were known: that is, the asymptotic distribution they have in the regression of \( ΔY_t \) on the stationary variables \( β'Y_{t-1} \) and \( ΔY_{t-1} \).

The asymptotic distribution of \( \hat{β} \) is mixed Gaussian, where the mixing parameter is the (random) limit of the observed information. Therefore, by normalizing on the observed information, we obtain asymptotic \( χ^2 \) inference for hypotheses on \( β \). The limit distribution of the likelihood ratio test statistic for rank, see (5), is given by a generalization of the Dickey–Fuller distribution:

\[
\text{DF}_{p-r} = \text{tr} \left( \int_0^1 (dW)' \left( \int_0^1 WW' du \right)^{-1} \int_0^1 W(dW)' \right),
\]

where \( W \) is a standard Brownian motion in \( p-r \) dimensions. The quantiles of this distribution can at present only be calculated by simulation if \( p-r > 1 \). The limit distribution has to be modified if deterministic terms are included in the model.

regime switching models

James D. Hamilton

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

If the parameters of a time-series process are subject to change over time, then a full description of the data-generating process must include a specification of the probability law governing these changes, for example, postulating that the parameters evolve according to the realization of an unobserved Markov chain. This article describes classical and Bayesian algorithms for estimation and inference in such models and discusses some of the issues that arise in particular cases such as GARCH and state-space models.

Keywords

ARMA models; asset prices; econometrics; GARCH models; Gaussian densities; Gibbs sampler; Kalman filter; Markov chain Monte Carlo methods; Markov processes; maximum likelihood; numerical optimization methods in economics; regime-switching models; state-space models; vector autoregressions

Article

Many economic time series occasionally exhibit dramatic breaks in their behaviour, associated with events such as financial crises (Jeanne and Masson, 2000; Cerra and Saxena, 2005; Hamilton, 2005) or abrupt changes in government policy (Hamilton, 1988; Sims and Zha, 2006; Davig, 2004). Of particular interest to economists is the apparent tendency of many economic variables to behave quite differently during economic downturns, when underutilization of factors of production rather than their long-run tendency to grow governs economic dynamics (Hamilton, 1989; Chauvet and Hamilton, 2006). Abrupt changes are also a prevalent feature of financial data, and the approach described below is quite amenable to theoretical calculations for how such abrupt changes in fundamentals should show up in asset prices (Ang and Bekaert, 2002a; 2000b; Garcia, Luger and Renault, 2003; Dai, Singleton and Yang, 2003).
Consider how we might describe the consequences of a dramatic change in the behaviour of a single variable $y_t$. Suppose that the typical historical behaviour could be described with a first-order autoregression,

$$
Y_t = c_1 + \psi Y_{t-1} + \epsilon_t
$$

(1)

with $\epsilon_t \sim N(0, \sigma^2)$, which seemed to adequately describe the observed data for $t = 1, 2, \ldots, t_0$. Suppose that at date $t_0$ there was a significant change in the average level of the series, so that we would instead wish to describe the data according to

$$
Y_t = c_2 + \psi Y_{t-1} + \epsilon_t
$$

(2)

for $t = t_0 + 1, t_0 + 2, \ldots$. This fix of changing the value of the intercept from $c_1$ to $c_2$ might help the model to get back on track with better forecasts, but it is rather unsatisfactory as a probability law that could have generated the data. We surely would not want to maintain that the change from $c_1$ to $c_2$ at date $t_0$ was a deterministic event that anyone would have been able to predict with certainty looking ahead from date $t = 1$. Instead, there must have been some imperfectly predictable forces that produced the change. Hence, rather than claim that expression (1) governed the data up to date $t_0$ and (2) after that date, what we must have in mind is that there is some larger model encompassing them both,

$$
Y_t = c_{s_t} + \psi Y_{t-1} + \epsilon_t
$$

(3)

where $s_t$ is a random variable that, as a result of institutional changes, happened in our sample to assume the value $s_t = 1$ for $t = 1, 2, \ldots, t_0$ and $s_t = 2$ for $t = t_0 + 1, t_0 + 2, \ldots$. A complete description of the probability law governing the observed data would then require a probabilistic model of what caused the change from $s_t = 1$ to $s_t = 2$. The simplest such specification is that $s_t$ is the realization of a two-state Markov chain with

$$
\Pr(s_t = j | s_{t-1} = i, s_{t-2} = k, \ldots, Y_{t-1}, Y_{t-2}, \ldots) = \Pr(s_t = j | s_{t-1} = i) = \rho_{ij}
$$

On the assumption that we do not observe $s_t$ directly, but only infer its operation through the observed behavior of $y_t$, the parameters necessary to fully describe the probability law governing $y_t$ are then the variance of the Gaussian innovation $\sigma^2$, the autoregressive coefficient $\varphi$, the two intercepts $c_1$ and $c_2$, and the two state transition probabilities, $p_{11}$ and $p_{22}$.

The specification in (4) assumes that the probability of a change in regime depends on the past only through the value of the most recent regime, though, as noted below, nothing in the approach described below precludes looking at more general probabilistic specifications. But the simple time-invariant Markov chain (4) seems the natural starting point and is clearly preferable to acting as if the shift from $c_1$ to $c_2$ was a deterministic event. Permanence of the shift would be represented by $p_{22} = 1$, though the Markov formulation invites the more general possibility that $p_{22} < 1$. Certainly in the case of business cycles or financial crises, we know that the situation, though dramatic, is not permanent. Furthermore, if the regime change reflects a fundamental change in monetary or fiscal policy, the prudent assumption would seem to be to allow the possibility of it changing back again, suggesting that $p_{22} < 1$ is often a more natural formulation for thinking about changes in regime than $p_{22} = 1$.

A model of the form of (3)–(4) with no autoregressive elements ($\varphi = 0$) appears to have been first analysed by Lindgren (1978) and Baum et al. (1980). Specifications that incorporate autoregressive elements date back in the speech recognition literature to Poritz (1982), Juang and Rabiner (1985), and Rabiner (1989), who described such processes as ‘hidden Markov models’. Markov-switching regressions were introduced in econometrics by Goldfeld and Quandt (1973), the likelihood function for which was first correctly calculated by Cosslett and Lee (1985). The formulation of the problem described here, in which all objects of interest are calculated as a by-product of an iterative algorithm similar in spirit to a Kalman filter, is due to Hamilton (1989; 1994). General characterizations of moment and stationarity conditions for such processes can be found in Tjøstheim (1986), Yang (2000), Timmermann (2000), and Francq and Zakoïan (2001).

**Econometric inference**

Suppose that the econometrician observes $y_t$ directly but can only make an inference about the value of $s_t$ based on what we see happening with $y_t$. This inference will take the form of two probabilities

$$
\xi_{jt} = \Pr(s_t = j|\Omega, \theta)
$$

(5)
for \( j = 1, 2 \), where these two probabilities sum to unity by construction. Here \( \Omega_t = \{ \Omega_t, \{ 1, \ldots, \Omega_t \} \} \) denotes the set of observations obtained as of date \( t \), and \( \Theta \) is a vector of population parameters, which for the above example would be \( \Theta = (\Theta, \Theta, \Theta, \Theta, \Theta, \Theta, \Theta, \Theta, \Theta, \Theta) \), and which for now we presume to be known with certainty. The inference is performed iteratively for \( t = 1, 2, \ldots, T \), with step \( t \) accepting as input the values

\[
\xi_{i,t-1} = \Pr(\Omega_t = \{ 1 \} | \Omega_{t-1}; \Theta)
\]

for \( i = 1, 2 \) and producing as output (5). The key magnitudes one needs in order to perform this iteration are the densities under the two regimes,

\[
\eta_{jt} = f(y_t|s_t = j, \Omega_{t-1}; \Theta) = \frac{1}{\sqrt{2\pi\sigma}} \exp \left[ -\frac{(y_t - \epsilon_j - \epsilon_{y_t-1})^2}{2\sigma^2} \right],
\]

for \( j = 1, 2 \). Specifically, given the input (6) we can calculate the conditional density of the \( r \)th observation from

\[
f(y_t|\Omega_{t-1}; \Theta) = \sum_{i=1}^{2} \sum_{j=1}^{2} p_{ij} \xi_{i,t-1} \eta_{jt}
\]

and the desired output is then

\[
\xi_{jt} = \frac{\sum_{i=1}^{2} p_{ij} \xi_{i,t-1} \eta_{jt}}{f(y_t|\Omega_{t-1}; \Theta)}.
\]
As a result of executing this iteration, we will have succeeded in evaluating the sample conditional log likelihood of the observed data

$$\log f(y_1, y_2, ..., y_T|y_0; \theta) = \sum_{t=1}^{T} \log f(y_t|\Omega_t-1; \theta)$$

(10)

for the specified value of $\theta$. An estimate of the value of $\theta$ can then be obtained by maximizing (10) by numerical optimization.

Several options are available for the value $\xi_{i0}$ to use to start these iterations. If the Markov chain is presumed to be ergodic, one can use the unconditional probabilities

$$\xi_{i0} = \Pr(s_0 = i) = \frac{1 - p_{jj}}{2 - p_{ii} - p_{jj}}.$$

Other alternatives are simply to set $\xi_{i0} = 1/2$ or estimate $\xi_{i0}$ itself by maximum likelihood.

The calculations do not increase in complexity if we consider an $(r \times 1)$ vector of observations $y_t$ whose density depends on $N$ separate regimes. Let $\Omega_t = \{Y_t, Y_{t-1}, ..., Y_1\}$ be the observations through date $t$, $P$ be an $(N \times N)$ matrix whose row $j$, column $i$ element is the transition probability $p_{ij}$, $\eta_t$ be an $(N \times 1)$ vector whose $j$th element $f(y_t|s_t = j, \Omega_{t-1}; \theta)$ is the density in regime $j$, and $\hat{\xi}_t$ an $(N \times 1)$ vector whose $j$th element is $\Pr(s_t = j|\Omega_t, \theta)$ Then (8) and (9) generalize to

$$f(y_t|\Omega_{t-1}; \theta) = \mathbf{1}' (P \hat{\xi}_t - \eta_{t-1} \odot \eta_t)$$

(11)

$$\hat{\xi}_t = \frac{P \hat{\xi}_t - \eta_{t-1} \odot \eta_t}{f(y_t|\Omega_{t-1}; \theta)}$$

(12)
where $1$ denotes an $(N \times 1)$ vector all of whose elements are unity and $\odot$ denotes element-by-element multiplication. Markov-switching vector autoregressions are discussed in detail in Krolzig (1997). Vector applications include describing the co-movements between stock prices and economic output (Hamilton and Lin, 1996) and the tendency for some series to move into recession before others (Hamilton and Perez-Quiros, 1996). There further is no requirement that the elements of $\eta_t$ be Gaussian densities or even from the same family of densities. For example, Dueker (1997) studied a model in which the degrees of freedom of a Student $t$ distribution change depending on the economic regime. One is also often interested in forming an inference about what regime the economy was in at date $t$ based on observations obtained through a later date $T$, denoted $\hat{\xi}_{t:T}$. These are referred to as ‘smoothed’ probabilities, an efficient algorithm for whose calculation was developed by Kim (1994).

Extensions

The calculations in (11) and (12) remain valid when the probabilities in $P$ depend on lagged values of $y_t$ or strictly exogenous explanatory variables, as in Diebold, Lee and Weinbach (1994), Filardo (1994) and Peria (2002). However, often there are relatively few transitions among regimes, making it difficult to estimate such parameters accurately, and most applications have assumed a time-invariant Markov chain. For the same reason, most applications assume only $N = 2$ or 3 different regimes, though there is considerable promise in models with a much larger number of regimes, either by tightly parameterizing the relation between the regimes (Calvet and Fisher, 2004), or with prior Bayesian information (Sims and Zha, 2006).

In the Bayesian approach, both the parameters $\theta$ and the values of the states $s = (s_1, s_2, \ldots, s_T)'$ are viewed as random variables. Bayesian inference turns out to be greatly facilitated by Monte Carlo Markov chain methods, specifically, the Gibbs sampler. This is achieved by sequentially (for $k = 1, 2, \ldots$) generating a realization $\theta^{(k)}$ from the distribution of $\theta | s^{(k-1)}, \Omega_T$ followed by a realization of $s^{(k)}$ from the distribution of $s | \theta^{(k)}$, $\Omega_T$. The first distribution, $\theta | s^{(k-1)}, \Omega_T$, treats the historical regimes generated at the previous iteration, $s_1^{(k-1)}, s_2^{(k-1)}, \ldots, s_T^{(k-1)}$, as if fixed known numbers. Often this conditional distribution takes the form of a standard Bayesian inference problem whose solution is known analytically using natural conjugate priors. For example, the posterior distribution of $\phi$ given other parameters is a known function of easily calculated OLS coefficients. An algorithm for generating a draw from the second distribution, $s | \theta^{(k)}$, $\Omega_T$, was developed by Albert and Chib (1993). The Gibbs sampler turns out also to be a natural device for handling transition probabilities that are functions of observable variables, as in Filardo and Gordon (1998).

It is natural to want to test the null hypothesis that there are $N$ regimes against the alternative of $N + 1$, for example when $N = 1$, to test whether there are any changes in regime at all. Unfortunately, the likelihood ratio test of this hypothesis fails to satisfy the usual regularity conditions because, under the
null hypothesis, some of the parameters of the model would be unidentified. For example, if there is really only one regime, the maximum likelihood estimate $\hat{\phi}_{11}$ does not converge to a well-defined population magnitude, meaning that the likelihood ratio test does not have the usual $\chi^2$ limiting distribution. To interpret a likelihood ratio statistic, one instead needs to appeal to the methods of Hansen (1992) or Garcia (1998). An alternative is to rely on generic tests of the hypothesis that an $N$-regime model accurately describes the data (Hamilton, 1996), though these tests are not designed for optimal power against the specific alternative hypothesis of $N + 1$ regimes. A test recently proposed by Carrasco, Hu and Ploberger (2004) that is easy to compute but not based on the likelihood ratio statistic seems particularly promising. Other alternatives are to use Bayesian methods to calculate the value of $N$ implying the largest value for the marginal likelihood (Chib, 1998) or the highest Bayes factor (Koop and Potter, 1999), or to compare models on the basis of their ability to forecast (Hamilton and Susmel, 1994).

A specification where the density depends on a finite number of previous regimes, $f(y_t|s_t, s_{t-1}, \ldots, s_{t-m}, \Omega_{t-1}; \theta)$, can be recast in the above form by a suitable redefinition of regime. For example, if $s_t$ follows a 2-state Markov chain with transition probabilities $\Pr(s_t = j|s_{t-1} = i)$ and $m = 1$, one can define a new regime variable $\hat{s}_t$ such that $f(y_t|\hat{s}_t, \Omega_{t-1}; \theta) = f(y_t|s_t, s_{t-1}, \ldots, s_{t-m}, \Omega_{t-1}; \theta)$ as follows:

$$
\hat{s}_t^* = \begin{cases} 
1 & \text{when } s_t = 1 \text{ and } s_{t-1} = 1 \\
2 & \text{when } s_t = 2 \text{ and } s_{t-1} = 1 \\
3 & \text{when } s_t = 1 \text{ and } s_{t-1} = 2 \\
4 & \text{when } s_t = 2 \text{ and } s_{t-1} = 2 
\end{cases}
$$

Then $\hat{s}_t^*$ itself follows a 4-state Markov chain with transition matrix

$$
P^* = \begin{bmatrix}
p_{11} & 0 & 0 & 0 \\
0 & p_{11} & 0 & 0 \\
0 & 0 & p_{12} & 0 \\
0 & 0 & 0 & p_{22}
\end{bmatrix}
$$

More problematic are cases in which the order of dependence $m$ grows with the date of the observation $t$. Such a situation often arises in models whose recursive structure causes the density of $y_t$ given $\Omega_{t-1}$ to
Regime-switching models: The New Palgrave Dictionary of Economics

Depend on the entire history \( V_{t-1}, V_{t-2}, \ldots, V_1 \) as is the case in ARMA, GARCH or state-space models. Consider for illustration a GARCH(1,1) specification in which the coefficients are subject to changes in regime, \( V_t = h_t V_t \) where \( V_t \sim N(0, 1) \) and

\[
h_t^2 = \gamma_s t + \alpha_s t V_{t-1}^2 + \beta_s t h_{t-1}^2. \tag{13}
\]

Solving (13) recursively reveals that the conditional standard deviation \( h_t \) depends on the full history \( \{ V_{t-1}, V_{t-2}, \ldots, V_0, s_t, s_{t-1}, \ldots, s_1 \} \). One way to avoid this problem was proposed by Gray (1996), who postulated that, instead of being generated by (13), the conditional variance is characterized by

\[
h_t^2 = \gamma_s t + \alpha_s t V_{t-1}^2 + \beta_s t \hat{h}_{t-1}^2 \tag{14}
\]

where

\[
\hat{h}_{t-1}^2 = \sum_{i=1}^{N} \hat{\xi}_{i,t-1} V_{t-1} - 2 (\gamma_i + \alpha_i V_{t-2}^2 + \beta_i \hat{h}_{t-2}^2).
\]

In Gray's model, \( h_t \) in (14) depends only on \( s_t \) since \( \hat{h}_{t-1}^2 \) is a function of data \( \Omega_{t-1} \) only. An alternative solution, due to Haas, Mittnik and Paolella (2004), is to hypothesize \( N \) separate GARCH processes whose values \( h_{it} \) all exist as latent variables at date \( t \),

\[
h_{it}^2 = \gamma_i + \alpha_i V_{t-1}^2 + \beta_i \hat{h}_{it, t-1}^2 \tag{15}
\]

and then simply pose the model as \( V_t = h_s t V_t \). Again, the feature that makes this work is the fact that \( h_{it} \) in (15) is a function solely of the data \( \Omega_{t-1} \) rather than the states \( \{ s_{t-1}, s_{t-2}, \ldots, s_1 \} \).
A related problem arises in Markov-switching state-space models, which posit an unobserved state vector $z_t$ characterized by

$$z_t = F_{s_t} z_{t-1} + Q_{s_t} v_t$$

with $v_t \sim N(0, I_n)$, with observed vectors $y_t$ and $x_t$ governed by

$$y_t = H_{s_t} z_t + A_{s_t} x_t + R_{s_t} w_t$$

for $w_t \sim N(0, I_r)$. Again, the model as formulated implies that the density of $y_t$ depends on the full history $\{s_t, s_{t-1}, \ldots, s_1\}$. Kim (1994) proposed a modification of the Kalman filter equations similar in spirit to the modification in (14) that can be used to approximate the log likelihood. A more common practice recently has been to estimate such models with numerical Bayesian methods, as in Kim and Nelson (1999).

regional and preferential trade agreements

Pravin Krishna

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses analytical developments in the literature on the economics and politics of preferential trade agreements (PTAs). It describes results obtained in the traditional theory that demonstrate the ambiguous welfare outcomes of preferential trade liberalization. Theoretical approaches to designing necessarily welfare-improving PTAs are also discussed. Finally, this article sets out recent analyses in the literature concerning the dynamic expansion of trade blocs, the endogenous determination of policy (relating to preferences within a PTA and to extra-union trade), and the effects of preferential agreements on the multilateral trade system.

Keywords

E.; Mercosur; most-favoured-nation (MFN) principle; multilateral free trade; Mundell, R.; natural trading partners hypothesis; North American Free Trade Agreement (NAFTA); preferential trade agreements; redistribution of income; regional and preferential trade agreements; sunk costs; tariffs; terms of trade; trade creation; trade diversion; Viner, J.

Article

Strongly influenced by the perception that restricted commerce and preferences in trade relations had contributed to the Great Depression of the 1930s and the subsequent outbreak of war, the discussions leading to the General Agreement on Tariffs and Trade (GATT) in 1947 were driven by the desire to create an international economic order based on a liberal and non-discriminatory multilateral trade system. Enshrined in Article I of the GATT, the principle of non-discrimination (commonly referred to as the most-favoured-nation or MFN clause) precludes member countries from discriminating against
imports based upon the country of origin. However, in an important exception this central prescript, the GATT, through its Article XXIV, permits its members to enter into preferential trade agreements (PTAs), provided these preferences are complete. In so doing, it sanctions the formation of free trade areas (FTAs), whose members are obligated to eliminate internal import barriers, and customs unions (CUs), whose members additionally agree on a common external tariff against imports from non-members. Additional derogations to the principle of non-discrimination now include the Enabling Clause, which allows tariff preferences to be granted to developing countries (in accordance with the Generalized System of Preferences) and permits preferential trade agreements among developing countries in goods trade. Among the more prominent existing PTAs are the North American Free Trade Agreement (NAFTA), the European Economic Community (EEC) and the European Free Trade Association (EFTA), all formed under Article XXIV, and the Mercosur (the CU between the Argentine Republic, Brazil, Paraguay, and Uruguay) and the ASEAN (Association of South East Asian Nations) Free Trade Area (AFTA), both formed under the Enabling Clause.

Static welfare analysis

Motivated by ongoing discussions concerning optimal trade arrangements in the post-war period, especially over the possibility of a European customs union, Jacob Viner (1950, pp. 41–50) developed a seminal analysis of the economics of preferential trade. Viner's analysis undermines the presumption that cutting tariffs is necessarily welfare improving. On the one hand, because of discriminatory liberalization, there will be commodities that a member country may ‘newly import from the other but which it formerly did not import at all because the price of the protected domestic good was lower than the price of any foreign source plus the duty’. Viner calls this shift from a high-cost to a lower-cost point ‘trade creation’ and associates it with welfare-improvement for the importing country. He also argues that, on the other hand, ‘there may be other commodities, which one of the members will now newly import from the other’, whereas before the PTA it ‘imported them from a third country, because that was the cheapest possible source of supply even after the payment of duty’. He calls this shift in imports from a low-cost third country to a higher-cost member country ‘trade diversion,’ associating it with an increase in the cost of imports and, thus, welfare losses for the importing country.

The demonstration that preferential trade liberalization may be welfare decreasing stimulated a substantial theoretical literature on the ‘static’ welfare effects of PTAs. Post-Vinerian analysis of the welfare effects of preferential trade include Meade's (1955) more explicit and comprehensive formulation of the problem in a three-country three-good setting. Meade argues that not only the magnitudes of trade creation and trade diversion but also the extent of cost reductions (in the former) and increases (in the latter) were necessary to arrive at a welfare evaluation. Subsequent analysis also developed examples of both welfare improving trade diversion and welfare-decreasing trade creation in general equilibrium contexts broader than those considered by Viner (see, for instance, Gehrels, 1956–7, Lipsey, 1957, and Bhagwati, 1971). However, the intuitive appeal of the concepts of trade creation and trade diversion has ensured their continued use in the economic analysis of preferential trade agreements, especially in policy analysis (see Panagariya, 2000, for a comprehensive survey).

The effects of preferences on intra-union and extra-union terms-of-trade are analysed by Mundell (1964), who argues that a country granting tariff preferences moves intra-union terms of trade against it
and in favour of its partner by increasing its demand for imports from its partner. Extra-union terms of trade are improved for the partner, but change ambiguously for the preference-granting country. Thus, tariff preferences have asymmetric effects on the preference-granting and preference-receiving country. More sharply, Panagariya (1997a) shows how, even with fixed extra-union terms of trade, if a preference-granting country continues to import from the rest of the world, intra-union terms-of-trade losses (manifesting themselves as intra-union tariff revenue transfers as also seen in Berglas, 1979, and Riezman, 1979) unambiguously worsen its welfare, while its preference-receiving partner unambiguously gains.

Wonnacott and Lutz (1987), Krugman (1991) and Summers (1991) propose geographic proximity between partner countries as important in ensuring that preferential liberalization improves welfare. Specifically, they suggest that countries entering into preferential arrangements with geographically proximate countries are likely to do better than in agreements with distant countries, because the former are more likely than the latter to be trade creating, leading to a larger improvement in welfare. Proximate countries are thus argued to be ‘natural’ partners for preferential trade. Bhagwati and Panagariya (1996) and Panagariya (1997b), however, provide a number of examples in which, between two otherwise identical potential partners, a country achieves a superior outcome by granting trade preferences to the distant partner. For instance, it may be that a preference granted to a distant partner leads to a smaller transfer (loss) of tariff revenue with a closer country, since, with an initial non-discriminatory tariff, the liberalizing country imports less from the more distant partner. Thus, the ‘natural trading partners’ hypothesis is shown to lack general theoretical validity.

Numerous studies have attempted to evaluate quantitatively the trade creation and trade diversion effects of PTAs. Recently, focusing on the effects of PTAs on excluded countries, Chang and Winters (2002) show how Mercosur was associated with significant declines in the prices of non-members' exports to the region. Yeats (1998) shows how under Mercosur the greatest increases of intra-union trade flows were in goods in which the member countries had the least comparative advantage, confirming the trade diversionary effects of preferential liberalization.

Srinivasan, Whalley and Wooton (1993) note that the econometric frameworks used in most ex post studies of trade flows generally lack microeconomic underpinnings, making an evaluation of the associated welfare consequences difficult. Krishna (2003) develops an econometric framework for the analysis of PTAs with a strong welfare-theoretic foundation, so that the estimated parameters relating to trade creation and trade diversion effects fit directly into theoretically derived welfare expressions. His application of this framework to the evaluation of the natural trading partners hypothesis does not find any support in US data.

Necessarily welfare-improving preferential trade areas

The generally ambiguous welfare results provided by the theoretical literature raised an important question relating to the design of necessarily welfare-improving PTAs. A classic result stated independently by Kemp (1964) and Vanek (1965) and proved subsequently by Ohyama (1972) and Kemp and Wan (1976) provides a welfare-improving solution for the case of CUs. Starting from a situation with an arbitrary structure of trade barriers, if two or more countries freeze their net external
trade vector with the rest of the world through a set of common external tariffs and eliminate the barriers to internal trade (which implies the formation of a CU), the welfare of the union as a whole necessarily improves (weakly) and that of the rest of the world does not fall. A Pareto-improving preferential trade agreement may thus be achieved. The logic behind the Kemp–Wan theorem is as follows. By fixing the combined, net extra-union trade vector of member countries at its pre-union level, non-member countries are guaranteed their original level of welfare. Moreover, if we take the extra-union trade vector as an endowment, the joint welfare of the union is maximized by allowing free trade of goods internally (thus equating the marginal rate of substitution and marginal rate of transformation for each pair of commodities to each other and across all agents in the union). The PTA thus constructed has a common internal price vector, implying further a common external tariff for member countries. This customs union is (weakly) welfare improving: the rest of the world is no worse off and the welfare of member countries is jointly improved (weakly). Welfare improvement is achieved even if additional ‘non-economic’ objectives (such as maintaining the output of a sector or its employment of a factor) are introduced, as Krishna and Bhagwati (1997) show. The Kemp–Wan–Ohyama design, by freezing the external trade vector and thus eliminating trade diversion, offers a way to sidestep the complexities and ambiguities inherent in the analysis of PTAs. It has played an important role in shaping the way that economists think about issues relating to the design and implementation of PTAs.

The Kemp–Wan–Ohyama analysis of welfare improving CUs does not extend easily to FTAs, however. In the case of an FTA, member-specific tariff vectors imply that the domestic-price vectors differ across member countries and the FTA generally fails to equalize marginal rates of substitution across its members. Without a common internal price vector, however, the Kemp–Wan–Ohyama methodology lacks application. Nevertheless, Panagariya and Krishna (2002) have provided a corresponding construction of necessarily welfare-improving FTAs. The Panagariya–Krishna FTA, in complete analogy with the Kemp–Wan CU, freezes the external trade vector of the area, with the essential difference that the trade vector of each member country with the rest of the world is frozen at the pre-FTA level. Since, in FTAs, different member countries impose different external tariffs, it is necessary to specify a set of rules of origin to prevent a subversion of FTA tariffs by importing through the lower-tariff member country and directly trans-shipping goods to the higher-tariff country (which, if allowed, would bring the FTA arbitrarily close to a CU). The Panagariya–Krishna solution requires that all goods for which any value is added within the FTA are to be traded freely. Importantly, the proportion of domestic value added in final goods does not enter as a criterion in the rules of origin.

Theory thus suggests that ensuring welfare improvement requires that, along with elimination of internal barriers, external tariff vectors should eliminate trade diversion – member countries should continue to import the same amounts from the rest of the world as they did initially. There have, however, been significant departures in practice. While Article XXIV of the GATT stipulates that internal restrictions be eliminated on ‘substantially all trade’, the qualifier ‘substantially’ is vulnerable to abuse. Numerous goods are typically exempt from internal liberalization by member countries. Furthermore, restrictive rules of origin also serve to ensure a level of protection from both intra- and extra-union imports, as Krueger (1999) notes. On external tariffs, Article XXIV requires that external barriers not be more restrictive than initially. For FTAs, since countries retain individual tariff vectors, this could be taken to imply that no tariff is to rise. For CUs, since a common external tariff is to be chosen and initial tariffs on the same good likely vary across countries, the tariff vector would necessarily change for each country. The expectation is that that the ‘general incidence’ of trade barriers should not be higher or
more restrictive than before. As Bhagwati (1993) notes, it is clear that Article XXIV's ambiguity in this regard leaves plenty of room for protectionist behaviour by member countries. The 1994 ‘Understanding on the Interpretation’ of Article XXIV issued by the GATT provides greater clarity on the issue of measurement and choice of the common external tariff – indicating that the GATT secretariat would compute weighted average tariff rates and duties collected in accordance with the methodology used in the assessment of tariff offers in the Uruguay Round of trade negotiations and examine trade flow and other data to arrive at suitable measures of non-tariff barriers. Nevertheless, it may be observed that leaving external barriers at their initial level and removing internal barriers do not eliminate trade diversion. Indeed, with this configuration, some trade diversion is practically guaranteed.

**Preferential trade agreements and multilateral free trade**

Recent analysis in the literature has focused on issues concerning the expansion of trade blocs, the endogenous determination of policy (relating to trade preferences within a PTA and extra-union trade), and the effects of preferential agreements on the multilateral trade system (that is, whether trade blocs will serve as ‘building blocs’ or ‘stumbling blocs’ in the path to multilateral free trade, in Bhagwati’s, 1993, phrasing).

Krugman (1993) analyses the welfare consequences of exogenously formed and expanded trade blocs. Considering a fully symmetric structure of countries, each specialized in production in a differentiated product variety, Krugman asks how world welfare is affected by the expansion of trade blocs if member countries liberalize fully their mutual trade but apply optimal tariffs against non-members. As the (symmetric) trade blocs increase in size, their market power increases and so do the (optimal) tariffs they impose on non-members. On the other hand, increasing the number of countries within a bloc increases the volume of goods that is traded freely. Krugman finds that the net effect on world welfare is non-monotonic in bloc size. Specifically, world welfare (which is maximized with global free trade) falls as the world is divided up into trade blocs but rises again as bloc sizes decrease and the trade diversion losses (relative to trade creation gains) fall. Bond and Syropoulos (1996) show how generalizing the assumptions of Krugman's model relating to consumption preferences and the pattern of production and trade may alter the relationship between optimal tariffs and market size so that optimal tariffs fall as bloc size increases. More severely, Deardorff and Stern (1994) and Srinivasan (1993) question the robustness of Krugman's conclusions concerning non-monotonicity of welfare itself, demonstrating a substantial divergence in results when Krugman's assumptions regarding the structure of endowments and comparative advantage are changed.

A different strand of the literature has examined endogenously determined trade blocs and the internal political and economic incentives (if any) for their successive expansion. Taking the ‘interest-group’ approach to trade policy determination, Grossman and Helpman (1995) and Krishna (1998) both model the influence of powerful producers in considering entry into a PTA. While the models and analytic frameworks differ in detail, they come to a similar and striking conclusion, namely, that PTAs that divert trade are more likely to win internal political support. This is so because governments must respond to conflicting pressures from their exporting sectors, which gain from lower trade barriers in the partner, and from their import-competing sectors, which suffer from lower trade barriers at home, when deciding on whether to form or enter a PTA.
As Krishna (1998) argues, trade diversion effectively shifts the burden of the gain to member-country exporters from member-country import-competing sectors and onto non-member producers, who have little political clout inside the member countries. Krishna (1998) also argues that such PTAs will lower the within-union incentives for any subsequent multilateral liberalization – producers in trade-diverting PTAs may oppose multilateral reform since this would take away the gains from benefits of preferential access that they enjoyed in the PTA that diverted trade to them. Under some circumstances, the within-union incentives for further multilateral liberalization are completely eliminated.

Levy (1997) models trade policy as being determined by majority voting. Countries are assumed to differ in their endowments of factors (labour and capital). Countries are also assumed to produce different varieties of goods – so that trade reform will result in gains to individuals due to the greater number of varieties that are available for consumption. However, it should also be clear that any changes in trade policy result in changes in the distribution of income (by altering the relative rewards to the different factors of production). The arguments that emerge out of this framework are as follows. First, preferential trade integration with partners with similar relative factor endowments (that is, with similar capital–labour ratios) is more likely to receive majority support – since this results in minimal income redistribution and still provides variety gains from trade. Second, bilateral agreements could render infeasible multilateral liberalization (which, even if it brings greater variety gains, would involve trade with countries with quite different relative endowments of capital and labour and could therefore result in much more drastic income redistribution).

McLaren (2002) provides an analysis of the role of sunk costs and trade policy determination. He argues, roughly speaking, that the expectation of a preferential trading agreement could induce agents in the economy to undertake costly and irreversible investments that makes the members within the bloc more specialized towards each other and less so towards the rest of the world. In other words, they increase dependence on each other and lower it towards the rest of the world, and thus reduce their desire to liberalize trade with other countries. Exploring the first-mover advantage that member countries gain having invested in sunk costs, Freund (2000a) finds that with preferential trade member countries gain and that non-members lose relative to multilateral outcomes, with the former dominating the latter in magnitude.

A parallel literature has raised the question of what external tariffs will be chosen by member countries, examining, in particular, whether external tariffs can be expected to rise or fall following a PTA. No clear answers to this question emerge. Panagariya and Findlay (1996) finds that external tariffs rise after tariff preferences are granted, as political lobbying for protection is directed away from imports from the partner country to imports from the rest of the world. Emphasizing tariff revenue competition between FTA members, Richardson (1995) finds that external tariff may fall in an FTA as welfare-minded member countries competitively reduce tariffs (so as to retain the source of extra-union imports and earn tariff revenue). In a general equilibrium context, with political lobbying over tariffs, Cadot, de Melo and Olarreaga (1999) reach a similar conclusion for FTAs, while finding that CUs are likely to raise their external tariffs. Cadot, de Melo and Olarreaga (2002) confirm these results for the case of quantity restrictions, where the protective effect that a quantity restriction imposed by a member country has in partner country markets proves central to the analysis. However, when collective action problems over lobbying for external trade policy dominate, FTAs may choose higher external tariffs than CUs, as Richardson (1994) argues. Finally, in a symmetric three-country oligopoly model, Ornelas (2005) finds
that a PTA’s endogenously determined external tariff may be lower than the pre-union MFN tariff. Cho and Krishna (2006) demonstrate that the opposite may obtain with asymmetric costs across partner countries, the likelihood of the external tariff being higher than the pre-union MFN tariff increasing with the inefficiency of the partner country relative to non-members.

Empirical analysis has offered mixed results as well. Bohara, Gawande and Sanguinetti (2004) report evidence of lowered external tariffs following Mercosur, while Cho (2006) finds tariffs in Mexico to be higher on average following NAFTA and systematically higher in goods in which its trading partners were inefficient suppliers (as proxied by pre-FTA export levels relative to the rest of the world). Limão (2006) examines data on US trade barriers and finds that those imported goods on which any partners received preferences were subject to smaller (subsequent) multilateral liberalization than others, suggesting a negative effect of preferences on multilateral reforms.

The economic incentives of non-member countries are considered by Baldwin (1995), who argues that PTA expansion could have ‘domino’ effects – increasing the size of a bloc increases the incentive for others to join it (as they then gain preferential access to increasingly large markets). On the assumption of open-membership rules (that is, insiders do not oppose the entry of new members who abide by the same rules as the members), the successive expansion of the PTA could then lead to multilateral free trade – a conclusion that is also reached by the work of Yi (1996), which develops a model of endogenous coalition formation to addresses this question.

Aghion, Antras and Helpman (2004) analyse the links between bilateral and multilateral negotiations over trade policy as a dynamic bargaining game in which a leading country endogenously decides whether to sequentially negotiate free trade agreements with subsets of countries or engage in simultaneous multilateral bargaining with all countries at once. They show that, if a coalition formed between the leading country and a follower generates a negative effect on outsiders (that is, there are negative coalitional externalities), the leader prefers sequential bargaining to multilateral bargaining. Conversely, positive coalition externalities imply that multilateral bargaining is preferred. Importantly, while political economy pressures may cause bilateral agreements to impede multilateral agreement, as in Levy (1997) and Krishna (1998), examples where bilateral agreements enable multilateral agreement are also found.

Self-enforcing trade agreements (which work by balancing any benefits that member countries may achieve by deviating from the agreement with the future losses they suffer due to punishments for the deviation) have been variously analysed in the international trade literature. Since bilateral (multilateral) agreements may alter both the benefits of deviating from an existing multilateral (bilateral) agreement and the future punishment costs of this deviation, self-enforcing agreements provide a context in which the links between preferential trade agreements and multilateralism may be studied. Bagwell and Staiger (1997a; 1997b) consider the impact of FTAs and CUs on multilateral tariff cooperation during a transition period when the exogenously agreed-upon lowering of tariffs within FTAs and CUs is implemented. Saggi (2006) shows how exogenously specified FTAs and CUs may undermine self-enforced multilateral tariff cooperation, the former by lowering the cooperation incentives of non-member countries and the latter by lowering the cooperation incentives of members. Freund (2000b) finds that exogenous multilateral liberalization may encourage and help sustain self-enforcing PTAs, thus explaining the recent trend towards bilateralism as a causal response to multilateralism. A similar
causal link is explored by Cadot, de Melo and Olarreaga (2001), which views bilateral agreements as an endogenous (protective) response to the competitive pressures that domestic producers face with multilateral liberalization.

Conclusions

A half-century of research has advanced significantly our understanding of the implications of trade discrimination even if the frequently equivocal theoretical and empirical results have established among economists and policymakers an ambivalent attitude towards preferential trade agreements. However, concerns regarding the fragmentation of the world trade system have grown with the rapid proliferation of preferential trade in recent years. Several hundred PTAs are currently in existence. Indeed, many countries belong to multiple PTAs – resulting in a confusing criss-crossing of trade preferences that Bhagwati (1995) has aptly described as ‘spaghetti-bowl’ regionalism. Several more preferential agreements are in process. With this inexorable erosion of non-discriminatory disciplines within the trade system, research on preferential trade is certain to remain central to the field of international trade policy for many years to come.

Abstract

New theoretical work on spatial concentration of industry – particularly the ‘new economic geography’ – has significantly helped our understanding why some regions develop more than others, why cities arise and where they are located. However, this work rarely incorporates Adam Smith’s observation that spatial differences in economic activity also reflect variations in physical geography, which make some places more productive than others at particular times; nor has it accommodated regional development policy – the use of economic incentives to attract industry to particular locations. A full theory of regional development would integrate theories of agglomeration economies with physical geography and with public economics.

Article

Differences in economic activity across regions have interested economists since Adam Smith, who argued that high overland transport costs in the interior of Africa and Asia ‘seem in all ages’ to have hindered economic development. However, economists’ attraction to the study of spatial variations in economic activity has fluctuated over time. Standard trade theory based on comparative advantage helps to explain how the location of economic activity is affected by the spatial distribution of primary
regional development, geography of: The New Palgrave Dictionary of Economics

resources (such as land, labour and water), but standard trade theory says little about the interdependence of location decisions by economic agents, nor does it consider in any depth the more detailed aspects of physical geography (climate, soils, topography, disease epidemiology).

Neoclassical growth models focus on the accumulation of physical, human and technological capital, which individually or together complement raw labour and land as factors of production, but only recent theory (particularly in the work dubbed the ‘new economic geography’) has begun to grapple with location choices and the spatial concentration of industry (Henderson, 1988; Krugman, 1991; Fujita, Krugman and Venables, 1999). While these newer theories have contributed importantly to our understanding of why some regions develop more than others, and why cities arise and where they are located, they rarely incorporate Smith's observation that spatial differences in economic activity are also related to variations in physical geography, which intrinsically make some places more productive than others at particular points in time. Nor do they yet go into depth on regional development policy, that is, the use of economic incentives to attract industry to one location or another. A full theory of regional development will integrate theories of agglomeration economies with physical geography and with public economics.

Theories of agglomeration

Economic activity and population around the globe are concentrated in highly dense metropolitan areas, which suggest that there is an important economic benefit of economic agglomeration (spatial co-location of economic agents). Alfred Marshall (1920) suggested that spatial concentration happens because of knowledge spillovers, larger markets for specialized skills, and backward and forward linkages associated with large local markets.

The initial literature to tackle the intractability of modelling economic geography grew from the von Thünen model (1826), which begins with the existence of a city and derives characteristics about land rents and land use surrounding the city; the resulting unplanned, efficient outcome is a concentric ring pattern of production referred to as ‘von Thünen cones’. The model doesn’t, however, attempt to explain the raison d’être of the city itself.

Later models aimed to explain why population and economic activity tend to agglomerate in the first place. Spatial concentration occurs because production is cheaper due to the large amount of nearby economic activity in agglomeration economies. These increasing returns to scale exist for several reasons: larger markets support more highly specialized products; efficiency increases as a large number of producers and consumers allows for less idle time (a source of increasing returns called demand smoothing); economies of scale of intermediate inputs make production cheaper even for sectors without increasing returns; externalities diffuse learning and expertise, as people can see each others' products and work methods; and search costs are lowered when the search process is spatially concentrated.

Florida (1995) pioneered the concept of the ‘learning region’: to minimize transport costs and maximize learning, firms benefit from spatially concentrating their activities, and thus firms looking to augment their capabilities have strong incentive to locate in these learning regions.

New economic geography
The ‘new economic geography’ of recent decades grew from the Dixit and Stiglitz (1977) model of monopolistic competition under increasing returns to scale. Though admittedly a special case, this model became a workhorse in many fields, and a foundation for the new economic geography. The theoretical backbone of new economic geography is the core–periphery model in Krugman (1991), which looks at three effects: the ‘market-access effect’ (monopolistic firms locate in big markets and export to small markets), the ‘cost-of-living effect’ (cost of living is cheaper where there are more firms, due to low transport costs), and the ‘market-crowding effect’ (imperfectly competitive firms look to locate in regions with few competitors). The model was an important step forward in understanding spatial dynamics, but has the downside of being difficult to manipulate analytically and requires numerical simulations (instead of explicit expressions) to derive results.

Another important concept in the location of economic activity is that of clusters, especially in the work of Porter (1990; 1995; 1998a; 1998b). A cluster is a group of interconnected companies and institutions in a particular location (perhaps a city, or a state, or even a group of neighbouring countries). Companies in a cluster benefit from important complementarities, spillovers and a relationship with public institutions, which improve productivity and productivity growth, and stimulate new business formation. The important contribution of this literature is that a firm’s competitive advantage (or ‘competitive advantage’ in the business phrase) can include characteristics outside the firm itself; often geography and location have important implications on how firms or industries can compete in the market.

One of the striking implications of the new economic geography is that spatial concentration arises in a homogeneous region, where there is no fundamental geographical advantage to locating in one place or another. The precise location of firms is accidental. Early advantages in agglomeration can lead to a snowball effect. First movers in regional development can achieve a lasting competitive advantage by attracting other mobile workers and investors. Growth proceeds with ‘preferential attachment’ to the places that get an early start.

The role of physical geography

In addition to the new economic geography models of agglomeration, a second basic approach seeking to shed light on growth poles and regional development is based on intrinsic geographical advantages. The assumption of homogeneous space is abandoned, and the role of coasts, hinterlands, rivers, mountains and a vast array of other geographical variables is brought to the fore. Adam Smith himself asserted that the division of labour is limited by the extent of the market, so that coastal regions, by virtue of their ability to engage in sea-based trade, enjoy a wider scope of the market than interior regions. More recently, climatic conditions have been found to have pervasive effects on regional development through disease ecology, agricultural productivity, transport costs, vulnerability to natural hazards, water stress and other factors that may affect economic performance.

Several studies (Gallup, Sachs and Mellinger, 1999; Bloom and Sachs, 1998) have noted that tropical areas are consistently poorer than temperate-zone areas, and hypothesize that this may be related to the effects of tropical ecology on human health and agricultural productivity. Tropical infectious diseases, for example, impose very high burdens on human health that in turn may lead to shortfalls in economic performance much larger than their direct short-run effects on health. Another study (Gallup and Sachs, 2000) found that, after purchased inputs such as capital, labour and fertilizers are controlled for,
average productivity of tropical food production falls short of the productivity of temperate-zone food
production. In the course of economic development, this poor performance in food productivity may
have had serious adverse effects on nutrition levels, with adverse consequences for human capital
accumulation, labour productivity and susceptibility to infectious disease. These geographical penalties
can often be compensated by other kinds of interventions (such as malaria control or improved
agronomic practices), but, since those interventions require added resources, affected regions may
persistently lag behind more fortuitously located regions.

Geographical advantages can trigger subsequent agglomeration based on increasing returns to scale. The
agglomeration is then self-reinforcing, even after the initial spatial advantage loses some of its
importance. For example, Chicago's port is not as important as when it was the main driver of the city's
growth in the middle of the 19th century. Glaeser (2005) illustrates that New York's rise in the 19th
century was due to a technological change that moved ocean shipping from a point-to-point system to a
hub and spoke system, and the city's geography made it the natural hub. Today, however, New York's
pre-eminence is based not mainly on the port, but on the legacies of the earlier success: finance,
business, remarkable infrastructure and the benefits of agglomeration.

Changing dimensions of geography

It is important to stress the changing nature of a region's geographic advantage as technology changes. In
early civilizations, when transport and communications were too costly to support much interregional
and international trade, regional advantage came from agricultural productivity and local transport rather
than from access to oceans. As a result, early civilizations almost invariably emerged in highly fertile
river valleys such as those around the Nile, Indus, Tigris, Euphrates, Yellow and Yangtze rivers. These
civilizations produced high-density populations that in later eras were often disadvantaged by their
remoteness from international trade. As the advantages of overland trade between Europe and Asia gave
way to oceanic commerce in the 16th century and later, and as the trade routes to the Americas were
discovered, economic advantage shifted from the Middle East and eastern Mediterranean to the North
Atlantic. In the 19th century, the high costs of transporting coal for steam power meant that
industrialization almost invariably depended on proximity to coal fields.

In the late 20th century, air transport and telecommunications have reduced the advantages of coastlines
relative to hinterlands. The telecommunications sector, in particular, is deeply affecting the global
division of labour and the nature of agglomeration economies. The disadvantages of interior and distant
regions may well be eased or eliminated by the advances in telecommunications which allow for more
disbursed production and new growth poles far from traditional trade routes. It is notable that Bangalore
has become a booming centre of global information technology, despite being an inland city in southern
India, and despite the weakness of India's roads and ports at the time of Bangalore's ascendancy. The
examples of Bangalore and of course California's Silicon Valley show that today's competitive
advantage has to do much more with the location of excellent universities and an attractive living
environment for highly skilled and mobile information workers, much like the ‘learning regions’
described by Florida (1995).

Regional policy design
regional development, geography of: The New Palgrave Dictionary of Economics

The presence of agglomeration economies, increasing returns and clusters suggests that countries can identify areas of potential growth poles and use policy tools and public investment to trigger these processes. Special policy instruments such as export-processing zones and special tax promotion schemes have helped developing countries to establish clusters in textiles and apparel, electronics, consumer appliances, software and automotive components, to name just a few industries where active industrial policy has played a hand. In the case of growth poles in the knowledge economy (such as Silicon Valley and Bangalore), the importance of government support for higher education and R&D and for the creation of science parks is especially apparent. Spillovers from military technology may play a role as well.

It is clear, however, that the successful development strategies of some countries cannot produce the same salubrious results when implemented in very different settings. When China opened some coastal pockets for foreign direct investment, these Special Economic Zones quickly blossomed into vibrant export platforms and created backward linkages with the immediate hinterland. When landlocked Mongolia turned the entire country into a free trade and investment zone in the late 1990s, however, the inflow of foreign capital was a trickle compared with China's experience, and was based mainly on primary commodities (such as copper). Even within China, the coastal provinces in the east have boomed relative to the interior provinces of western China. Physical geography therefore continues to condition economic development. Geographical determinism should be avoided, however; special geographical hindrances may well call for special compensating investments (in roads, disease control, telecommunications, and so on), or for promotion of a judicious choice of industries (those that can be sustained in the face of high transport costs, for example).

Empirical studies

Empirical evidence supports the idea that economies of scale, agglomeration forces (Davis and Weinstein, 1998; 1999; Midelfart-Knarvik et al., 2000; Overman and Puga, 2002; Hanson, 2005), and backward and forward linkages (Midelfart-Knarvik and Steen, 1999) help explain why economic activity clusters together, and that the von Thünen model helps explain economic dynamics near cities (Fafchamps and Shilpi, 2003). The traditional core–periphery model has considerable empirical support, given that the core regions of the global economy (particularly North America, Western Europe, and Japan), enjoy ever-increasing levels in productivity. At a smaller scale, studies of wages in the United States and in developing countries show that ceteris paribus workers earn much more in urban areas than rural areas, reflecting their higher productivity (Glaeser and Mare, 1994; Bairoch, 1988).

While looking for the presence of increasing returns to scale yields insights, it does not address the constraints physical geography may place upon economic growth. For example, Adam Smith's observations on the role of access to navigable water still hold. Cross-country empirical research affirms that the level and growth rate of per capita income continue to be strongly positively correlated with geographic variables such as climate and coastal proximity (Gallup, Sachs and Mellinger, 1999; Mellinger, Sachs and Gallup, 2000), while within-country differences in growth rates in India and China are clearly related to geography as well (Demurger et al., 2002; Sachs, Bajpai and Ramiah, 2002). Smith's observations also implicitly underscore the highly favourable economic geography enjoyed by the nations of western Europe. Extensive ocean shorelines host a succession of natural harbours, and
numerous navigable rivers penetrate deep into the interior. In addition, despite the large landmass of the United States, 57 per cent of income was generated in counties within 80 km from the coast, though these counties account for only 13 per cent of land mass (Rappaport and Sachs, 2003).

Future theoretical and empirical work in understanding regional development should aim to disentangle the forces of differential geography and self-organizing agglomeration economies. Policy studies should examine in depth how regional development policy has been used in the past, and which instruments are particularly important. Economists and business specialists should aim to provide new tools to help specific regions identify appropriate instruments for regional development, including which kinds of industries are likely to flourish in which kinds of spatial settings.

Abstract

In recent years regression discontinuity analysis has grown into a popular approach for evaluating causal relationships in empirical economics. The method takes advantage of a discontinuity in the probability of treatment as a function of a continuous variable to identify a meaningful average treatment effect. This article summarizes the regression discontinuity approach to identifying and estimating causal effects and describes several validity tests.

Keywords

assignment mechanisms; control function approach; identification; instrumental variables; kernel estimators; propensity score; regression discontinuity analysis; selection bias; semiparametric estimation; treatment effect

Article

The regression discontinuity (RD) data design is a quasi-experimental evaluation design first introduced by Thistlethwaite and Campbell (1960) as an alternative approach to evaluating social programmes. The design is characterized by a treatment assignment or selection rule which involves the use of a known cut-off point with respect to a continuous variable, generating a discontinuity in the probability of treatment receipt at that point. Under certain comparability conditions, a comparison of average outcomes for observations just left and right of the cut-off can be used to estimate a meaningful causal impact. While interest in the design had previously been mainly limited to evaluation research methodologists (Cook and Campbell, 1979; Trochim, 1984), the design is currently experiencing a renaissance among econometricians and empirical economists (Hahn, Todd and van der Klaauw, 1999; 2001; Angrist and Krueger, 1999; Porter, 2003). Among the main econometric contributions have been the formal derivation of identification conditions for causal inference and the introduction of semiparametric estimation procedures for the design. At the same time, a large and rapidly growing
number of empirical applications are providing new insights into the applicability of the design, which have led to the development of several sensitivity and validity tests.

The popularity of the RD design in applied economic research can be linked to several of its features. First, the assignment rules in many existing programmes and procedures for allocating social resources, frequently lend themselves to RD evaluations. In many cases, programme resources are allocated based on some type of formula that has a cut-off structure. One area of economic research where the design has proven especially fruitful in recent years has been the evaluation of educational interventions. Education programmes are frequently assigned to schools or students who score below a cut-off on some scale (student performance, poverty), and school and programme funding decisions are often based on allocation formulas containing discontinuities. Similarly, the design has proven useful in evaluating the socio-economic impacts of a diverse set of government programmes and laws, many of which use eligibility cutoffs or funding formulas involving thresholds in allocating scarce resources to those potential recipients who need or deserve them most (see van der Klaauw, 2007a). A second attractive feature of the design is that it is intuitive and its results can be easily communicated, often with a visual portrayal of sharp changes in both treatment assignment and average outcomes around the cut-off value of the assignment variable (Bloom et al., 2005). Third, a researcher can choose from among several different methods to estimate effects that have credible causal interpretations (Hahn, Todd and van der Klaauw, 2001).

Consider the general problem of evaluating the impact of a binary treatment on an outcome variable, using a random sample of individuals where for each individual $i$ we observe an outcome measure $y_i$ and a binary treatment indicator $t_i$, equal to one if treatment was received and zero otherwise. The evaluation problem that arises in determining the effect of $t$ on $y$, is due to the fact that each individual either receives or does not receive treatment and is never observed in both states. Let $y_i(1)$ be the outcome given treatment, and $y_i(0)$ the outcome in absence of treatment. Then the actual outcome we observe equals $y_i = t_i y_i(1) + (1 - t_i) y_i(0)$. A common regression model representation for the observed outcome can then be written as

$$y_i = \beta + \alpha_i t_i + u_i \tag{1}$$

where $\alpha_i = y_i(1) - y_i(0)$ and $y_i(0) = E[y_i(0)] + u_i = \beta + u_i$. Non-random assignment or selection into treatment implies that a comparison of average outcomes of treatment recipients and non-recipients ($E[y_i(1) | t_i=1]$ and $E[y_i(0) | t_i=0]$) would generally not provide us with a valid treatment effect estimate. Hahn, Todd and van der Klaauw (HTV) (2001) analysed the conditions under which a discontinuity in the treatment assignment or selection rule can be exploited to solve the selection bias problem and to identify a meaningful causal effect. Following Trochim (1984) they distinguish between two different forms of the design, depending on whether the treatment assignment is related to the assignment variable by a deterministic function (sharp design) or a stochastic one (fuzzy design). In the case of a sharp RD
design, individuals are assigned to or selected for treatment solely on the basis of a cut-off score on an observed continuous variable $x$. This variable, alternatively called the assignment, selection, running or ratings variable, could represent a single characteristic or a composite variable constructed using several characteristics. Those who fall below some distinct cutoff point $\bar{x}$ are placed in the control group ($t_i=0$), while those on or above that point are placed in the treatment group ($t_i=1$) (or vice versa). Thus, assignment occurs through a known and measured deterministic decision rule: $t_i = t(x_i) = 1\{x_i \geq \bar{x}\}$ where $1\{\cdot\}$ is the indicator function. As the assignment variable itself may be correlated with the outcome variable, the assignment mechanism is clearly not random.

However, if we have reason to believe that persons close to the threshold with very similar $x$ values are comparable, then we may view the design as almost experimental near $\bar{x}$, suggesting that we could evaluate the causal impact of treatment by comparing the average outcome for those with ratings just above to those with ratings just below the cutoff. More formally, consider the following local continuity (LC) assumption:

$$E[u_i|x] \text{ and } E[\alpha_i|x] \text{ are continuous in } x \text{ at } \bar{x},$$

then on the assumption that the density of $x$ is positive in a neighbourhood containing $\bar{x}$,

$$\lim_{x \uparrow \bar{x}} E[y_i|x] - \lim_{x \uparrow \bar{x}} E[y_i|x] - \lim_{x \downarrow \bar{x}} E[\alpha_i|x] - \lim_{x \downarrow \bar{x}} E[u_i|x] + \lim_{x \uparrow \bar{x}} E[u_i|x] - \lim_{x \downarrow \bar{x}} E[u_i|x] = E[\alpha_i|x = \bar{x}].$$ (2)

The RD approach therefore identifies the average treatment effect for individuals close to the discontinuity point. Note that the continuity assumption formalizes the idea that individuals just above and below the cut-off need to be ‘comparable’, requiring them to have similar average potential outcomes when receiving and when not receiving treatment. While in the absence of additional assumptions (such as a common effect assumption) one could learn about treatment effects only for a sub-population of persons near the discontinuity point, as pointed out by HTV this local effect is highly relevant to policymakers who are contemplating less restrictive eligibility rules and marginal expansions of programmes via a change in the cut-off.

The continuity assumption required for identification is not innocuous. Even if treatment receipt is determined solely on the basis of a cut-off score on the assignment variable, this is not a sufficient condition for the identification of a meaningful causal effect. The continuity assumption rules out coincidental functional discontinuities in the $x-y$ relationship such as those caused by other programmes employing assignment mechanisms based on the exact same assignment variable and cut-off. In addition, the continuity restriction generally rules out certain types of behaviour both on the part of potential treatment recipients who exercise control over their value of $x$ and programme administrators in choosing the assignment variable and cut-off point. Lee (2007) analyses the conditions under which an ability to manipulate the assignment variable may invalidate the RD identification
assumptions. He shows in the context of a sharp RD design that as long as individuals do not have perfect control over the position of the assignment variable relative to the cut-off score, the continuity assumption will be satisfied.

While in the sharp RD design treatment assignment is known to depend on the selection variable \( x \) in a deterministic way, in the case of a fuzzy design (Campbell, 1969), treatment assignment depends on \( x \) in a stochastic manner but in such a way that the propensity score function \( \Pr(t=1|x) \) is again known to have a discontinuity at \( \bar{x} \). Instead of a 0 – 1 step function, the selection probability as a function of \( x \) would now contain a jump smaller than 1 at \( \bar{x} \). The fuzzy design can occur in case of misassignment relative to the cut-off value in a sharp design, with values of \( x \) near the cut-off appearing in both treatment and control groups. This situation is analogous to having no-shows (treatment group members who do not receive treatment) and/or crossovers (control group member who do receive the treatment) in a randomized experiment. This could occur if in addition to the position of the individual's score relative to the cut-off value, assignment is based on additional variables observed by the administrator, but unobserved by the evaluator.

A comparison of average outcomes of recipients and non-recipients, even if near the cut-off, would not generally lead to correct inferences regarding an average treatment effect. However, as shown by HTV, one can again exploit the discontinuity in the selection rule to identify a causal impact of interest by noting that under the LC assumption and with a locally constant treatment effect \( \alpha \), the treatment effect is identified by

\[
\frac{\lim_{x \uparrow \bar{x}} \mathbb{E}[y|x] - \lim_{x \downarrow \bar{x}} \mathbb{E}[y|x]}{\lim_{x \uparrow \bar{x}} \mathbb{E}[t|x] - \lim_{x \downarrow \bar{x}} \mathbb{E}[t|x]},
\]

where the denominator is always non-zero because of the known discontinuity of \( \mathbb{E}[t|x] \) at \( \bar{x} \).

In the case of varying treatment effects, HTV show that under the local continuity assumption, and a local conditional independence assumption requiring \( t_i \) to be independent of \( \alpha_i \) conditional on \( x \) near \( \bar{x} \), the ratio above identifies \( \mathbb{E}[\alpha_i|x = \bar{x}] \), the average treatment effect for cases with values of \( x \) close to \( \bar{x} \). The conditional independence assumption is a strong assumption which may be violated if individuals self-select into or are selected for treatment on the basis of expected gains from treatment. HTV show that, under a weaker local monotonicity assumption similar to that assumed by Imbens and Angrist (1994), the ratio (3) will instead identify a local average treatment effect (LATE) at the cut-off point, which represents the average treatment effect of the ‘compliers’, that is, the subgroup of individuals whose treatment status would switch from non-recipient to recipient if their score \( x \) crossed the cut-off.

More recently Battistin and Rettore (2003) considered the special case where an eligibility rule divides the population into eligibles and non-eligibles according to a sharp RD design, and with eligible individuals self-selecting into treatment. In this case the LC assumption alone is sufficient for the ratio to identify \( \mathbb{E}[\alpha_i|t_i = 1, x = \bar{x}] \), the average treatment effect on the treated, for those near the cut-off.

As indicated by these identification results, estimation of treatment effects in an RD design involves
estimating boundary points of conditional expectation functions. The most common empirical strategy in the literature has been to adopt parametric specifications for the conditional expectations functions. Consider the following alternative representation of outcome eq. (1) in case of a sharp RD design:

$$y_i = m(x_i) + \delta t_i + \varepsilon_i$$

(4)

where $\varepsilon_i = y_i - E[y_i|t_i, x_i]$, $t_i = 1\{x_i \geq \bar{x}\}$, $m(x) = E[u|x] + E[\alpha|x] - E[\alpha|x] \cdot \{x \geq \bar{x}\}$. Then under the local continuity assumption $m(x)$ will be a continuous function of $x$ at $\bar{x}$, and $\delta = E[\alpha|x]$ (the average treatment effect at $\bar{x}$) will measure the discontinuity in the average outcome at the cut-off. This suggests that if the correct specification of $m(x)$ were known, and was included in the regression, we could consistently estimate the treatment effect for the sharp RD design. This idea of including a specification of $m(x)$ in the regression of $y$ on $t$ in order to correct for selection bias caused by selection on observables, is in the econometrics literature known as the control function approach (Heckman and Robb, 1985). A popular choice among empirical researchers has been to use global polynomials or to use splines (piecewise polynomials) which, even though globally continuous, have a knot at the cut-off (Trochim, 1984; van der Klaauw, 2002; McCrary, 2007).

In the case of a fuzzy RD design, when assuming local independence of $t_i$ and $\alpha_i$ conditional on $x$, then in a neighbourhood of $\bar{x}$,

$$y_i = m(x_i) + \delta E[t_i|x_i] + w_i$$

(5)

where $w_i = y_i - E[y_i|x_i]$ and $m(x) = E[u|x] + E[\alpha|x] - E[\alpha|x] \cdot E[t|x]$. With the local continuity assumption again implying that $m(x)$ will be continuous at the cut-off, and with $E[t_i|x_i]$ being discontinuous at $\bar{x}$, $\delta$ in this regression will measure the ratio in (3), which in this case equals the average local treatment effect $E[\alpha|x]$. Similarly, $\delta$ can be interpreted as a local average treatment effect if we replaced the local independence assumption with the local monotonicity condition of Imbens and Angrist (1994).

This naturally leads to the two-stage procedure adopted by van der Klaauw (2002), where in the first stage we estimate the propensity score function specified as $t_i = E[t_i|x_i] + \nu_i = f(x_i) + \gamma \{x_i \geq \bar{x}\} + \nu_i$ where $f(\cdot)$ is continuous in $x$ at $\bar{x}$ and $\gamma$ measures the discontinuity in the propensity score function at $\bar{x}$. In the second stage the control function-augmented outcome equation is then estimated with $t_i$ replaced by the first-stage estimate of $E[t_i|x_i] = Pr[t_i = 1|x_i]$ as in Maddala and Lee (1976). With correctly specified $f(x)$ and $m(x)$ functions, this two-stage procedure yields a consistent estimate of the treatment effect. The approach is similar in spirit to those proposed earlier in the RD evaluation literature by
Spiegelman (1979) and Trochim and Spiegelman (1980). Note that in case of a parametric approach, if we assume the same functional form for \(m(x)\) and \(f(x)\), then the two-stage estimation procedure described here will be equivalent to two-stage least squares (in case of linear-in-parameter specifications) with \(1\{x_i \geq \bar{x}\}\) and the terms in \(m(x)\) serving as instruments. Because of the popularity of this particular parametrization, the RD approach is often interpreted as being equivalent to an instrumental variable approach, as it implicitly imposes an exclusion restriction by excluding \(1\{x_i \geq \bar{x}\}\) as a variable in the outcome equation.

Valid parametric inference for the estimation of the treatment effect requires a correct specification of the control function \(m(x)\) and of \(f(x)\) in the treatment equation. To mitigate the potential for misspecification bias, several semiparametric estimation procedures have been proposed for estimating \(m(x)\) and \(f(x)\), or equivalently for estimating the limits \(\lim_{x \uparrow \bar{x}} E[z|x]\) and \(\lim_{x \downarrow \bar{x}} E[z|x]\) in (3) semiparametrically. These methods rely on less-restrictive smoothness conditions away from the discontinuity, with estimates based mainly on data in a neighbourhood on either side of the cut-off point. Asymptotically this neighbourhood needs to shrink, as with usual nonparametric estimation, implying that we should expect a slower than parametric rate of convergence in estimating treatment impacts.

HTV considered the use of kernel and local linear regression estimators, while Porter (2003) proposed estimating the limits using local polynomial regression and partially linear model estimation. RD estimators based on local polynomial regression and partially linear model estimation have better boundary behaviour than the kernel-based estimator and as shown by Porter, achieve the optimal rate of convergence. This result is based on a known degree of smoothness of the conditional expectation functions. Sun (2005) proposed an adaptive estimator to first estimate the degree of smoothness in the data prior to implementing either estimator.

The internal validity of the RD approach relies on the local continuity of conditional expectations of potential outcomes around the discontinuity point. While this assumption is fundamentally untestable, a number of validity tests have been developed to bolster the credibility of the RD design. First, economic behaviour may lead to sorting of individuals around the cut-off point, where those below the cut-off may differ on average from those just above the cut-off. Such precise sorting around the cut-off would generally be accompanied by a discontinuous jump in the density of the assignment variable at the cutoff. Several approaches have been used for assessing this possibility (McCrary, 2007; Lee, 2007; Chen and van der Klaauw, 2007; Lemieux and Milligan, 2004). Second, one can test for evidence that individuals on either side of the cut-off are observationally similar by directly comparing average characteristics (McEwan and Urquiola, 2005) or by repeating the RD analysis treating the characteristics as outcome variables (van der Klaauw, 2007b). Alternatively, one can test for an imbalance of relevant characteristics by assessing the sensitivity of RD estimates to the inclusion of observed characteristics as controls (van der Klaauw, 2002; Lee, 2007). Third, in some applications data are available from a baseline period in which the programme did not yet exist, or for a group of individuals that was not eligible for treatment. In such a case the credibility of the design can be significantly enhanced by repeating the RD analysis with such data. Finding a zero treatment effect in such a falsification test would suggest that a non-zero post-programme effect was not an artifact of the specific RD model specification, estimation approach chosen or caused by another programme using the same cut-off and assignment variable.

Finally, while this exposition has focused on the binary treatment case with a selection rule containing a
single discontinuity at a known cut-off, the approach can be readily extended to one where there are multiple treatment dose levels and multiple cut-offs or ‘cut-off ranges’ within which the treatment dose varies continuously (van der Klaauw, 2007a). Similarly, the approach can be modified to cover cases where the assignment or selection variable is discrete instead of continuous (Lee and Card, 2006).

General equilibrium theory describes those states of an economy in which the individual plans of many agents with partially conflicting interests are compatible with each other. Such a state is called an equilibrium. The concept of an equilibrium simply being based on a consistency requirement lends itself to the study of specific questions of quite different character. Indeed, equilibrium theory provides a unifying framework for the analysis of questions arising in various branches of economic theory. In our opinion it is fruitful to view equilibrium theory as a method of thinking applicable to a variety of problems of different origin. Ideally one would like to have general principles which ensure that equilibria exist, that they are unique, and that, therefore, the equilibria resulting from different policy measures can unequivocally be compared. Moreover, one would like to know whether equilibria have some desirable properties when no single agent can exert an essential influence on the global outcome to his personal advantage. These welfare questions are particularly interesting because the concept of an equilibrium itself is not based on the well-being of the economic agents. Finally, although the concept of an equilibrium as described above is static in nature, one would like to have a dynamic theory according to which some equilibrium is approached in the course of time.

These and related questions such as the computability of equilibria have been studied in the past with different degrees of success. There are general principles which yield the existence of an equilibrium in an astonishingly large variety of cases. Furthermore, the welfare properties of equilibria are well understood. However, it is easy to construct examples of economies with an infinite number of equilibria and it appears to be very difficult to provide conditions which lead, without being artificial or and hoc, to the uniqueness of an equilibrium. As a consequence, comparative statics does not have a basis which makes it generally a well-defined problem. Also, the difficulties encountered when studying the uniqueness issue present severe obstacles for the development of a dynamic theory.

The theory of regular economies may be viewed as an effort to advance general equilibrium theory in the absence of a satisfactory uniqueness result. The seminal paper is Debreu (1970). Debreu explicitly allows for the multiplicity of equilibria. However, he requires each equilibrium to be locally unique. Each equilibrium is well determined and robust in the sense that it is not destroyed by a small change in the parameters.

A regular economy is an economy with a certain, finite number of equilibria, all of which respond continuously to small parameter changes. Hence each of these equilibria can be traced for some while during a parameter change. Thus there is a basis for doing comparative statics locally, that is to say as long as the equilibrium under consideration stays robust. If, at a certain point, it ceases to be robust, a drastic change is to be expected, the size and direction of which are probably hardly predictable. The focus of the theory of regular equilibria is more on the continuous behaviour of robust equilibria than on drastic changes.

It is most remarkable that Debreu (1970), by using concepts and techniques developed in the mathematical field of differential topology, has introduced a new kind of thought into economic analysis. In the meantime this way of thinking has penetrated many areas of economic theory at different levels. One of the first applications has occurred in the technically advanced area of core theory, where the continuous dependence of the set of price equilibria on the characteristics of the agents, which is guaranteed in a regular economy, plays an important role. An application on a purely conceptual level in oligopoly theory is incorporated in the notion of a demand function which an oligopolist faces in the Cournot–Nash context. The graph of this function is considered as given by the equilibria of an exchange economy with initial endowments as varying parameters.

The dependence of the equilibria on initial endowments will be discussed in detail in the next section because this case is particularly suited to illustrate basic ideas of the theory of regular economies.

Debreu's theorem on regular equilibria
The purpose of this section is to describe the kind of reasoning typical for the theory of regular economies in a prototypical situation. It is desirable to deal with parameter variations taking place in some Euclidean space because the mathematical structures to be used are most familiar in this case. We shall study exchange economies which differ by the allocation of initial endowments.

There are $l$ commodities and $m$ consumers. Individual initial endowments are supposed to be positive in each component. If we denote the strictly positive orthant in $\mathbb{R}^l$ by $P$, then an initial allocation is a vector $(e_1, \ldots, e_m) \in P^m$. Since the demand function $f_i$ of each consumer $i$ is considered as fixed, an economy $E$ is fully specified by $(e_1, \ldots, e_m)$. The space of all economies under consideration can thus be identified with $P^m$, an extremely simple subset of a Euclidean space. We want to examine how the exchange equilibria of an economy—there may be several such equilibria—depend on the particular economy $E \in P^m$.

We assume that all goods are desired so that attention may be restricted to strictly positive relative prices. Price systems are normalized; to be specific we consider price systems in

$$S = \left\{ \rho - (p_1 \ldots p_2) \in \mathbb{R}^l : \left( \sum_{k=1}^l p_k^2 \right)^{1/2} - 1 \right\}.$$

If consumer $i$ initially possesses the commodity bundle $e_i$, his demand at the price system $\rho$ is $f_i(\rho, p \cdot e_i) \in \mathbb{R}^l$, where $p \cdot e_i = w_i > 0$ is $i$'s wealth. Hence the aggregate excess demand of the economy $E$, given by the initial allocation $(e_1, \ldots, e_m) \in P^m$, at $p$ is

$$Z_E(\rho) = \sum_{i=1}^m [f_i(\rho, p \cdot e_i) - e_i].$$

We assume Walras's Law which states that the value $\rho \cdot Z_E(\rho)$ of the excess demand is identically equal to zero. Furthermore, every $f_i$ is supposed to be continuous.

The desirability of all commodities will be captured in the following condition, which is always satisfied when consumers have strictly monotone preferences.

**(D)** If the price of at least one good approaches zero and the wealth $w_i > 0$ of every agent stays away from zero, then

$$\sum_{i=1}^m \|f_i(\rho, w_i)\|$$

tends to infinity.

An equilibrium price system of $E$ is a price system $\rho \in S$ at which the consumption plans $f_i(\rho, p \cdot e_i)$ of all agents are consistent, i.e. a zero of the excess demand function $Z_E$. It is not difficult to show the following consequence of the desirability assumption (D) by a fixed point argument:

*Every economy $E \in P^m$ has at least one equilibrium if (D) holds.*

We would like to know how the equilibrium prices vary when the initial allocation is modified. Therefore we look at the graph $\Gamma$ of the correspondence ('multi-valued function') $\Pi$ which assigns to every economy $E \in P^m$ its set $\{ \rho \in S : Z_E(\rho) = 0 \}$ of equilibrium price systems. Defining $Z : P^m \times S \to \mathbb{R}$ by $Z(E, \rho) = Z_E(\rho)$ we get

$$\text{graph } (\Pi) = \Gamma = Z^{-1}(0).$$
Since $Z$ is a continuous function, $\Gamma$ is a closed set. It is well known that, in the case of a (single-valued) function, the closedness of the graph is intimately related to the continuity of the function. Here, where $\Pi$ is a correspondence rather than a function, we obtain the following continuity result: the graph $\Gamma$ of the equilibrium price correspondence $\Pi$ is upper hemi-continuous and compact-valued, if (D) holds.

This is tantamount to the following explicit statement. If $(E_n)$ is a sequence of economies in $P^m$ converging to $E \in P^m$ and if $\rho_n \in \Pi(E_n)$ is an equilibrium price system to $E_n$ for all $n$, then the sequence $(\rho_n)$ has a subsequence which converges to an equilibrium price system of the limit economy $E$, provided (D) holds.

To improve our understanding of $\Gamma$, we assume that the demand functions $f_i$ are continuously differentiable ($C^1$ for short) and we invoke the implicit function theorem in the following manner. Walras's Law allows us to disregard one market, say the $l$th, and to concentrate on

$$\tilde{Z} : P^m \times S \to \mathbb{R}^{l-1}$$

which is obtained from $Z$ by deleting the last component. Let $\rho$ be an equilibrium price system of $E$, i.e. $\tilde{Z}(E, \rho) = 0$. A simple calculation yields that the derivative $\partial \tilde{Z}(E, \rho)$ has maximal rank at $(E, \rho)$. Therefore, the graph $\Gamma$ is given by a smooth surface of dimension $lm$. That is to say each point in $\Gamma$ has a neighbourhood in $\Gamma$ which can be mapped onto an open subset of $\mathbb{R}^{lm}$ by a $C^1$ diffeomorphism, i.e. a $C^1$ map with a $C^1$ inverse. Such a locally Euclidean space is called a $C^1$ manifold: see Figure 1.

Figure 1
We have seen that the graph $\Gamma$ of the equilibrium price correspondence $\Pi$ is a $C^1$ manifold, but Figure 1 suggests more. In Figure 1, $\Gamma$ is not only locally Euclidean, there is even a global diffeomorphism between $\Gamma$ and $\mathbb{R}^n$. Indeed, one can show that this global equivalence holds (see Balasko, 1975).

The equilibrium price correspondence is continuous except at two points, $E_1$ and $E_2$. If a parameter variation leads through $E_1$ (or $E_2$) the equilibrium may be forced to jump. The equilibrium reached after the jump, however, is robust in the sense that no sudden change must occur when one passes through $E_1$ (or $E_2$) again. One can imagine a situation such as in $E_1$ takes place when a slight reduction in the supply of an important raw material leads to a drastic increase in its price. If later on the supply begins to increase again prices perhaps vary but stay at their high level. A reversion of this phenomenon may occur when the supply has reached the much higher level corresponding to $E_2$.

In Figure 2 we have drawn a two-dimensional parameter space. The following remarkable phenomenon may happen here.

Figure 2
There are two paths, A and B, in the parameter space which have their starting point and endpoint in common. Following either path there is no need for the equilibrium to jump. However, the two equilibria reached at the end are quite different equilibria of the same economy. In other words, if two or more policy variables are at one's disposal one must be aware of the possibility that the final outcome depends very well on the order in which the variables are utilized.

The economies $E_1$ and $E_2$ in Figure 1 are characterized by the fact that the graph $\Gamma$ has a vertical tangent above $E_1$ and above $E_2$. Similarly, in Figure 2, $\Gamma$ has vertical tangents above all points on the cusp drawn in the bottom plane, which represents $P^m$. Apparently qualitative changes of the equilibrium price set at an economy $E$ are associated with vertical tangents of $\Gamma$ above $E$. This motivates the following definitions. A critical point of the projection $pr: \Gamma \to P^m$ is a point in $\Gamma$ at which the derivative of $pr$ has rank less than $\dim P^m = lm$. A critical value of $pr: \Gamma \to P^m$ is the image of a critical point. A regular value of $pr: \Gamma \to P^m$ is a point in $P^m$ which is not a critical value. Figures 1 and 2 suggest that almost all points in $P^m$ are regular values. Indeed, the concepts introduced above are defined in differential topology in a quite general context and Sard's theorem, an analytical tool of great importance, asserts that the critical values of a sufficiently differentiable mapping are rare. More precisely, Sard's theorem applied to our particular problem yields that the set of critical values of $pr: \Gamma \to P^m$ is a (Lebesgue) null set. Null sets are small in a probabilistic sense. At this point we make essential use of the space of economies $P^m$ being part of a Euclidean space. If, for instance, consumers' demand functions or preferences are allowed to vary instead of consumers' endowments, it is not clear how null sets are to be defined. However, one can express quite easily when two demand functions or preference orderings are close to each other. That is to say metric structures are very often naturally given when there is no obvious way to define null sets. A set can then be defined to be small in a topological sense if its closure is nowhere dense. Furthermore, if the concepts of smallness in the probabilistic and in the topological sense are both well-defined, as they are in the case of variable initial endowments, one has to be aware of the fact that the two variants of the intuitive notion of smallness apply to quite different sets. Defining a critical economy $E \in P^m$ as a critical value of $pr: \Gamma \to P^m$ and regular economy as a regular value of $pr$ we ask ourselves whether the null set of critical economies has a null closure. We know already that the desirability assumption (D) implies that the equilibrium price correspondence is upper hemi-continuous and compact-valued or, in more intuitive terms, that $\Gamma$ has only finitely many layers above some compact ball $B$ of economies in $P^m$. Hence the points in $\Gamma$ which lie above $B$ and have a vertical tangent form a compact set. Projecting this set down to $B$ yields a compact set, the set of critical economies in $B$. Since this set is also null by Sard's theorem, it is nowhere dense. We obtain:

The set of critical economies in $P^m$ is a closed null set if (D) holds.

Let $E \in P^m$ be a regular economy. Then $E$ has a finite number of equilibria and this number is locally constant. If $E$ has $r$ equilibria, then there is a neighbourhood $U$ of $E$ and there are $r \in C^1$ functions $g_1, \ldots, g_r$ such that the set $\Pi(E')$ of equilibrium price systems of any economy $E' \in U$ is given by $\{g_1(E'), \ldots, g_r(E')\}$. In particular, the equilibrium price correspondence $\Pi$ is continuous in a neighbourhood of a regular economy.

These results, with minor differences, have been obtained by G. Debreu (1970), whose proof, however, differs from the exposition given here.

Extensions
When one wants to extend the theory of regular equilibria to more general spaces of economies, it is often useful to employ a definition of a regular economy which focuses on the given economy and does not refer to the graph $Γ$ or to the parameter space. To motivate the following definition we contrast Figure 3, in which the excess demand of a critical economy such as $E_1$ or $E_2$ in Figure 1 is drawn, with Figure 4, which shows the graph of a regular economy such as $E_3$. It is assumed that there are two goods so that it suffices, according to Walras's Law, to look at the excess demand $ζ_1$ for good 1.

Figure 3

Good 1

$ζ_1$

$P_1$
In Figure 3 there is one equilibrium at which $\frac{d \xi_1}{d \rho_1}$ vanishes. Shifting the graph of $\xi_1$ a little upwards destroys this equilibrium. In Figure 4, however, $\frac{d \xi_1}{d \rho_1}$ does not vanish at any equilibrium and all equilibria are robust.

Let the excess demand function $\xi: S \to \mathbb{R}$ of an economy $E$ be $C^1$. A price system $\rho \in S$ is called a regular equilibrium price system if $\xi(\rho) = 0$ and the matrix

$$
\left[ \frac{\partial \xi_{kh}}{\partial \rho_k} (\rho) \right]_{h,k=1,\ldots,n-1}
$$

is regular. A regular economy is an economy all equilibrium price systems of which are regular. One can show that this definition, introduced by E. and H. Dierker (1972), is independent of the way in which goods are indexed and that it is consistent with the definition given above.

The results on regular economies obtained in various frameworks are quite similar to those established in the previous section. It is shown that almost all economies, in an appropriate sense, are regular. Every regular equilibrium is locally unique and can be traced along its path when the economy varies gradually, as long as it stays regular. Economic models in which results of this kind have been precisely formulated and verified deal with variations in consumption and production (see, in particular, Smale, 1974). Also the case of many consumers, that is to say of consumption sectors described by the distribution of consumers' characteristics, has been treated. The basic mathematical tool is always some variant of Sard's Theorem. References can be found in my survey article (Dierker, 1982).

The study of regular equilibria has led to a revival of the differentiable viewpoint in general equilibrium theory and related areas. Readers interested in this modern development are referred to the excellent book by A. Mas-Colell (1985), which also contains an extensive, systematic presentation of the theory of regular equilibria.

regulation

Robert Boyer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Régulation’ theory analyses the long-term transformation in capitalist economies and their consequences for growth patterns and cyclical adjustments. The degree of coherence of a specific configuration of the major institutional forms – monetary regime, wage-labour relation, form of competition, state–citizen institutionalized compromise and mode of support of the international regime – defines various accumulation regimes and ‘régulation’ modes. Over one century, several regimes have been observed along with a succession of changing patterns for the related structural crises. The demise of the post-Second World War Fordist regime has been associated with an uncertain process of institutional restructuring and the coexistence of various brands of capitalism.

Article

Since the 1980s, the term ‘régulation’ has suggested state intervention in the name of economic management though its opposite, ‘dérégulation’, has been more widely used. In the area of economic policy and in accordance with Keynesian precepts, regulation indicates the adjustment of macroeconomic activity by means of budgetary or monetary contra-cyclical interventions. In the area of public management, a complete body of literature, under the name of regulation theory, has investigated the methods for organizing the decentralization of the supply of various public utilities. This term is also used in physics and biology. In mechanics, a regulator is a means to stabilize the rotary speed of a machine. In biology, regulation corresponds to the reproduction of substances such as DNA.
In general terms, the theory of systems involves the study of the role of a set of negative and positive feedback loops in relation to the stability of a complex network of interactions. Here, a third and different, but not totally unrelated, meaning of the term will be developed. Theories of régulation constitute an area of research which has focused on analysing long-term transformations in capitalist economies. Initially, it focused on American and French capitalisms (Aglietta, 1982; Benassy, Boyer and Gelpi, 1979) but it was progressively extended first to major OECD economies (Mazier, Basle and Vidal, 1999) then to Latin American countries (Hausmann, 1981; Ominami, 1985) and ultimately Asian countries (Bertoldi, 1989; Boyer, 1994). A general presentation of the present state of the theory is to be found in Boyer and Saillard (2002) and a large sample of national case studies in Jessop (2001). Basically, the theory of régulation combines Marxian intuitions and Kaleckian macroeconomics with institutionalist and historicist studies, mobilizing most of the tools of modern economic analysis.

At a primary level, a form of régulation denotes any dynamic process of adaptation of production and social demand resulting from a conjunction of economic adjustments linked to a given configuration of social relations, forms of organization and productive structures (Boyer, 1990).

Most economic theories emphasize the general invariables of eminently abstract systems, in which history serves merely as a confirmation or, failing that, as a perturbation. Neoclassical theory studies the shift of a stable equilibrium after an external shock, Keynesian economists stress the role of effective demand and fine tuning whatever the context and the period. Even Marxists tend to extrapolate, as general laws, the quite specific evolutions observed in the early phases of capitalism. In contrast, the régulation approach seeks a broader interaction between history and theory, social structures, institutions and economic regularities (de Vroey, 1984).

The starting point is the hypothesis that accumulation has a central role and is the driving force of capitalist societies. This necessitates a clarification of factors that reduce or delay the conflicts and disequilibria inherent in the formation of capital, and which allow for an understanding of the possibility of periods of sustained growth (Boyer and Mistral, 1978). These factors are associated with particular regimes of accumulation, namely, the form of articulation between the dynamics of the productive system and social demand, the distribution of income between wages and profits on the one hand, and on the other hand the division between consumption and investment. It is then useful to explain the organizational principles which allow for mediation between such contradictions as the extension of productive capacity under the stimulus of competition on product markets, for labour and finance. The notion of institutional form – defined as a set of fundamental social relations (Aglietta, 1982) – enables the transition between constraints associated with an accumulation regime and collective strategies; between economic dynamics and individual behaviour. A small number of key institutional forms, which are the result of past social struggles and the imperatives of the material reproduction of society, frame and channel a multitude of partial strategies which are decentralized and limited in terms of their temporal horizon. Five main institutional forms do shape accumulation regimes.

The forms of competition describe by what mechanisms the compatibility of a set of decentralized decisions by firms and individuals is ensured. They are competitive while the ex post adjustment of prices and quantities ensures a balance; they are monopolist if the ex ante socialization of revenue is such that production and social demand evolve together (Lipietz, 1979). The type of monetary constraint explains the interrelations between credit and money creation: credit is narrowly limited in terms of
movement of reserves when money is predominantly metallic; the causality is reversed when on the contrary the dynamics of credit conditions the money supply in systems where the external parity represents the only constraint weighing upon the national monetary system (Benassy, Boyer and Gelpi, 1979). The nature of institutionalized compromises defines different configurations of relations between the state and the economy (André and Delorme, 1983; Jessop, 1990): the state-as-referee when only general conditions of commercial exchange are guaranteed; as the interfering state when a network of régulation and budgetary interventions codifies the rights of different social groups. Modes of support for the international regime are also derived from a set of rules which organize relations between the nation state and the rest of the world in terms of commodity exchange, migration, capital movements and monetary settlements. History goes beyond the traditional contrast between an open and a closed economy, free trade and protectionism; it makes apparent a variety of configurations (Mistral, 1986; Lipietz, 1986a). Finally, forms of wage relations indicate different historical configurations of the relationship between capital and labour, that is, the organization of the means of production, the nature of the social division of labour and work techniques, type of employment and the system of determination of wages, and finally, workers' way of life including the welfare state. If, in the first stages of industrialization, wage-earners are defined first of all as producers, during the second stage they are simultaneously producers and consumers.

At this point appears the notion of régulation, as a conjunction of mechanisms and principles of adjustment associated with a configuration of wage relations, competition, state interventions and hierarchization of the international economy. Finally, a distinction between ‘small’ and ‘big’ crises is called for (Boyer, 1990). The former, which are of a rather cyclical nature, are the very expression of régulation in reaction to the recurrent imbalances of accumulation. The latter are of a structural nature: the very process of accumulation throws into doubt the stability of institutional forms and the régulation which sustains it because the profit does not recover by contrast with conventional business cycles. Thus, in long-term dynamics as well as in short-term development, institutions are important. Historical research confirms that sometimes institutional forms make an impression on the system in operation; at other times they register major changes in direction. At the end of a period which can be counted in decades, the very mode of development – that is, the conjunction of the mode of régulation and the accumulation regime – is affected: there will be changes in the tendencies of long-term growth and eventually in inflation, specificities of cyclical processes (Mazier, Basle and Vidal, 1999).

So a periodization of advanced capitalist economies emerges which is not part of the traditional Marxist theory. Despite the rise in monopoly, the interwar period is still marked by competitive regulation. After the Second World War an accumulation regime without precedent is instituted – that of intensive accumulation centered on mass consumption (Bertrand, 1983) – known as Fordist and channelled through monopolist-type regulation.

In fact, the alteration in wage relations – in particular the transition to Fordism, that is, the synchronization of mass production and wage-earners' access to the ‘American way of life’ – and in monetary management, that is, transition to internally accepted credit money – seems to have played a greater role than the change in modes of competition or conjunctural fine tuning à la Keynes (Aglietta, 1982; Aglietta and Orlean, 1982; Boyer, 1988).

Since the 1960s, many economies have been experiencing a big crisis without historical precedent: stagflation, absence of cumulative depression, breaking-down of most previous economic regularities,
length of the period of technological and institutional restructuring (Boyer and Mistral, 1978; Lipietz, 1985). In consequence, it is logical that former economic policies lose their efficacy (Boyer, 1990). First, because the crisis is not cyclical but structural; this invalidates the policy of fine-tuning; second, because the structural changes which permitted the 1929 crisis to be overcome have become blocked and cannot be repeated (Lipietz, 1986b).

Since the formative years, the research programme has been developing both extensively and intensively. The collapse of the Soviet bloc economies has pointed to the need to investigate the necessary and sufficient institutions required for a viable capitalist economy (Emergo, 1995; Hollingsworth and Boyer, 1997): economic viability depends on the compatibility of a complete set of institutional forms. In the epoch of financialization (Aglietta, 1998), information and communication technologies diffusion (Boyer, 2004), rise of services (Petit, 1986) and strengthening of foreign competition (Lipietz, 1986a), no clear follower to Fordism has yet emerged and diffused. Nevertheless, since the mid-1970s a series of trials and errors concerning the reform of the monetary regime, the tax and welfare system, competition and wage relations has finally delineated a new institutional architecture, quite complex to analyse. Conversion, layering and recomposition of existing institutional forms have replaced the strong synchronization associated with major crises and world wars (Boyer, 2005b).

The large number of international comparisons has systematically exhibited the persisting diversity of various brands of capitalism. Within industrialized countries: market dominated, corporate-led, state governed and social democratic versions, with some possible sub-variants, coexist (Amable, 2004). An equivalent but different variety is observed for Latin American countries (Quémia, 2001). Consequently, the financial crises experienced by Mexico, Brazil and Argentina are quite different, even if they all point out the destabilizing role of global finance upon contrasted domestic accumulation regimes (Boyer and Neffa, 2004).

These numerous structural changes call for new directions for the research agenda of régulation theory. Can the concepts of complementarity, hierarchy, isomorphism and coevolution explain how various mixes of institutions can cohere and define a coherent accumulation regime (Boyer, 2005a; Socio-Economic Review, 2005)? What kind of political economy analysis can explain the emergence and restructuring of institutional forms, especially the choice of monetary regime, the configuration of the welfare state or the nature of insertion into the world economy (Palombarini, 1999)? How to analyse multilevel régulation modes, especially in order to understand the complex process of European integration (Boyer and Dehove, 2001)? Finally, is not the anthropogenetic model, based on the production of humankind by education, health care and culture, a possible follower of the Fordist regime (Boyer, 2004)?

Margaret Reid, a leading scholar in analysis of the economics of consumer behaviour, was made a distinguished fellow of the American Economic Association in 1980. She was Professor of Economics at Iowa State College (1930–43), the University of Illinois (1948–51), and the University of Chicago (1951–61).

A realistic theorist, Reid always looked behind data to processes that generate structural relationships. Her 1934 book on household production anticipated by three decades analyses built on the allocation of time, and she was the first (1947) to use wage-equivalent time measures of household work. Already in Iowa she had questioned attempts to improve resource allocations by farm women that disregarded the nature of income effects. She went on to criticize assessments of the war-time cost-of-living index that neglected effects of changing incomes on the quality of goods traded, and she became the ‘directing’ member of the technical committee responsible for a report to the President's Commission on the Cost of Living (1945). Later on she challenged conventional treatments of income elasticities of consumption in general and of housing expenditures in particular (1952; 1962).

The concepts of ‘permanent’ and ‘transitory’ income were early a part of Reid's thinking (1952; 1953). Friedman drew on Reid in his 1957 application of the permanent income hypothesis to short-term shifts in consumption and saving, and Modigliani built on her work in his treatment of ‘life stages’ (Modigliani and Ando, 1960 and subsequently). In Reid's hands the concepts of ‘permanent’ and ‘transitory’ income evolved subtly and progressively in multiple facets of the analysis of consumer behaviour. After her retirement she probed interactions between health and income both over life cycles and across cohorts.

The role of religion in economic development warrants a nuanced perspective that integrates economic theory with an understanding of socio-political structures, appreciating the econometric issues that arise in quantifying religious processes. Existing research focuses on religious structures and organizations, state religions, faith-based welfare programmes, the regulation of religion, and the impact of religion on measures of well-being such as income and education. Viewing religion as spiritual capital, with the attendant role played by religious network externalities in fostering economic development, is vital for development policy. Contemporary research in religion and economic development is flourishing, encompassing all these diverse concerns.

Article
The number of micro-level social anthropological studies is continually growing. Many of these concentrate on what to the economist may appear odd aspects of society such as ritual and religion … and to which he pays little or no attention. For instance, an understanding of the complex of Hindu religious beliefs as they operate at village level … is directly relevant to the problem of developing India's economy. This is but one of numerous examples which can be quoted to support the claim that development economists work in the dark unless they acquaint themselves with the relevant socio-
How times have changed since Scarlett Epstein first lamented economists’ general neglect of the role of religion in the study of economic development. She need not have been quite so fearful: contemporary economics has seen the light, as it were, increasingly demanding a perspective on religion in order better to understand how it interacts with economic decision making. The increasing resilience of religion in both developed and developing countries, influencing globally both political will and popular debate, has been observed by scholars investigating the economics of religion (Iannaccone, 1998; Stark and Finke, 2001; Glaeser, 2005). Recent studies have investigated how religion affects growth (Guiso, Sapienza and Zingales, 2003; North and Gwin, 2004; Noland, 2005; Barro and McCleary, 2003; Glahe and Vorhies, 1989) with emphasis on particular religious traditions such as Islam, Hinduism or Catholicism (Kuran, 2004; Sen, 2004; Fields, 2003). Other studies have focused on the impact of religion on fertility (Lehrer, 2004; McQuillan, 2004). Still others examine the impact of religion on political outcomes (Glaeser, Ponzetto and Shapiro, 2005) and the role of religious organizations as insurance (Dehejia, DeLeire and Luttmer, 2005). Other studies examine how the causality may run the other way, from economic development to religion (Berman, 2000; Botticini and Eckstein, 2005; Goody, 2003).

Several theories have been advanced to account for the links between religion and development. First, there are theories that typify the ‘rational choice’ approach to religion and development. This approach considers the resilience of religion as a rational economic response to changes in the political, ecological and economic environments in which religions operate. In addition, a range of other structural theories encompass family socialization, social networks and a belief in other-worldly or supernatural elements. However, regardless of the scholastic tradition from which one approaches the study of religion, examining the interactions between religion and development poses significant challenges: first, to understand the endogenous interactions between religion and economic growth; second, to examine the techniques and methods needed to quantify these interactions; and third, to evaluate the impact of religion on development policy more widely.

Early writings

The economic concern with religion and development is not new, nor is it restricted to scholars of the 21st century. The writings of Thomas Aquinas, notably the De Regno (De Regimine Principum) ad Regem Cypri, written in 1267, dealt extensively with religion and public finance. Indeed, some scholars have considered the ideas in this work, as in Aquinas’s Summa Theologica (1265–72), strikingly relevant for poverty reduction today; their themes of the ‘universal common good’ and ‘global civil society’ have implications for current debates about globalization and human development (Linden, 2003). The links between religion and development also feature in Joseph Schumpeter's History of Economic Analysis (1954). Jacques Le Goff authored La Naissance du Purgatoire (1981), which argued that purgatory was a necessary religious innovation for medieval capitalist development. However, it was in 1904 that Max Weber put forward his famous theory of the Protestant ethic and the spirit of capitalism, arguing that economic development in northern Europe could be explained by developments that were associated
with Protestantism – the concern with savings, entrepreneurial activity, the frugality which Puritanism demanded, and the literacy needed to read the scriptures. The essence of Weber's thesis was that nascent capitalism emerged in the 16th century in Europe on account of the Protestant ethic which arose from the Reformation. Ascetic Protestantism encouraged diligence, discipline, self-denial and thrift. Both Lutheran and Calvinist doctrines urged adherents robustly to undertake their ‘calling’. Spiritual grace from religion was attained by demonstrating temporal success in one's calling. The Protestant ethic thus involved the diligent undertaking of one's calling as a religious obligation, which promoted a work ethic that increased savings, capital accumulation, entrepreneurial activity, and investment, all of which in turn fostered economic development. Many scholars have criticized Weber's thesis, typified in the writings of Tawney (1926) and Gorski (2005). Tawney was concerned with reverse causality: how religion affected development, and in turn how economic and social changes themselves acted on religious beliefs. In his words, “The capitalist spirit” is as old as history, and was not, as has sometimes been said, the offspring of Puritanism’ (1926, p. 225). Tawney argued that Puritanism both helped mould the social order and in turn was moulded by it. Gorski (2005) focuses more on whether Weber's thesis stands up to closer historical scrutiny, highlighting other aspects of the Reformation that contributed to economic development such as Protestant migration, reforms to landholding, fewer religious holidays, and insurgencies, all of which influenced labour supply and the actions of government in Protestant countries.

The economic view of religion

Against this backdrop, recent academic interest linking religion and development has centred on the economics of religion. Studies in the economics of religion have focused on applying the tools of modern economic analysis to the analysis of religious institutions, faith-based welfare programmes and the economic regulation of the church (Oslington, 2003). Three principal themes emerge: first, identifying what determines religion and religiosity; second, examining how religion and religiosity may be described as social capital; and third, understanding the micro and macro consequences of religiosity. Adam Smith (1776) made reference to the church in the Wealth of Nations; and recent work by economists such as Becker and Iannaccone has been very important for the development of this field. The broadly socio-economic view of religion, which expounds the rational choice approach, is set out in the work of Azzi and Ehrenberg (1975), Iannaccone (1998), Stark, Iannaccone and Finke (1996), and Stark and Finke (2000). The focus here has been both on the supply side (the structures of religious organizations) and on the demand side (the preferences of consumers in religious economies). The micro view explains religious activity as the outcome of rational choice, with utility derived both in the individual's lifetime and in the afterlife. For example, if we think of religion as a club good, then many practices are used by religions to screen potential free riders and to ensure better monitoring of the existing faithful (Iannaccone, 1992). Religion also influences individual welfare through the externalities occasioned by social behaviour (Becker and Murphy, 2000). Religious forces are important as they change the environment in which individuals operate, directly affecting individuals' choices and behaviour by changing the utilities of goods. Moreover, greater trust fostered by the religious environment can encourage repeated interactions, leading to more cooperative behaviour within networks.
It is in this way that the second theme – religion as social capital – becomes important. Three aspects are emphasized here: social networks, social norms, and sanctions to penalize deviations from norms. Corresponding to this emphasis, economists of religion have been examining ‘spiritual capital’ – or religious capital – which embodies the norms, networks and sanctions exercised by groups that are organized on the basis of religion and religious networks.

Finally, the macro and micro consequences of religiosity have been examined. For example, there are a number of channels through which religious capital might affect economic growth. Religious capital affects output by changing the manner in which technology and human capital are used. Religious capital exerts a positive impact on human capital by increasing education. For example, particularly in many less developed countries, religious networks are important not only for the religious services they provide but also for their non-religious services, specifically with respect to health and education. Moreover, as religious institutions provide this insurance function, these networks determine the extent to which education is taken up (Borooah and Iyer, 2005). In developed countries, too, this would have implications for religious market structure and the growth of residential neighbourhoods that may be based upon faith-based activities (Gruber, 2005). So understanding the economic consequences of religion is of central concern.

The empirics of religion and development

Most empirical economic studies of religion and development attempt to solve classic decompositions of the form $Y_i - Y_j = \sum \beta(X_i - X_j)$ where the idea is to examine the various factors ($X$) that affect measures of religious attendance or behaviour ($Y$) across individuals ($i, j$), or more widely across countries, or alternatively in varied historical time periods, thence to arrive at conclusions based on the effects suggested by the parameters ($\beta$) estimated.

Empirical studies of religion and development across countries have investigated religious movements, examining particularly sect behaviour, with an emphasis on contrasting the ‘European experience of religious monopoly’ with the ‘American case of religious cacophony’ (Warner, 1993, p. 1081), drawing implications for the issue of whether regulation of religious organizations is necessary. This concern manifests itself in a plethora of research projects, especially on religion in the United States (Marty, 1986–96; Finke and Stark, 1988; Warner, 1993). In cross-country studies, economists have also revisited Weber's hypothesis. Barro and McCleary (2003) assess the effect of religious participation and beliefs on a country's rate of economic progress. Using international survey data for 59 countries drawn from the World Values Survey and the International Social Sciences Program conducted between 1981 and 1999, these authors find that greater diversity of religions is associated with higher church attendance and stronger religious beliefs. For a given level of church attendance, increases in some religious beliefs – notably belief in heaven, hell and an afterlife – tends to increase economic growth.

Other studies have focused more on particular religions in varied historical time periods. For example, very useful insights have been gained by focusing on Islam and on Judaism. For Islam, there have been detailed investigations into financial systems in the Middle East including zakat (alms for charity) and the manner in which Islamic banks have been using a financing method equivalent to the rate of interest to overcome adverse selection and information problems. There has also been more detailed investigation into Islamic law and financial activity historically with implications for poverty reduction.
in the Middle East (Kuran, 2004). There is research that has examined Jewish occupational selection using historical data from the eighth and ninth centuries onward to explain the selection of Jews into urban, skilled occupations prompted by educational and religious reform in earlier centuries (Botticini and Eckstein, 2005). Data are also being used to elucidate the role of religion in explaining historical differences in education among Hindus and Muslims in India (Borooah and Iyer, 2005).

A primary focus of current studies of religion and development is on explaining differences across individuals. For example, using data from the General Social Survey and the US Census, Gruber (2005) investigates religious market structure by estimating the effects of religious participation on economic measures of well-being, and concluded that residing in an area with more co-religionists improves well-being through the impact of increased religious participation. This particular study is also valuable from the methodological point of view, as it addresses a common problem in empirical studies of religion and development – the persistent endogeneity of religion to economic measures of well-being – and consequently the common econometric problem of how best to identify religion effects. While this particular study successfully uses ethnic heritage to provide an exogenous source of variation, and is thereby able to draw out cleanly the effects of religious participation on the variables of interest, econometrically the potential endogeneity of most religion variables is possibly the single most significant limitation of incorporating religion into empirical work in economics. This is mirrored in the many efforts to identify the effects of religion which generally have not been able to deal with self-selection issues easily.

To this end, fields such as economic demography have much to offer the study of religion and development. For example, recent research in economics has made a start towards examining the religious and economic reasons behind fertility differences between religious groups, especially in developing countries (Iyer, 2002). The economics of religion has also elucidated the study of politics, both local and international: Glaeser (2005) presents an economic model of religious group behaviour and the so-called ‘political economy of hatred’. The economic approach to religion has been evaluating whether religion and politics are mutually exclusive. Glaeser, Ponzetto and Shapiro (2005) link religion with strategic extremism – the issues and platforms espoused by political parties, and the manner in which private information matters for this. Other studies have focused on terrorism and display a more general preoccupation with understanding views and attitudes in the Muslim world (Gentzkow and Shapiro, 2004).

Drawing a perspective from all these classes of studies, it strikes one that emerging economies are experiencing appreciable modern economic growth, yet this is coterminous with the increasing resilience of religious institutions. And it is this dichotomy between the sacred and the secular which epitomises the puzzle of the relationship between religion and economic development. It seems reasonable to address this puzzle by combining quantitative analysis of sample data with nuanced qualitative evaluations of the textual theology of religion, linking these to the manner in which individuals and institutions interpret religion at a local level. As well, an appreciation of the approach of the interdisciplinary economist would permit a more informed understanding of all these concerns. Economists will enthusiastically study religion and economic development in the future, and they will do so with ascetic assiduity – researching data with all the intensity of religious fervour in order to provide thoughtful prophecy for development policy.

Bibliography

How to cite this article

Adam Smith invented the economics of religion, famously arguing for church-state separation on efficiency grounds since state religions become inefficient monopoly providers of religious services and because competition for monopoly status is often violent. Smith also developed theories of religious sects and sectarian violence. Modern applications of theory and data generally support Adam Smith's conjectures. Recent work also explores: religious activity as a consumer choice, the demand for spiritual services, religious human capital and religious social capital, club models of sects – benign and violent – and the macroeconomic consequences of beliefs and religiosity.

Article
Adam Smith laid the foundations for the economic study of religion in *The Wealth of Nations* (1776, pp. 788–814). He argued that self-interest motivates the clergy; that market forces constrain churches just as they constrain secular firms; that competition improves the quality of religious services provided; and that government regulation distorts the provision of religion, reducing quality and promoting conflict. He also outlined a theory of sectarianism, a theory of religious violence and civility, and a general theory of Church and State.

After this inspired start the economics of religion lay dormant and nearly dead for two centuries. It is now enjoying a rebirth, animated by new data, methods and theory. Economists and other social scientists have harnessed rational choice models and modern empirical tools to study secularization, pluralism, church growth, religious extremism, conversion, fertility, Church–State relations, and more. The field now claims hundreds of papers, scores of contributors, an annual conference and international association (the Association for the Study of Religion, Economics, and Culture), university research centres, and even an AEA subject code (Z12). (New university centres are at Harvard, George Mason University, the University of Southern California and in Canberra, Australia.)

Current research on religion and economics falls into three related subfields: economic theories of religion, studies of religion's economic consequences, and religious assessments of economic policy. Adam Smith's critique of state-supported religion in *The Wealth of Nations* exemplifies the first subfield; Max Weber's 'Protestant ethic' conjecture the second. Together these two subfields constitute the economics of religion – the subject of this article. Our goal is to introduce readers to the distinctive economic ideas and models that have enhanced the social-scientific study of religious beliefs, behaviour, and institutions. (For a more complete review of the literature prior to 1998, see Iannaccone, 1998.)

This article makes no attempt to survey the field of religious economics, both because the latter tends to be religion-specific and because it is far from the mainstream of economic research. Religious economics seeks to evaluate economic behaviour and institutions in the light of sacred precepts. Mahmoud El-Gamal's recent book, *Islamic Finance* (2006), is a good example, examining whether current practices in banks that follow Islamic law actually serve the objectives of those laws. The literature on religious economics is large, diverse, and as old as religion itself – including, for example, the many biblical injunctions concerning property, slavery, wages, tithing, interest, wealth and poverty. With the help of
economists and philosophers, contemporary clerics continue to debate the merits of income inequality, tax laws, private property, deficit spending, monetary policy, income redistribution, workers rights, interest rates, banking laws, entrepreneurship, government regulation, international trade, debt relief, unionization, entitlement programmes and much more. For representative readings in religious economics, see Oslington (2003) and the Journal of Markets and Morality (published by the Acton Institute for the Study of Religion and Liberty).

Social scientists once viewed religion as a dying vestige of our primitive and pre-scientific past. Modern research and contemporary events have destroyed this simplistic view of human history. The rise of radical Islam, the revival of religious practice in much of the former Soviet Union, the explosive growth of Protestantism in Latin America and sub-Saharan Africa, and the contribution of religion to identity (and often to conflict) all over the world testify to the continuing vitality of religion. And although religious belief and activity have declined in many economically advanced countries since the 1960s, the corresponding US data display remarkable stability, whether one focuses on rates of attendance, contributions, membership, or belief. Indeed, religiosity has become one of the strongest predictors of voting patterns and political orientation in America (Glaeser et al., 2006).

We cannot say why economics ignored religion for so long. The brilliant and iconoclastic economist Kenneth Boulding discussed economic features of religion long before the modern revival, but his insights seem to have gone largely unnoticed by economists or sociologists. (Boulding's essays on religion and economics from the 1950s appear in Boulding, 1970.) The other social sciences have subfields dedicated to the study of religion and most have sought to understand the connection between religious and economic trends – the most famous and influential generalization being Max Weber's 'Protestant ethic' thesis. (Weber studied economic history and was well-acquainted with Smith's Wealth of Nations.

His essay, 'The Protestant Sects and the Spirit of Capitalism', describes how denominational membership enhanced the reputation and business prospects of Americans around 1900: see Weber, 1920. The essay appears to have been inspired by Smith's theory about the ways in which sect membership benefits a poor person: see Smith, 1776.) It seems likely, however, that most economists saw religion as too far removed from the realm of rational choice and market behaviour. We encourage the reader to revisit the issue of religion and rationality after reading this essay.

1 Economics, sociology, and rational choice

Nearly all economic theories rely on the twin assumptions of rational choice and stable preferences. In the realm of religion, this means choosing which religion, if any, to accept and how extensively to participate in it. These optimal choices need not be permanent. Economic models do a good job explaining differences in religious activity, both over time and across individuals. In keeping with the assumption of stable preference, however, these explanations rarely invoke varied norms, tastes or beliefs. A good economic story explains behaviour in terms of optimal responses to varying circumstances – such as prices, incomes, skills, experiences, technologies or resource constraints.

Although the previous paragraph merely extends modern economic orthodoxy to the realm of religion, it borders on sociological heresy. The commitment of economists to rational choice and stable preferences must be understood as relative, not absolute. Since the late 1970s, economists have devoted a great deal of attention to modelling preference formation. Formal models of religious capital formation (Iannaccone, 1984; 1990) are, in fact, directly linked to Becker’s (1996) subsequent work on rational addiction and taste change. Recent work in the fields of behavioural, experimental and evolutionary economics underscores the extent to which choice systematically deviates from rationality; and social norms, social networks and imperfect information constrain choices further still. But it would be wrong to conclude that economists and sociologists now embrace a common ‘world view’ – as is readily apparent when one contrasts the papers presented by economists and sociologists at the joint annual meetings of the Association for the Study of Religion, Economics, and Culture and the Society for the [Social] Scientific Study of Religion. Most sociologists remain very sceptical about the value of formal models, rational choice theory and methodological individualism – a legacy passed down from the founders of the field, who promoted sociology as a corrective to errors and omissions of economics (Swedberg, 1990).

Add the influence of Weber (1920; 1963), who made ‘rationality’ central to his analysis of religion while using the word in ways foreign to most contemporary economists, and ‘doctrinal’ debate is unavoidable. But the overall response to economic forays into religion has been surprisingly ecumenical, with several leading sociologists of religion going so far as to characterize economic theory and market models as ‘the new paradigm’ for religious research (Stark and Finke, 2000; Warner, 1993; Young, 1997).

2 Households and consumer choice

Economists finally returned to the study of religion in the 1970s, inspired by Gary Becker’s path-breaking work on economics of the family. The first papers modelled church attendance and religious contributions as a special form of household production – one that involved trade-offs between time and money inputs, secular versus religious outputs, and present versus afterlife utility (Azzi and Ehrenberg, 1975; Ehrenberg, 1977). Formally, households maximize an intertemporal utility function \( U = U(Z_1, \ldots, Z_n, A) \), where \( Z_t \) denotes secular consumption activities in period \( t \), and \( A \) is consumption activity in an afterlife (of possibly infinite duration). In each period (of this life) households can spend their time, \( T \), and goods, \( X \), on either secular consumption or religious activities, \( Z_t = Z(T, Z_T, X), R_t = R(T, R_T, X) \). Religious activities over a lifetime create afterlife consumption, \( A = A(R_1, \ldots, R_n) \). Combined with a standard lifetime budget constraint, and on the assumption that the marginal product of religious activity does not decrease with age, the Azzi–Ehrenberg model predicts that religious activity increases with age, ceteris paribus. The model also predicts that households with high value of time (high wages) will substitute...
goods for time in producing religious activity.
As Azzi and Ehrenberg (and many others) have shown, religious activity does tend to increase with age. But it is not at all clear that the Azzi–Ehrenberg model captures the principal cause of this age effect. Ulbrich and Wallace (1983) found that activity increases with age even among those who do not believe in the afterlife. And Iannaccone (1984) showed that even in the absence of afterlife expectations, the rational accumulation of religious human capital (that is, rational religious ‘addiction’) could simultaneously account for the observed age effect as well as observed patterns of religious conversion, intermarriage, and marital stability (see also Lehrer and Chiswick, 1993; Neuman, 1986).
Predictions concerning religious substitution are on much stronger ground. Substitution of goods for time is observed across individuals, households and denominations. Although we cannot directly observe most religious commodities, we can observe the inputs used to produce them. The principal time and money inputs—attendance and contributions—are routinely measured in surveys. More specialized studies provide detailed information on time (such as time devoted to religious services, private prayer and worship, religious charity, and many other religious activities) and money (such as expenditures for special attire, transport, religious books and paraphernalia, sacrificial offerings, and contributions used to finance staff, services and charitable activities of religious organizations). Several studies, including Ehrenberg (1977), Iannaccone (1990), Hungerman (2005) and Gruber (2004), have found that attendance and donations are substitutes—and the recent work demonstrates that substitution remains strong even after one controls for endogeneity bias.
Both in theory and in fact, substitution induces different methods of religious organization and worship across different socio-economic strata. High-income congregations tend to hold shorter services, make heavy use of professional staff and inhabit more elaborate facilities. Longer services, volunteer workers, rented meeting halls and pot-luck dinners are typical of poorer congregations. We observe these differences within denominations and even within congregations (as members improve their socio-economic status), but the differences are especially stark across the denominations of a religious tradition, such as Reform Judaism versus Orthodox Judaism or Episcopalians versus Southern Baptists. Many Episcopalians or Presbyterian congregations have plenty of money to cover salaries and operating expenses but remain hard-pressed to recruit volunteers for their choirs, youth programmes, committees and other traditional programmes. For such denominations prosperity has proved a mixed blessing.
Economic trends forced adaptation and none more so than the growth of women’s wages and workforce participation. As women have moved into the labour force and overall family earnings have grown, congregations have had to purchase many services formerly supplied by volunteers. The pattern is illustrated by Luidens and Nemeth’s (1994) study of expenditure trends in Presbyterian denominations, which found that their (fourfold) increase in real per-capita giving from the 1940s to the 1990s was spent primarily on local congregational services previously supplied by volunteers.

3 Religion, magic and uncertainty

Contemporary theories of rational religious belief begin with just a few assumptions about human nature and the human condition—in essence scarcity, rationality, and the capacity to conceive of supernatural beings or forces (Iannacone and Berman, 2006; cf. Stark and Bainbridge, 1987). From these, they derive a universal demand for supernaturalism and a universal distinction between magic (emphasizing control of impersonal supernatural forces) and religion (emphasizing interaction with supernatural beings). Specialized suppliers arise naturally in both realms, but markets for magic and religious operare quite differently. It is relatively easy to test (and disprove) a magician’s ability to control supernatural forces, but much harder to falsify a priest’s claims concerning God. In practice, only religion can sustain long-term relationships, high levels of commitment, and moral communities.
As Emile Durkheim (1915, p. 42) famously observed, ‘there is no church of magic’.
As we shall see in Section 6, a strong religion can induce its members to foreshare all other suppliers of supernatural goods and services. But exclusivity is not a ‘natural’ outcome. Given the tremendous uncertainty that surrounds the supernatural, rational consumers are inclined to patronize many different suppliers—investing, so to speak, in diversified portfolios of supernatural commodities (Iannaccone, 1995). Diversification over different supernatural products and suppliers is pervasive in the (non-communal) market for magic, including the so-called ‘New Age’ movement. It also prevails in most polytheistic settings, including in the Greco-Roman world, and it remains common in Asian religious traditions.
Judaism, Christianity and Islam display a much greater capacity to sustain exclusivity, but (as we shall discuss in Section 6) only within communal settings that promote collective action, strong social ties, and large investments in religious capital.

4 Religious capital

James Coleman’s (1988, p. 97) concept of ‘social capital’ helps connect rational choice theory to sociological analysis. Iannaccone’s (1984; 1990) concept of ‘religious capital’ offers an analogous bridge from rational choice theory to the sociology of religion. Both concepts are inspired by human capital theory (Becker, 1964; Schultz, 1961), and both emphasize relationships rather than purely individual capacities.
Let denote the stock of relationships, sensitivities and skills that alter a person’s real or perceived benefits from religious activity at time . Religious commodity production thus depends on current inputs of time and money and the current stock of religious capital . The SR variable can encompass a range of concepts, including religious habits, spiritual capital and social capital. Indeed, the mathematical models and empirical analyses remain essentially the same whether one frames the model in terms of the
Second, most religious experience is 'context specific', where religion, economics of: The New Palgrave Dictionary of Economics alters the value of current religious activities and thereby affects rates of religious participation: \( S_{R} = F(T R_P \times R_P S_{R-1}) \). Second, most religious experience is 'context specific', yielding maximal benefits within the context of specific relationships, congregations, denominations and traditions. Religious capital remains a distinctive form of social and human capital because religions claim to promote relationships with supernatural beings. This enables religious institutions to maintain exceptionally high levels of commitment, but not without collective production, exclusivity and sacrifice. The bundle appeals less to people with better secular opportunities; hence we observe a 'church-to-sect' spectrum of denominations within most religious traditions. For details, see Iannaccone (1995) and Iannaccone and Berman (2006).

Capital models yield predictions that are well supported by evidence, including: (a) children tend to choose the same or similar religious denominations as did their parents; (b) conversion (like career choice) tends to occur early in adulthood, leaving time to accumulate religion-specific capital; (c) interfaith marriage is less likely when religious capital accumulation is high; (d) shared-faith marriages lead to higher rates of religious participation (due to complementarities in household production, and not mere sorting of more religious partners into shared-faith marriages); and (e) shared-faith marriages have lower rates of divorce and higher rates of fertility (Iannaccone, 1990; Lehrer and Chiswick, 1993; Waite and Lehrer, 2003).

Religion also contributes to extended relationships, social networks and shared norms. Indeed, Coleman's (1988) seminal article on social capital concerned the impact of (Catholic) religious schools. Empirical studies find that nearly half of all associational memberships, personal philanthropy and volunteering in the United States is church-related, leading Putnam (2000) to conclude that '[f]aith communities … are arguably the single most important repository of social capital in America'. Yet social capital research has yet to give much attention to religion – see, for example, the literature review by Sobel (2002). There remain tremendous opportunities for policy-relevant research on religion's contribution to cooperation (Sosis and Ruffle, 2003), social multipliers (Becker and Murphy, 2000), threshold effects (Granovetter, 1978), public preferences (Kuran, 1995), and much more.

5 Measuring the effects of religious capital

Numerous empirical studies suggest that religious belief and participation yield a wide range of benefits, including mental and physical health, longevity, reduced substance abuse and marital stability (see Koenig, McCullough and Larson, 2001, for an extensive review of the relevant research). The statistical results must, however, be viewed with caution. We lack good instruments for religion on both the supply and demand sides, and most research examines only contemporary American data. Problems of spurious correlation and unobserved heterogeneity may afflict many published studies, as Heaton (2006) notes in his re-analysis of data on religion and crime. On the other hand, the positive association between religion and health has held up despite many different efforts to root out spuriousness, and Freeman's (1986) careful data analysis provides compelling evidence that church attendance really does lead to higher employment rates, higher school attendance, less crime and lower alcohol consumption and drug use among Black males in the United States.

There are many plausible reasons why religiosity might promote beneficial outcomes. As Adam Smith emphasized in his Theory of Moral Sentiments (1759), faith in an omniscient deity can solve otherwise intractable problems of self- and social control. Since religion is the quintessential credence good, religious institutions tend to be relatively efficient producers of moral restraint. And there can be no doubt that communities of faith do provide many concrete services while seeking to instill faith in the young, maintain faith among adults and constrain deviant behaviour. The potential benefits from these mechanisms are underscored by the (not undisputed) evidence that religious constraints on sexual conduct have reduced or limited AIDS among Muslims in central Africa and Christians in Uganda (Green, 2003).

6 Club models of religion

Club models have made major contributions to our understanding of 'cults', 'sects' and religious extremism. They also account for characteristics of religion that seem inconsistent with rational choice and risk-aversion – including the success of groups that demand exclusivity, sacrifice and stigma.

Club models start with the fundamental fact that religious 'commodities' are more compelling and gratifying when they are produced and consumed in groups. Effective congregations require highly committed members, not mere customers. In this respect, effective congregations are more like families than firms. This suggests that models in which the ith member's religious satisfaction has the form \( R_i = F(T R_P \times Q) \), where \( Q \) is an index of the religious inputs of all the other group members.

As economists well know, shirking and free-riding constantly threaten collective action, especially in large groups. Paying people to attend church, accept church doctrine or support fellow members fails to solve the problem because a member's commitment and inputs to the group are difficult to observe, and payment rewards the wrong motivations. But the problems can be mitigated by seemingly gratuitous costs – the sacrifice and stigma characteristic of deviant religions. Sacrifice and stigmas enhance utility by screening out people who lack commitment and boosting involvement among those who remain in the group. Such groups manifest many distinctive characteristics that empirical researchers have long associated with 'sectarian' religions, including distinctive diet, dress or sexual conduct; physical separation from mainstream society; painful or costly rites; rules that limit social contact with non-members; and prohibitions restricting normal economic or recreational activities. (For more on the modern theory of church and sect, see Iannaccone, 1988; 1991.)
Sect theory also accounts for people's willingness to forgo religious diversification despite the obvious risk associated with most religious assurances. Sectarian religions can maintain levels of commitment and involvement that compensate for the increased risk associated with exclusivity. Corresponding constraints can almost never be sustained in standard, secular markets (nor in the impersonal market for magic) because exclusivity does not enhance the production of non-collective goods and services (Iannaccone, 1995). The club model has received wide acceptance, in part because it fits the data so well. Both cross-sectional surveys and case studies find substantially higher levels of mutual aid and social cohesion in more sectarian religious communities. Iannaccone's work on (mostly Christian) sects has been extended to radical religious Jews (Berman, 2000) and Muslims (Berman and Stepanyan, 2003; Chen, 2004). Despite some lingering debate over the extent of free-rider problems in mainline churches or the actual level of costs imposed by conservative religious churches, the basic model remains the natural starting point for studies of high-cost groups. The club model works well not only for religious groups routinely called sects, cults and fundamentalists, but also for communes, gangs, radical militias and terrorist organizations. The basic insight is that an organization designed to exclude free-riders and limit free-riding will be well equipped to exclude defectors and limit defection, the Achilles’ heel of militias and terrorists. Thus religious sects prove to be especially effective at terrorism, militia activity and suicide terrorism (Berman, 2003; Berman and Laitin, 2005; Berman and Stepanyan, 2003).

7 Churches as firms

Many religious organizations are legally designated as firms, and many more look surprisingly firm-like. Around the time economists became interested in religious households, several sociologists of religion began thinking of churches as firms, re-examining old data sources with new theories of rational exchange, entrepreneurship and market competition (Finke and Stark, 1988; Stark and Bainbridge, 1985). Finke and Stark (1992) trace the explosive growth of Methodist and Baptist churches in 19th century America to superior marketing, organization and clergy incentives. By the 1990s, these economic and sociological streams of scholarship together included studies of sectarianism, denominational vitality, ‘franchising’ of religious brands, religious extremism, doctrinal innovation, Church and State, religious markets, non-Western faiths, religious history, and more. Ekelund et al. (1996) analyse numerous features of medieval Catholicism in terms of its monopoly status. Drawing upon standard theories of monopoly, rent seeking and transaction costs, they offer economic explanations for interest rate restrictions, marriage laws, the Crusades, the organization of monasteries, indulgences, and the doctrines of heaven, hell and purgatory (see also Ekleund, Hébert, and Tollison, 2006). Work on churches as firms continues to grow rapidly, in part because firms are easier to model than clubs, but also because the theory of the firm is so rich in predictions and data.

8 Religious markets and government intervention

Whether we think of them as clubs or as firms, individual denominations collectively constitute a religious market as long as they provide services that are substitutes. The theories of religion described above predict the existence of different market segments: exclusive ‘sects’ that operate like clubs, inclusive ‘churches’ sustained by a core of professionals which are more firm-like, and markets for ‘magic’ organized around simple exchanges between practitioners and clients. Almost all economists and sociologists of religion accept the notion that religion in America constitutes a vast competitive market, overflowing with ‘products’ that range from New Age paraphernalia to orthodox liturgies. Scholars likewise accept that market success requires entrepreneurship, innovation, and sensitivity to the demands of consumers. As a result, themes that rarely surfaced prior to Finke and Stark's Churching of America (1992) now parade as common sense. Even the harshest critics of rational choice theory (such as Bruce, 1999), emphasize the centrality of religious choice in today's world. The most informative studies closely study how markets actually work. Market-oriented research must carefully address numerous issues, including product attributes, marketing strategies, incentive structures, exchange relationships, consumer characteristics, and Church–State relationships. Andrew Chesnut's (2003) study of rapidly growing religious movements in Latin America illustrates this point by showing how specific religions offer distinctive products that directly address the health- and family-oriented concerns of poor and middle-class women. Anthony Gill (1998) shows that Catholic bishops are much more likely to side with the poor in Latin American countries where Protestant growth threatens the Church’s historic monopoly. Adam Smith (1776, pp. 788–814) argued that established religions face the same incentive problems that plague other state-sponsored monopolies: lack of competition generates a low quality product.

The teachers of [religion] …, in the same manner as other teachers, may either depend altogether for their subsistence upon the voluntary contributions of their hearers; or they may derive it from some other fund to which the law of their country many entitle them…. Their exertion, their zeal and industry, are likely to be much greater in the former situation than the latter. In this respect the teachers of new religions have always had a considerable advantage in attacking those ancient and established systems of which the clergy, reposing themselves upon their benefices, had neglected to keep up the fervour of the faith and devotion in the great body of the people.
Iannaccone tested Smith's conjecture with modern data. Figure 1 illustrates that within predominantly Protestant countries, church attendance declines sharply as the religious market becomes more concentrated. (The Herfindahl-style ‘Protestant Concentration Index’ proxies state support for particular religions and has the form $H = \sum S_i^2$, where $S_i$ is the population share of the $i$th Protestant denomination.) All other surveyed measures of religiosity, including belief in God, fall with concentration as well. The data, and Smith's theory, strongly suggest that America's 'religious exceptionalism' is largely a product of religious laissez-faire. North and Gwin (2004) report similar results using a much larger number of countries and more direct measures of Church–State relationships.

Figure 1
Guest, and Stark (1996). But much of this work suffers from specification problems that inevitably arise when rates of religious membership (as opposed to more direct measures of belief and participation) are regressed onto (membership-based) measures of religious diversity (Voas, Olson and Crockett, 2002). Nor is it clear that concentration should signal the presence of inefficient religious ‘monopoly’ across cities or states given the nation’s minimal barriers to religious entry and innovation. There is, however, strong historical evidence that religious competition raises religious participation (note especially the work of Finke and Stark, 1992, and Olds, 1994, who show that post-colonial disestablishment led to the rapid growth in overall church membership rates, clergy demand, and the – primarily Baptist and Methodist – non-established denominations, while the major denominations that had enjoyed the support of colonial governments – primarily Episcopal, Presbyterian, and Congregational) rapidly lost market share.

9 Macroeconomic consequences of religion

Weber’s The Protestant Ethic and the Spirit of Capitalism (1920) famously claimed that the Calvinist doctrine of predestination triggered a mental revolution within Protestantism that gave rise to modern capitalism. This remains the most influential single conjecture on the macroeconomic effects of religion, which is unfortunate since nearly all subsequent empirical research has shown it to be false.

Almost all the capitalistic institutions that Weber emphasized actually preceded the Reformation (Stark, 2005; Tawney, 1998). Across and within European countries economic development was uncorrelated with religion (Samuelsson, 1993; Delacroix and Nielsen, 2001). The second country to industrialize was Belgium, which is Catholic. Although Germany and the Netherlands were early developers and majority Protestant, the fastest growth within those countries was among Catholic families of the Rhineland and Amsterdam, which were majority Catholic.

Despite much work by historians and sociologists, there is no consensus concerning the macroeconomic impact of Protestantism, Christianity, monotheism, or religiosity in general. Economists have recently entered this field of enquiry with cross-national studies of survey and census data. Barro and McCleary’s (2003) cross-national analysis of survey and census data suggests that belief in hell boosts economic growth whereas frequency of church attendance retards growth (perhaps because the former induces honest and industry whereas the latter reduced time spent working). Using cross-national data from the World Value Surveys, Guiso, Sapienza and Zingales (2003) find that religious beliefs in general, and Christian beliefs in particular, are positively associated with economic attitudes conducive to higher per capita income and growth. Many other economists have begun doing similar studies, but data problems abound. In addition to standard econometric difficulties, there are scarcely any cross-national religious surveys that predate the 1980s; we cannot validate most responses concerning religion; and the meaning of religious participation and belief varies dramatically across cultures. There is better evidence of links between religious and socio-economic variables at the level of individuals and groups than for countries or cultures. For example, average family size and socio-economic status differ quite substantially across different religious groups in both rich and poor nations (Chiswick, 1983; Iyer, 2002). Historical studies do suggest strong relationships between religious and economic institutions, most notably those of medieval Europe. Ekelund, Hébert and Tollison (1996) interpret many distinctive features of medieval Catholicism as forms of rent seeking, and there is no doubt that the Church was by far the most important economic institution in medieval Europe. Richardson (2005) offers strong evidence that the doctrine of purgatory gained rapid acceptance because it served to link religious and economic activities (within guilds) in a way that solved commitment problems that arose because of the social disruptions induced by the Black Death. Timur Kuran (2004) makes a compelling case that specific Islamic legal institutions contributed significantly to the economic decline in Muslim countries relative to those of Europe over the past 500 years.

Recent attempts to promote development in poor and post-Communist countries affirm the importance of ethical norms and moral precepts, many of which have religious foundations (Hayek, 1988, pp. 135–40). Communism may be the most striking example of an economically and socially destructive religion, albeit a religion without traditional deities. In this sense, the strongest evidence for Weberian-style theory may be negative: some powerful systems of belief do retard economic progress.

10 Religious militancy

American economists have tended to ignore religion as a subject of public policy, in part because the ‘establishment’ and ‘free exercise’ clauses of the First Amendment radically limit the religious role of government. Within this constitutionally mandated environment of religious laissez-faire (which initially constrained the federal government, but later extended to the states), Americans have maintained extraordinarily high rates of religious activity, diversity and tolerance. But elsewhere, religion remains a major factor in wars, civil unrest and ethnic conflict.

Adam Smith recognized that a detached and lazy clergy was just one cost associated with the marriage of Church and State. When government favours a particular religion in return for its support of the state, the favoured group inevitably demands the suppression of its competitors, and all other groups resist suppression and fight to capture favoured status. It is no coincidence that the USA has remained remarkably free of religious partisanship and militancy while other nations burn with religious conflict. Policies analogous to those embodied in the First Amendment’s free exercise and establishment clauses may be key components of the so-called ‘war on terror’ (Iannaccone and Berman, 2006).
Conclusion

The economics of religion has animated research on secularization, pluralism, church growth, religious extremism, religious markets, the consequences of religion, and more. Forecasting the future of the field is a task best left to prophets. Yet promising areas include the study of non-Western religions, religious militancy, religion and demography, the relationship between religious decline and the growth of the welfare state, and the role of religion in the formation of preferences and social capital. Insights from experimental economics, behavioural economics, game theory, industrial organization, and the economics of information and uncertainty have scarcely been explored. And if the past is any indication of the future, economists still have much to learn from religious historians, sociologists, anthropologists, and other scholars after 200 years of wandering in the secular wilderness.

Rent control generically describes a range of regulations governing rents, as well as related contract features such as security of tenure and required maintenance. There is debate in the literature about the efficacy of controls based on (1) whether the housing market is best modelled as a competitive market, or one where landlords have market power; and (2) whether regulators have sufficient information and appropriate mechanisms to improve imperfect market outcomes. Many empirical studies find that rent controls score badly as redistributive systems. Many basic questions, especially regarding dynamic effects on the supply of housing, have yet to be credibly answered.

Keywords

asymmetrical information; housing markets; housing supply; loss aversion; market power; property taxation; rent control; tax incidence

Article

Rent controls of one kind or another affect roughly 40 per cent of the world's urban dwellers. Rent control is usually thought of as a policy applied to private markets, but publicly provided housing (for example, much urban housing in Russia and in China) is also subject to controls. In addition to regulations governing rents, controls often address additional contract features such as security of tenure and required maintenance. Actual rent control regimes vary enormously in their design and in their effects.

History

Rent controls are often instituted in response to a major economic or political shock which limits the responsiveness of the housing market. Controls were introduced in the Second World War in Europe,
North America, and, under European colonial influence, much of the developing world as well. Most jurisdictions in the United States and Canada removed controls in the post-war years; however, controls of varying degrees of stringency were maintained in much of Europe and the developing world. Poorer countries tend to have more stringent regimes, though enforcement patterns vary at least as much as *de jure* codes.

Exactly why controls exist, or at least are retained after wartime or similar emergencies are clearly over, is still debated. An obvious point of political economy is that there are more tenants than landlords; but there is little correlation between the fraction of a country's population renting and the stringency of controls, according to Malpezzi and Ball (1991). On the other hand the relatively small number of US cities with rent control tend to have large renter populations, notably New York. Fischel (2001) presents several interesting conjectures about the political economy of controls, notably that homeowners might ally with landlords to oppose controls because they fear negative spillovers from reduced maintenance of stringently controlled buildings, as well as shifting property tax burdens. The strong opposition to relaxation of controls in New York, while nearby uncontrolled jurisdictions see little agitation for imposition, might be analysed in Kahneman and Tversky's (1979) loss aversion framework. A clear understanding of the political economy of controls awaits future research.

**Features**

One key feature is whether regulations set the level of rents, or control increases in rent. Others include how controlled rents are adjusted for changes in costs (with cost pass-through provisions, or adjustments for inflation); how close the adjustment is to changes in market conditions; how it is applied to different classes of units; or whether rents are effectively frozen over time. Other key provisions which vary from place to place include breadth of coverage, how initial rent levels are set, treatment of new construction, whether rents are reset for new tenants, and tenure security provisions. Rent control's effects can vary markedly depending on these specifics, and on market conditions, as well as enforcement practices.

**Theory**

Rent control can be analysed as an implicit tax on housing capital. In the simplest case, where imposition of controls reduces the price of an existing stock of rental housing, the tax is borne by landlords for the benefit of tenants. Over time, as the market adjusts to controls, the incidence of the ‘tax’ becomes more complicated.

Much of the debate in the literature about the efficacy of controls stems from maintained assumptions about the nature of the housing market, and the regulator, in turn. The first question is: is the housing market best modelled as a competitive market, or one where landlords have market power, for example from information asymmetries? If the former, then clearly rent control reduces the efficiency of the rental market, although the magnitude of such effects can be debated, and distributional arguments remain. If the latter, a second question readily follows: does the regulator have sufficient knowledge, and an appropriately designed set of regulations, to improve on the market outcome? Arnott (1995) ably reviews the contrast between competitive and ‘market power’ theoretical approaches, and also discusses why it is so difficult to resolve these issues empirically.
Whatever one's priors about market power, there are many alternative adjustment mechanisms which can arise in a notionally controlled market. Four of the adjustments can be embodied in rent control laws: (a) indexing (keeping real rents constant), (b) reassessment for new tenants, (c) differential pricing of new and existing units, and (d) differential pricing for upgraded units. Three are market responses which many would generally consider undesirable outcomes, namely, (e) outright evasion, (f) side payments such as key money, (g) adoption by tenants of maintenance expenditures, and (h) accelerated depreciation and abandonment, (i) distortions in consumption, not only in the composite housing services but also crowding, length of stay, mobility and tenure choice.

Key questions are: What are the efficiency losses from controls? Are the benefits to some tenants worth the costs? Do they redistribute income as intended? Several broad approaches have been taken in the empirical literature to answer these questions.

**Static analysis**

One of the first published studies of the costs and benefits of rent control is Olsen's. Using data from New York City in 1968, Olsen (1972) found the average controlled rent for an apartment was $999 a year (for comparison, the average income was $6,229). Olsen first estimated how much the controlled units would rent for in the absence of controls. The average estimated uncontrolled rent for controlled units was $1,405, implying a subsidy (static cost to landlords) of $406. Olsen next estimated how much households in controlled units would spend in the uncontrolled market, given their income and family size. The average estimated market expenditure for the controlled households was $1,470, indicating that they consumed slightly less housing than they would have in the free market. Olsen then computed the economic benefit of rent control to each surveyed controlled tenant using a simple consumer surplus model. Olsen's estimate of the average net benefit is $213, little more than half the gross subsidy of $406. Examining the distribution of these benefits among controlled households, Olsen found the annual benefit decreased by about one cent for every dollar of additional income, $9 a year of head's age, and $69 per additional household member. Rent control in New York City in 1968 appears to redistribute income, but very weakly, and in no way proportional to its cost.

A number of other studies have been carried out along these lines (Malpezzi and Ball, 1991, review several). For example, in Cairo, Egypt, monthly rents for a typical unit are less than 40 per cent of estimated market rents. But 'key money' (illegal upfront payments to landlords) and other side payments make up about a third of the difference.

**Dynamic analysis**

Murray et al. (1991) is an early study of rent control dynamics. A simulation model was used to predict the time path of rents and the quantity of housing services given alternative control regimes. The magnitude of the effects varied substantially with details of the regime. In general, Murray et al. find that dynamic losses can be substantial; in fact they outweigh static consumer's surplus losses by as much as a factor of 18. Generally tenant benefits are were substantially less than landlord costs; the transfer efficiency in three representative cases ranged from 65 per cent to 83 per cent.

Another potential dynamic effect of controls, with possible spillovers to labour markets, is reduced
household mobility. Several studies, such as Munch and Svarer (2002) and Simmons-Moseley and Malpezzi (2006), find that household mobility is inversely related to the estimated net benefits received from a control regime. Given their potential importance, dynamic effects of controls are understudied. For example, no one has yet credibly analysed the effects of controls on the aggregate supply of housing. Reviews of the theoretical literature by Arnott (1995), and of the empirical literature by Turner and Malpezzi (2003), point out that empirical work lags theory in this area. Malpezzi and Ball (1991) did find that countries with stricter rent control regimes invested less in housing, in the aggregate; but while the analysis accounted for income and demographics on the demand side, other potential constraints on housing supply (for example, land use constraints, financial constraints) were not well specified. Since these may well be correlated with the strength of controls, these results cannot be viewed as the final word. Given the myriad ways real world regimes work, and the variety of possible ways around controls (legal and illegal) the size of the net aggregate effect on supply remains unknown.

Distributional issues

Such evidence as exists casts doubt on controls' effectiveness as income transfer mechanisms. In Kumasi and Rio, benefits were found to be somewhat ‘progressive’ in the common sense of the term (larger benefits to poorer households). On the other hand, in Cairo and Bangalore, no relationship was found between the benefits gained from reduced rent and household income, because rent control is not well targeted to low-income groups (Malpezzi and Ball, 1991). In fact, research on New York controls by Glaeser and Luttmer (2003) suggests that previous research largely underestimates the misallocation of housing under controls, and that, because of excess demand for controlled units, benefits are more or less randomly distributed.

Another questionable assumption behind redistribution as a rationale for controls is the notion that landlords are rich and tenants are poor. In Cairo, Kumasi and Bangalore, the income of tenants and landlords was compared; and, while the landlords' median income was higher in all three, there was significant overlap. In Cairo, for example, about 25 per cent of tenants had incomes that were higher than the landlord median, and about 25 per cent of landlords had incomes lower than the tenant median. There is no guarantee the transfers will occur only from high-income landlords to low-income tenants. Most careful empirical studies find that at least some tenants are, on balance, worse off under controls because of constraints on housing consumption. And in markets with significant uncontrolled sectors, rent controls can drive up the price of uncontrolled housing, an important unintended consequence further complicating the incidence of its costs.

rent seeking

Gordon Tullock
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Rent seeking ’ refers to the investment of resources in efforts to create monopolies. Such investments impose a social cost (which may outweigh the benefit to the monopolist) because they are unproductive. That cost is greater than the mere cost of lobbying by special interests for privilege when the privilege is conferred in a way that is economically inefficient but politically feasible (which is often true of regulations). Research on rent seeking has demonstrated that the true social costs of promoting special interests thus greatly exceed the deadweight costs of the distortions introduced into the economy.

Keywords

Article

The term ‘rent-seeking’ was introduced by Ann O. Krueger (1974), but the relevant theory had already been developed by Gordon Tullock (1967). The basic and very simple idea is best explained by reference to Figure 1. On the horizontal axis we have as usual the quantity of some commodity sold, on the vertical axis its price. Under competitive conditions the cost would be the line labelled PP and that would also be its price. Given a demand curve, DD, quantity Q would be sold at that price. If a monopoly were organized, it would sell Q’ units at a price of P’.

Figure 1
The traditional theory of monopoly argued that the net loss to society is shown by the shaded triangle, which represents the consumer surplus that would have been derived from the
rent seeking: The New Palgrave Dictionary of Economics

Note that in this case the argument against rent seeking turns out also to be an argument against political corruption. Suppose you are in a society which has an exchange control. Politically possible. The necessity of using inefficient methods of transferring funds to the potential beneficiary, because the efficient methods would be just too open and above stockholders. Regulation, which has a similar effect but at a very much higher cost to the users of airlines per dollar of profit to the owners, was however, 1937, when the US Civil Aeronautics Board was organized, it would not have been politically feasible to put a direct tax on purchasers of airline tickets and use it to pay off the stockholders. Of course it is not true that everyone in society is in an equally good position to seek rents. Some kinds of interest are more readily organized than others and we would anticipate that these highly intelligent people could otherwise be doing something of higher productivity and because the economy's use of resources has been further distorted by the creation of the monopoly. Further, although so far the discussion has been primarily about monopoly, actually very many possible interventions in the market process raise the same problem. A simple maximum or minimum price may have very large redistributive effects and the people who thus benefit may put considerable resources into receiving them. Of course there are many situations in which one lobbyist is pushing for a particular restriction and another lobbyist is pushing against it. The second activity is sometimes called ‘rent avoidance’, but it is costly and of course would not exist if there were not also rent seeking activity. Another area is simple direct transfers. A tax on A for the purpose of paying B will lead to lobbying activity for the tax on the part of B and against it on the part of A. The total of these two lobbying activities could very well equal the total amount transferred (or prevented from being transferred), although one or other of these entrepreneurs will of course gain if his lobby is successful. Assume that A puts in $50 for lobbying to get $100 from B and B puts in $50 lobbying against that. Regardless of the outcome, one party will gain $50 from his lobbying. Society has lost $100. Of course it is not true that everyone in society is in an equally good position to seek rents. Some kinds of interest are more readily organized than others and we would anticipate that they would win. There are however very many such interests and anyone who spends any time in Washington quickly realizes that there is a major industry engaged in just this kind of activity. Actual social cost however is clearly very much greater than the mere cost of the various lobbying organizations in Washington. In particular it is normally necessary for the rent-seeking group to undertake directly productive activities in a way that is markedly inefficient, because it is necessary to introduce a certain element of deception into the process. In 1937, when the US Civil Aeronautics Board was organized, it would not have been politically feasible to put a direct tax on purchasers of airline tickets and use it to pay off the stockholders of the airline companies. Regulation, which has a similar effect but at a very much higher cost to the users of airlines per dollar of profit to the owners, was however, politically possible. The necessity of using inefficient methods of transferring funds to the potential beneficiary, because the efficient methods would be just too open and above board, is often one of the major costs of rent seeking. The rent avoidance lobbyist would have had too easy a time if the proposal had been a tax on uses of airlines for the benefit of the stockholders. Note that in this case the argument against rent seeking turns out also to be an argument against political corruption. Suppose you are in a society which has an exchange control.
system and that it is possible to buy foreign currency by bribing an official in the exchange control office. This is the kind of situation dealt with by Krueger (1974), who was able to obtain a measure of the total social cost in Turkey and India where the amounts of the necessary bribes were well known; the cost varied from 7–15 per cent of the total volume of transactions.

Traditionally economists have tended to view this kind of bribery as in itself desirable, because it gets around an undesirable regulation. However, it leads to rent seeking. In this case the rent seeking does not come from the users of the permits but from the competition to get into the position where you can receive the bribe. Throughout the underdeveloped world, large numbers of people take fairly elaborate educational programmes which have no real practical value for their future life and engage in long periods of complicated political manoeuvring in hope that they will be appointed. Let us say, a customs inspector in Bombay. Since these young men have a free career choice presumably the expected returns from this career are the same as in any other. The difference is that a doctor, say, begins earning money immediately on completing medical school whereas the young man who has studied economics and is now trying to obtain appointment as customs inspector will have a considerable period of time in which he is not appointed at all. Indeed, there will probably be enough such candidates that he has only perhaps one chance in five of being so appointed. The total cost of the rent seeking is the inappropriate education and the political manoeuvring of the five people of whom only one is appointed.

So far we have assumed that the total cost of rent seeking is the present discounted value of the income stream represented by the dotted rectangle in Figure 1. This assumes a special form for the function which ‘produces’ the monopoly or other privilege. It must be linear, with each dollar invested having exactly the same payoff in probability of achieving the monopoly as the previous dollar (Tullock, 1980). Most functions do not have this form, instead they are either increasing or decreasing cost functions.

If the organizing of private monopolies, or of influencing the government into giving you public monopolies, is subject to diseconomies of scale, then total investment in rent seeking will be less than the total value of the rents derived even if we assumed a completely competitive market with completely free entry. When there are economies of scale the situation is even more unusual. Either there is no equilibrium at all or there is a pseudo-equilibrium, in which total investment to obtain the rents is greater than the rents themselves. This is called a pseudo-equilibrium, because although it meets all the mathematical requirements for an equilibrium, it is obviously absurd to assume that people would, to take a single example, pay $75.00 for a 50–50 chance of $100.

Obviously, what is needed is empirical research, and an effort to measure the production functions appropriate to rent seeking. So far, however, no one has been able to develop a very good way of making such measurements. It seems likely that it would be easier to measure the costs of generating political influence than of private monopolies, if only because many of the expenditures used to influence the government appear in accounts in various places. The costs of private monopolies on the other hand, tend to be much more readily concealed. This does not mean that they do not exist.

The reader has no doubt been wondering what is wrong with rents and why we concern ourselves deeply with rent seeking. The answer to this is that the term itself is an unfortunate one. Obviously, we have nothing against rents when they are generated by, let us say, discovering a cure for cancer and then patenting it. Nor do we object to popular entertainers like Michael Jackson earning immense rents on a rather unusual collection of natural attributes together with a lot of effort on his part to build up his human capital. On the other hand, we do object to the manufacturer of automobiles increasing the rent on his property, and his employees increasing the rent on their union memberships, by organizing a quota against imported cars. All of these things are economic rents, but strictly speaking the term ‘rent seeking’ applies only to the latter. Its meaning might be expanded to seeking rents from activities which are themselves detrimental. The man seeking a cure for cancer is engaged in an activity which clearly is not detrimental to society. Thus we may observe immediately that activities aimed at deriving rents cover a continuum, but that the term ‘rent seeking’ is only used for part of that continuum.

The analysis of ‘rent seeking’ has been one of the most stimulating fields of economic theory in recent years. The realization that the explanation of the social cost of monopoly which was contained in almost every elementary text in economics was wrong, or at the very least seriously incomplete, came as quite a surprise. Revision of a very large part of economic theory in order to take this error into account is necessary. And history also needs to be revised. That J.P. Morgan was an organizer of cartels and monopolies during most of his life is well known, as is the fact that he received very large fees for this, fees which were part of the rent seeking cost of generating these monopolies. It is possible to argue that as a stabilizing factor in the banking system, Morgan more than repaid to the United States the social cost of his monopolistic activities in industry. But that there was a very large rent seeking cost is obvious. This cost is in addition to the deadweight cost of the monopolies.

To date, research on rent seeking has to a considerable extent changed our way of looking at things. We now talk of a great deal of government activity as rent seeking on the part of somebody or other. It was known that special interest existed, but we have traditionally tended to underestimate its cost greatly because we looked only at the deadweight costs of the distortion introduced into the economy. The realization that the actual cost is much greater socially, that the large-scale lobbying industry is truthfully a major social cost, is new although presumably, at all times, anyone who thought about the matter must have realized that these highly talented people could produce more in some other activity.

Rent

Armen A. Alchian
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Rent’ is the payment for use of a resource, whether it be land, labour, equipment, ideas, or even money. The term is often restricted to payment for use of land or equipment. ‘Economic rent’ is payment for use of any resource whose supply is fixed. Rent serves a social purpose because market levels of rent indicate which uses of fixed resources are the highest valued, and direct such resources to those uses. ‘Monopoly rent’ is paid to producers in markets that are artificially restricted; it may be dissipated by ‘rent seekers’ who compete for monopoly status.

Keywords

Article

‘Rent’ is the payment for use of a resource, whether it be land, labour, equipment, ideas, or even money. Typically the rent for labour is called ‘wages’; the payment for land and equipment is often called ‘rent’; the payment for use of an idea is called a ‘royalty’; and the payment for use of money is called ‘interest’. In economic theory, the payment for a resource where the availability of the resource is insensitive to the size of the payment received for its use is named ‘economic rent’ or ‘quasi-rent’ depending on whether the insensitivity to price is permanent or temporary.

To early economists, ‘rent’ meant payments for use of land; Ricardo, in particular, called it the payment for the ‘uses of the original and indestructible powers of the soil’ (Ricardo, 1821, p. 33). Subsequently, in recognition that a distinctive feature of what was called ‘land’ was its presumed indestructibility (i.e. insensitivity of amount supplied to its price), the adjective ‘economic’ was applied to the word ‘rent’ for any resource the supply of which is indestructible (maintainable for ever at no cost) and non-augmentable, and hence invariant to its price. In the jargon of economics, the quantity of present and future available supply is completely inelastic with respect to price, a situation graphically represented by a vertical supply line in the usual ‘Marshallian’ price-quantity graphs.

Economic rent

The concept of ‘economic rent’ is graphically depicted by the standard demand and supply lines in Figure 1 with a vertical supply curve (quantity supplied invariant to price) at the amount \(X_r\). At all prices the supply is constant. The entire return to the resource is an ‘economic rent’. If the aggregate quantity of such resources may in the future be increased by production of more indestructible units of the resource in response to a higher price (but the amount available at any moment is fixed regardless of the rent for its services), the supply line at the current moment is vertical. The supply curve for future amounts slopes upward from the existing amount, as depicted by the line FF in Figure 1. The long run rent would be \(P_r\) and the equilibrium stock would be \(X_r\); at that equilibrium stock the ‘market supply’ (in Marshall’s terminology) would be a vertical line. Thus, the supply of indestructible units would have depended on past anticipated prices about the present prices, but the supply of current units would be insensitive to the current price or rent. The return could be called...
‘economic rent’, except that no convention has been developed with respect to the terminology for this situation of indestructible but augmentable resources.
Quasi-rent

Closely related to ‘economic rent’ is ‘quasi-rent’, a term apparently initiated by Alfred Marshall (Marshall, 1920, pp. 74, 424–6). Because virtually every existing resource is unresponsive to a change in price for at least some very small length of time, the return to every resource is like an ‘economic rent’ for at least a short interval of time. In time, the supplied amount will be altered, either by production or non-replacement of current items. Yet, the fact that the amount available is not instantly affected by price led to the term ‘quasi-rent’, which denotes a return, variations in which do not affect the current amount supplied to the demander but do affect the supply in the future.

If a rental (payments) stream to an existing resource is not sufficient to recover the costs incurred in its production the durability of that existing resource will nevertheless enable the resource to continue to provide services, at least for some limited time. In other words, because of the resource’s durability it will continue for some interval to yield services even at a rent insufficient to recover its cost of production, but sufficient for current costs of use including interest on its salvage value (which is its highest value in some other use). Any excess over those current costs is a ‘quasi-rent’.

Quasi-rent resembles an ‘economic rent’ in that it exceeds the amount required for its current use, albeit temporarily – except that a flow of rents that did not cover all ‘quasi-rent’ would preserve it for only a finite future interval, after which the resource would be diminished until not worth more than its salvage value. If the resource received a payment exceeding all the initially anticipated and the realized costs of production and operation, it will have achieved a profit, that is, more than pure interest on the resource’s investment cost. The question exists as to whether ‘quasi-rent’ means just that portion of the rent in excess of the minimum operating costs over the remaining life of the asset, or all the excess, including profits, if any. Convention seems still to be missing. Marshall seems to have excluded interest on the investment as well as any profits from what he called quasi-rents, so that any excess over variable costs of operation were partitioned into quasi-rents, interest on investment and profits (Marshall, 1920, pp. 412, 421, 622).

Composite quasi-rent

‘Composite quasi-rent’ was another important, but subsequently ignored, concept coined by Marshall (Marshall, 1920, p. 626). When two separately owned resources are so specific to each other that their joint rent exceeds the sum of what each could receive if not used together, then that joint rent to the pair was called ‘composite quasi-rent’. The two resources presumably already had been made specific to each other (worth more together than separately) by some specializing interrelated investments. Marshall cited the example of a mill and a water power site, presumably a mill built next to a dam to serve the mill, each possibly separately owned. One or both of the parties could attempt to hold up or extract a portion of the other party’s expropiable quasi-rent. It is interesting to quote Marshall about this situation:

The mill would probably not be put up till an agreement had been made for the supply of water power for a term of years; but at the end of that term similar difficulties would arise as to the division of the aggregate producer’s surplus afforded by the water power and the site with the mill on it. For instance, at Pittsburg when manufacturers had just put up furnaces to be worked by natural gas instead of coal, the price of the gas was suddenly doubled. And the history of mines affords many instances of difficulties of this kind with neighbouring landowners as to rights of way, etc., and with the owners of neighbouring cottages, railways and docks (Marshall, 1920, p. 454).

A reason for attributing importance to the concept of ‘composite quasi-rent’ is now apparent. If it arises with resources that have been made specific to each other in the sense that the service value of each depends on the other’s presence, the joint value of composite quasi-rent might become the object of attempted expropriation by one of the parties, especially by the one owning the resource with controllable flow of high alternative use value. To avoid or reduce the possibility of this behaviour, a variety of preventative arrangements,
rent: The New Palgrave Dictionary of Economics

contractual or otherwise, can be used prior to making the investments in resources of which at least one will become specific to the other. These include, among a host of possibilities: joint ownership, creation of a firm to own both, hostages and bonding, reciprocal dealing, governmental regulation, and use of insurers to monitor uses of interspecific assets. This is not the place to discuss these arrangements, beyond asserting that without the concept of ‘quasi-rent’ and especially ‘expropriable quasi-rent’ – which Marshall called ‘composite quasi-rent’ – a vast variety of institutional arrangements would otherwise be inexplicable as a means of increasing the effectiveness of economic activity. Though Marshall briefly mentioned similar problems between employers and employees, I have not found any subsequent exposition by him about the precautionary contractual arrangements and institutions that attempt to avoid this problem, which has become a focus of substantial important research on what is called, variously, ‘opportunism, shirking, expropriable quasi-rents, principal–agent conflicts, monitoring, problems of measuring performance, asymmetric information, etc.’.

Ricardian rent

The rents accruing to different units of some otherwise homogeneous resource may differ and result in differences of rent over the next most valued use, differences that are called ‘Ricardian rents’. This occurs where the individual units, all regarded as of the same ‘type’ in other uses, are actually different with respect to some significant factor for its use here, though this factor, which is pertinent here, is irrelevant in any other uses. Examples of such factors can be location, special fertility, or talent that is disregarded in the other potential uses. For some questions, the inaccurate ‘homogenization’ can be a convenient simplification, but for explaining each unit’s actual rents, it can lead to confusion and misunderstanding. The service value, hence rents, for the use of the services here may differ, though equal in every relevant respect elsewhere. Whether the specific use uniqueness is created by natural talent or sheer accident, the special differences in use value here imply differences in payments, often called ‘Ricardian rents’ to distinguish them from differences in rents (prices) obtained because of monopolizing or unnatural restrictions on any potential competitors, which may lead to higher rents, called ‘monopoly rents’ for the protected resources.

Differential rents

‘Differential rents’ are another category representing rent differences in a sort of reverse homogeneity. Units of resource that are equal with respect to their value in use here differ among themselves in their values of use elsewhere. This can be represented graphically as in Figure 2. The differential rents of successive units are represented by the differences between the price line and the curve RR, which arrays the units from those with the lowest alternative use values to the highest, a curve labelled RR. The arrayed units are not homogeneous for uses elsewhere, so even if identical for use here, calling them successive units of the same good is misleading. They are not totally homogeneous; if they were, each unit would have the same as any other unit’s use value and rent elsewhere. A curve like RR is equivalent to Marshall’s particular expenses curve, which arrayed units according to each individual unit’s cost of production, or use value elsewhere, from lowest to highest (Marshall, 1920, p. 810n). The difference between price or rent here and the value on the RR curve is called ‘producers' surplus’ or ‘differential rent’. In sum, ‘Ricardian rents’ indicate differences in rents to units that are equal in their best alternative use values, but different in their rent value here, while ‘differential rents’ are the premia to units that are the same value here but different in their best alternative use values.
It is worth digressing to note that an upward rising true supply curve, which reflects increasing marginal costs of production, is different from the RR curve. In the true supply curve the area between the supply curve and the price line does not represent any of the above mentioned rents nor 'producers' surplus' (as it does with the RR curve). It is the portion of earnings of the supplier that exceed the variable costs and are applicable to cover the costs (possibly past investment costs) that are invariant to the rate of output. That area does not represent any excess of rental or sale value of units produced over their full costs, since only the variable costs are under the marginal cost curve. It represents the classic distribution of income to capital, if, for example, labour is presumed to be a variable input and capital a fixed input.

High rents a result, not cause, of high prices
An earlier unfortunate analytic confusion occurred in the common misimpression that high rents of land made its products more expensive. Thus the high rent of land in New York was and is still often believed to make the cost of living, or the cost of doing business, higher in New York. Or higher rent for some agricultural land is believed to increase the cost of growing corn on that land. Proper attention to the meaning of ‘demand’ and ‘costs’ would have helped avoid that confusion. Demand here for some unit for resource is the highest value use of that resource if used here. The cost of using it here is the highest valued forsaken alternative act elsewhere. For any resource the cost of its use here is its best value elsewhere, that is, its demand elsewhere. Land rent is high for ‘this’ use because the land’s value in some other use is high. The reason the rent is high here and can be paid is that its use value here is bid by competitors for its use here into the offered rent and exceeds the value in some other use. The product of the land can get higher price here; that is why the rent is bid up so high, even though the particular winning bidder then believes a high price of the products must be obtained because the rent was high, rather than the reverse. As with every marketable resource, its highest value use here determines its rent, rather than the reverse. It was the implication of this kind of analysis that Marshall attempted to summarize in the famous aphorism, which he attributed to Ricardo (1817): ‘Rent does not enter into [Money] Cost of production’ (Marshall, 1890, p. 482).

Probably the source of the confusion in believing that high rents of land caused high prices for products produced on expensive land is that an individual user of that expensive resource has to be able to charge a higher price for the product, if the rent is to be covered. Bidders for that land compete for the right to the land that can yield a service worth so much – though to any individual successful bidder that rent has to be paid regardless of how well the successful bidder may be at actually achieving the highest valued use of the land. Hence it may appear to an individual bidder that the rent determines the price that must be charged, rather than, as is the correct interpretation, the achievable high valued use enables the high bid for the land for the person best able to detect and achieve that highest valued use.

Function of rent

Some people were aware of this bidding for the ‘land’ and concluded that the rent served no social purpose, since the land would exist anyway. But the high receipt resulting from competitive bidding for its uses serves a useful purpose. It reveals which uses are the highest valued and directs the land to that use. In principle, a 100 per cent tax on the land rent would not alter its supply (assuming initially that ‘land’ is the name of whatever has a fixed indestructible supply). This would be correct if in this case the ‘owner’ of the land had any incentive left to heed the highest bidder where the highest bid determines the rent. The assertion assumes that somehow the highest valued use can be known and that amount of tax be levied without genuine bona fide competitive bids for its use, a dubious if not plainly false proposition.

Monopoly rent

Let the word ‘monopoly’ denote any seller whose wealth potential is increased by restrictions on other potential competitors, restrictions that are artificial or contrived in not being naturally inevitable. Laws prohibiting others from selling white wine, or opening restaurants, or engaging in legal practice are examples. It should be immediately emphasized that this does not imply nor is it to be inferred that all such restrictions are demonstrably undesirable. Nevertheless, the increased wealth potential is a ‘monopoly rent’. Whether it is realized by the monopolist as an increase in wealth depends upon the costs of competing for the imposition of such restrictions. Competition for ‘monopoly rents’ may transfer them to, for example, politicians who impose the restrictions, and in turn may be dissipated by competition among politicians seeking to be in a position to grant such favours. The ‘monopoly rents’ may be dissipated (by what is often called ‘rent-seeking’ competition for such monopoly status of rights to grant it) into competitive payments for resources that enable people to achieve status to grant such restrictions. Those who initially successfully and cheaply obtained such ‘monopoly’ status may obtain a wealth increase, just as successful innovators obtain a profit stream before it is eliminated by competition from would-be imitators.

repeated games

Kandori Michihiro
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article shows why self-interested agents manage to cooperate in a long-term relationship. When agents interact only once, they often have an incentive to deviate from cooperation. In a repeated interaction, however, any mutually beneficial outcome can be sustained in an equilibrium. This fact, known as the folk theorem, is explained under various information structures. This article also compares repeated games with other means to achieve efficiency, and briefly discusses the scope for potential applications.

Article

Repeated games provide a formal and quite general framework to examine why self-interested agents manage to cooperate in a long-term relationship. Formally, repeated games refer to a class of models where the same set of agents repeatedly play the same game, called the ‘stage game’, over a long (typically, infinite) time horizon. In contrast to the situation where agents interact only once, any mutually beneficial outcome can be sustained as an equilibrium when agents interact repeatedly and frequently. A formal statement of this fact is known as the folk theorem.

Repeated games and the general theories of efficiency

Thanks to the developments since the mid-1970s, economics now recognizes three general ways to achieve efficiency: (a) competition; (b) contracts; and (c) long-term relationships. For standardized goods and services, with a large number of potential buyers and sellers, promoting market competition is an effective way to achieve efficiency. This is formulated as the classic First and Second Welfare Theorems in general equilibrium theory. There are, however, other important resource allocation problems which do not involve standardized goods and services. Resource allocation within a firm or an organization is a prime example, as pointed out by Ronald Coase (1937), and examples abound in social and political interactions. In such cases, aligning individual incentives with social goals is essential for efficiency, and this can be achieved by means of incentive schemes (penalties or rewards). The incentive schemes, in turn, can be provided in two distinct ways: by a formal contract or by a long-term relationship. The penalties and rewards specified by a formal contract are enforced by the court, while in a long-term relationship the value of future interaction serves as the reward and penalty to discipline the agents' current behaviour. The theory of contracts and mechanism design concern the former case, and the theory of repeated games deals with the latter. These theories provide general methods to achieve efficiency, and have become important building blocks of modern economic theory.

An example: collusion of gas stations and the trigger strategy
Consider two gas stations located right next to each other. They have identical and constant marginal cost \( c \) (the wholesale price of gasoline) and compete by publicly posting their prices. Suppose their joint profit is maximized when they both charge \( P = 10 \), whereby each receives a large profit \( \pi \). Although this is the best outcome for them, they have an incentive to deviate. By slightly undercutting its price, each can steal all the customers from its opponent, and its profit (almost) doubles. The only price free from such profitable deviation is \( P = \xi \), where their profit is equal to zero. In other words, the only Nash equilibrium in the price competition game is an inefficient (for the gas stations) outcome where both charge \( P = \xi \). This situation is the rule rather than the exception: the Nash equilibrium in the stage game, the only outcome that agents can credibly achieve in a one-shot interaction, is quite often inefficient for them. This is because agents seek only their private benefits, ignoring the benefits or costs of their actions for their rivals.

In reality, however, gas stations enjoy positive profits, even when there is another station nearby. An important reason may well be that their interaction is not one-shot. Formally, the situation is captured by a repeated game, where the two gas stations play the price competition game (the stage game) over an infinite time horizon \( t = 0, 1, 2, \ldots \). Consider the following repeated game strategy:

1. Start with the optimal price \( P = 10 \).
2. Stick to \( P = 10 \) as long as no player (including oneself) has ever deviated from \( P = 10 \).
3. Once anyone (including oneself) deviated, charge \( P = \xi \) for ever.

This can be interpreted as an explicit or implicit agreement of the gas stations: charge the monopoly price \( P = 10 \), and any deviation triggers cut-throat price competition (\( P = \xi \) with zero profit). Let us now check whether each player has an incentive to deviate from this strategy. Note that, if neither station deviates, each enjoys profit \( \pi \) every day. As we saw above, a player can (almost) double its stage payoff by slightly undercutting the agreed price \( P = 10 \). Hence the short-term gain from deviation is at most \( \pi \). If one deviates, however, its future payoff is reduced from \( \pi \) to zero in each and every period in the future. Now assume that the players discount future profits by the discount factor \( \delta \in (0, 1) \). The number \( \delta \) measures the value of a dollar in the next period. The discounted future loss is \( \delta \pi + \delta^2 \pi + \ldots = \frac{\delta}{1-\delta} \pi \). If this is larger than the short-term gain from defection (\( \pi \), no one wants to deviate from the collusive price \( P = 10 \). The condition is \( \pi \leq \delta / (1-\delta) \pi \), or equivalently, \( 1 / 2 \leq \delta \).

Next let us check whether the players have an incentive to carry out the threat (the cut-throat price competition \( P = \xi \)). Since \( P = \xi \) is the Nash equilibrium of the stage game, charging \( P = \xi \) in each period is a best reply if the opponent always does so. Hence, the players are choosing mutual best replies. In this sense, the threat of \( P = \xi \) will be again subject to renegotiation and will not be enforceable.

In summary, under the strategy defined above, players are choosing mutual best replies after any history, as long as \( 1 / 2 \leq \delta \). In other words, the strategy constitutes a subgame perfect equilibrium in the repeated game. Similarly, in a general game, any outcome which Pareto dominates the Nash equilibrium can be sustained by a strategy which reverts to the Nash equilibrium after a deviation. Such a strategy is called a trigger strategy.

Three remarks: multiple equilibria, credibility of threat and renegotiation, and finite versus infinite horizon

A couple of remarks are in order about the example. First, the trigger strategy profile is not the only equilibrium of the repeated game. The repetition of the stage game Nash equilibrium \( P = \xi \) for ever) is also a subgame perfect equilibrium. Are there any other equilibria? Can we characterize all equilibria in a repeated game? The latter question appears to be formidable at first sight, because there are an infinite number of repeated game strategies, and they can potentially be quite complex. We do have, however, some complete characterizations of all equilibria of a repeated game, such as folk theorems and self-generation conditions as will be discussed subsequently.

Second, one may question the credibility of the threat \( P = \xi \) for ever). In the above example, credibility was formalized as the subgame perfect equilibrium condition. According to this criterion, the threat \( P = \xi \) is credible because a unilateral deviation by a single player is never profitable. The threat \( P = \xi \), however, may be upset by renegotiation. When players are called upon to carry out this grim threat after a deviation, they may well get together and agree to ‘let bygones be bygones’. After all, when there is a better equilibrium in the repeated game (for example, the trigger strategy equilibrium), why do we expect the players to stick to the inefficient one \( P = \xi \)? This is the problem of renegotiation proofness in repeated games. The problem is trickier than it appears, however, and economists have not yet agreed on what is the right notion of renegotiation proofness for repeated games. The reader may get a sense of difficulty from the following observation. Suppose the players have successfully renegotiated away \( P = \xi \) to play the trigger strategy equilibrium again. This is self-defeating, however, because the players now have an incentive to deviate, as they may well anticipate that the threat \( P = \xi \) will be again subject to renegotiation and will not be carried out. For a comprehensive discussion of this topic (and also of a number of major technical results on repeated games), see an excellent survey by D. Pearce (1990).

Third, let me comment on the assumption of an infinite time horizon. Suppose that the gas stations are to be closed by the end of next year (due to a new zoning plan, for ex). This situation can be formulated as a finitely repeated game. On the last day of their business, the gas stations just play the stage game, and therefore they have no other choice but to play
the stage game equilibrium \( P = \tau \). In the penultimate day, they rationally anticipate that they will play \( P = \tau \) irrespective of their current action. Hence they are effectively playing the stage game in the penultimate day, and again they choose \( P = \tau \). By induction, the only equilibrium of the finitely repeated price competition is to charge \( P = \tau \) in every period. The impossibility of cooperation holds no matter how long the time horizon is, and it is in sharp contrast to the infinite horizon case.

Although one may argue that players do not really live infinitely long (so that the finite horizon case is more realistic), there are some good reasons to consider the infinite horizon models. First, even though the time horizon is finite, if players do not know in advance exactly when the game ends, the situation can be formulated as an infinitely repeated game. Suppose that, with probability \( r > 0 \), the game ends at the end of any given period. This implies that, with probability \( 1 \), the game ends in a finite horizon. Note, however, that the expected discounted profit is equal to \( \pi(0) + (1 - r)\pi(1) + (1 - r)^2\pi(2) + \ldots \), where \( \pi(t) \) is the stage payoff in period \( t \). This is identical to the payoff in an infinitely repeated game with discount factor \( \delta' = (1 - r)\delta \). Second, the drastic 'discontinuity' between the finite and infinite horizon cases in the price competition example hinges on the uniqueness of \( v \), the game ends at the end of any given period. This implies that, \( v \) is indeed equal to \( v \).

**The repeated game model**

Now let me present a general formulation of a repeated game. Consider an infinitely repeated game, where players \( i = 1, 2, \ldots, N \) repeatedly play the same stage game over an infinite time horizon \( t = 0, 1, 2, \ldots \). In each period, player \( i \) takes some action \( a_t \in A_t \) and her payoff in that period is given by a stage game payoff function \( g_i(a_t) \), where \( a = (a_1, \ldots, a_T) \) is the action profile in that period. The repeated game payoff is given by

\[
\Pi = \sum_{t=0}^{\infty} g_i(a(t))\delta^t,
\]

where \( a(t) \) denotes the action profile in period \( t \) and \( \delta \in (0, 1) \) is the discount factor. It is often quite useful to look at the average payoff of the repeated game, which is defined to be \( (1 - \delta)\Pi \). Note that, if one receives the same payoff \( x \) in each period, the repeated game payoff is \( \Pi = x + \delta x + \delta^2 x + \ldots = x / (1 - \delta) \).

A history up to time \( t \) is the sequence of realized action profiles before \( t \): \( h_t = (a(0), a(1), \ldots, a(t-1)) \). A repeated game strategy for player \( i \), denoted by \( s_i \), is a complete contingent action plan, which specifies a current action after any history: \( a_t(\cdot) = s_i(h_t) \). A repeated game strategy profile \( s = (s_1, \ldots, s_N) \) is a subgame perfect equilibrium if it specifies mutual best replies after any history.

**The folk theorem**

Despite the fact that a repeated game has an infinite number of strategies, which can be arbitrarily complicated, we do have a complete characterization of equilibrium payoffs. The folk theorem shows exactly which payoff points can be achieved in a repeated game. Before stating the theorem, we need to introduce a couple of concepts. First, let us determine the set of physically achievable average payoffs in a repeated game. Note that, by alternating between two pure strategy outcomes, say \( u \) and \( v \), one may achieve any point between \( u \) and \( v \) as the average payoff profile. Hence, an average payoff profile can be a weighted average (in other words, a convex combination) of pure strategy payoff profiles in the stage game. Let us denote the set of all such points by \( V \). Formally, the set of feasible average payoff profiles \( V \) is the smallest convex set that contains the pure strategy payoff profiles of the stage game.

Second, let us determine the points in \( V \) that cannot possibly be an equilibrium outcome. For example, if a player has an option to stay out to enjoy zero profit in each period, it is a priori clear that her equilibrium average payoff cannot be less than zero. In general, there is a payoff level that a player can guarantee herself in any equilibrium, and this is formulated as the minimax payoff. Formally, the minimax payoff for player \( i \) is defined as \( v_i = \min_{\alpha} \max_{\cdot} \pi_i(\cdot) \), where \( \alpha = (a_1, \ldots, a_N) \) is a mixed action profile (\( \alpha_i \) is a probability distribution over player \( i \)'s pure actions) and \( g_i(\alpha) \) is the associated expected payoff. To understand why min and max are taken in that particular order, consider the situation where player \( i \)
always correctly anticipates what others do. If player $i$ knows that others choose $\alpha_i = (\alpha_1, \ldots, \alpha_j, \alpha_{j+1}, \ldots, 0_N)$, he can play a best reply against $\alpha_i$ to obtain $\max g_i(\alpha)$. Note well that $\alpha_i$ is a function of $\alpha_{-i}$. In the worst case, where others take the most damaging actions $\alpha_{-i}$, player $i$ obtains the minimax payoff (this is exactly what the definition says). From this definition it is clear that, in any equilibrium of the repeated game, the average payoff to each player is at least her minimax payoff. In any equilibrium, each player correctly anticipates what others do, and simply by playing the stage game best reply in each period, any player can make sure that her average payoff is more than her minimax payoff. (A comment: we consider mixed strategies in the definition of the minimax payoff because in many games the minimax payoff is smaller when we consider mixed strategies.)

From what we saw, now it is clear that the set of equilibrium average payoff profiles of a repeated game is at most $V^\ast = \{ v | \forall i v_i \geq Y_i \}$. (The points with $v_i = Y_i$ are excluded to avoid minor technical complications.) The set $V^\ast$ is called the feasible and individually rational payoff set. This is the set of physically achievable average payoff profiles in the repeated game where each player receives more than her minimax payoff. The folk theorem shows that any point in this ‘maximum possible region’ can indeed be an equilibrium outcome of the repeated game. (Throughout this article, I maintain a minor technical assumption that each player has a finite number of actions in the stage game.)

Folk th: In an $N$-player infinitely repeated game, any feasible and individually rational payoff profile $v \in V^\ast$ can be achieved as the average payoff profile of a subgame perfect equilibrium when the discount factor $\delta$ is close enough to 1, provided that either $N = 2$, or $N \geq 3$ and no two players have identical interests.

Formally, no two players have identical interests if there are no players $i$ and $j$ ($i \neq j$) whose payoffs satisfy $g_j(\alpha) = b g_j(\alpha) + \epsilon$, $b > \Omega$ (that is, no two players have the same preferences over the stage game outcomes). This is a ‘generic’ condition that is almost always satisfied: the case where players have identical interests is very special in the sense that the equality $g_j(\alpha) = b g_j(\alpha) + \epsilon$ fails by even a slight change of the payoff functions. Hence, the folk theorem provides a general theory of efficiency: it shows that, for virtually any game, any mutually beneficial outcome can be achieved in a long term relationship, if the discount factor is close to 1. Although game-theoretic predictions quite often depend on the fine details of the model, this result is a notable exception for its generality.

The crucial condition in the folk theorem is a high discount factor. The discount factor $\delta$ may measure the (subjective) patience of a player, or, it may be equal to $1 \over (1 + r)$, where $r$ is the interest rate per period. Although the discount factor may not be directly observable (in particular, in the former case), it should be high when one period is short. Hence, an empirically testable implication is that players who have daily interaction (such as the gas stations in our ex) have a better scope for cooperation than those who interact only once a year. An important message of the folk theorem is that a high frequency of interaction is essential for the success of a long term relationship.

The name ‘folk th’ comes from the fact that game theorists had anticipated that something like it should be true long before it was precisely formulated and proved. In this sense, the assertion had been folklore in the game theory community. The proof is, however, by no means obvious, and there is a body of literature to prove the theorem in various degrees of generality. Early contributions include Aumann (1959), Friedman (1971) and Rubinstein (1979). The statement above is based on Fudenberg and Maskin (1986) and its generalization by Abreu, Dutta and Smith (1994). The proof is constructive: a clever strategy, which has a rather simple structure, is constructed to support any point in $V^\ast$.

Repeated games versus formal contracts

To discuss the scope of applications, I now compare a long-term relationship (repeated game) and a formal contract as a means to enforce efficient outcomes. As our gas station example shows, quite often an agent has an incentive to deviate from an efficient outcome, because it increases her private returns at the expense of the social benefit. Such a deviation can be deterred if we impose a sufficiently high penalty so that the incentive constraint

\[ \text{gain from deviation} \leq \text{penalty} \]

is satisfied. This is the basic and common feature of repeated games and contracts. A formal contract explicitly specifies the penalty and it is enforced by the court. In repeated games, the penalty is indirectly imposed through future interaction. In this sense the theory of repeated games can be regarded as the theory of informal or relational contracts.

When is a long-term relationship a better way to achieve cooperation than a formal contract? First, a long-term relationship is useful when a formal contract is too costly or impractical. For example, it is often quite costly for a third party (the court) to verify whether there was any deviation from an agreement, while defections may be directly observed by the players themselves. In practice, what constitutes ‘cooperation’ is often so fuzzy or complicated that it is hard to write it down explicitly, although the players have a common and good understanding about what it is. ‘Pulling enough weight’ in a joint research project may be a good example. In those situations, a long-term relationship is a more practical way to achieve cooperation than a formal contract. In fact, a classic study by Macaulay (1963) indicates that the vast majority of business transactions are executed without writing...
formal contracts. Second, there are some cases where a court powerful enough to enforce formal contracts simply does not exist. For example, in many problems in development economics and economic history, the legal system is highly imperfect. Even for developed countries in the modern age, there are no legal institutions which have enough binding power to enforce international agreements. Hence, repeated games provide a useful framework to address such problems as the organization of medieval trade, informal mutual insurance in developing countries, international policy coordination, and measures against global warming. Lastly, there is no legal system to enforce cartels or collusion, because the existing legal system refuses to enforce any contract that violates antitrust laws. Hence a long-term relationship is the only way to enforce a cartel or collusive agreement.

Is the folk theorem a negative result?

The theory of repeated games based on the folk theorem is often criticized because it does not, as the criticism goes, have any predictive power. The folk theorem basically says that anything can be an equilibrium in a repeated game. One could argue, however, that this criticism is misplaced if we regard the theory of repeated games as a theory of informal contracts. Just as anything can be enforced when the players agree to sign a binding contract, in repeated games any (feasible and individually rational) outcome is sustained if the players agree on an equilibrium. Enforceability of a wide range of outcomes is the essential property of effective contracts, formal or informal. The folk theorem correctly captures this essential feature.

This criticism is valid, however, in the sense that the theory of repeated games does not provide a widely accepted criterion for equilibrium selection. When we regard a repeated game as an informal contract, where the players explicitly try to agree on which equilibrium to play, the problem of equilibrium selection boils down to the problem of bargaining. In such a context, it is natural to assume that an efficient point (in the set of equilibria) is played. In the vast majority of applied works of repeated games with symmetric stage games (such as the gas stations ex), it is common to look at the best symmetric equilibrium. In contrast, when players try to find an equilibrium through trial and error, the theory of repeated games is rather silent about which equilibrium is likely to be selected. A large body of computer simulation literature on the evolution of cooperation, pioneered by Axelrod (1984), may be regarded as an attempt to address this issue.

Imperfect monitoring

So far we assumed that players can perfectly observe each other's actions. In reality, however, long term relationships are often plagued by imperfect monitoring. For example, a country may not verify exactly how much CO$_2$ is emitted by neighbouring countries. Workers in a joint project may not directly observe each others effort. Electronic appliance shops often offer secret discounts for their customers, and each shop may not know exactly how much is charged by its rivals. In such situations, however, there are usually some pieces of information, or signals, which imperfectly reveal what actions have been taken. Published meteorological data indicates the amount of CO$_2$ emission, the success of the project is more likely with higher effort, and a shop's sales level is related (although not perfectly) to its rivals' prices.

According to the nature of the signals, repeated games with imperfect monitoring are classified into two categories: the case of public monitoring, where players commonly observe a public signal, and the case of private monitoring, where each player observes a signal that is not observable to others. Hence, the CO$_2$ emission game and the joint-project game are examples with imperfect public monitoring (published meteorological data and the success of the project are publicly observed), while the secret price-cutting game by electronic shops is a good example with imperfect private monitoring (one's sales level is private information).

This difference may appear to be a minor one, but, somewhat surprisingly, it is not. The imperfect public monitoring case shares many features with the perfect monitoring case, and we now have a good understanding of how it works. In contrast, the imperfect private monitoring case is not fully understood, and we have only some partial characterizations of equilibria. In what follows, I sketch the main results in the imperfect public and private monitoring cases.

Imperfect public monitoring

At first sight, this case might look much more complicated than the perfect monitoring case, but those two cases are similar in the sense that they share a recursive structure. Consider the set $W^*$ of all average payoff profiles associated with the subgame perfect equilibria of a perfect monitoring repeated game. Any point $w \in W^*$ is a weighted average of the current payoff $g$ and the continuation payoff $W' : (1 - \delta) g + \delta W'$. The continuation payoff typically changes when a player deviates from $g$, in such a way that the short-term gain from deviation is wiped out. Subgame perfection requires that all continuation payoffs are chosen from the equilibrium set $W^*$. In this sense, $W^*$ is generated by itself, and this stationary or recursive structure turns out to be quite useful in characterizing the set of equilibria.

The set of equilibria in an imperfect public monitoring game also shares the same structure. Consider the equilibria where the public signal determines which continuation equilibrium to play. When a player deviates from the current equilibrium action, it affects both her current payoff and (through the public signal) her continuation payoff. The equilibrium action should be enforceable in the sense that any gain in the former should be wiped out in the latter, and this is easier when the continuation payoff admits large variations. Formally, given
the range of continuation payoffs $W$, we can determine the set $B(W)$ of enforceable average payoffs. The larger the set $W$ is, the more actions can be enforced in the current period (and therefore the larger the set $B(W)$ is). As in the perfect monitoring case, the equilibrium payoff set $W = W^*$ generates itself: it satisfies the \textit{self-generation condition} of Abreu, Pearce and Stacchetti (1990). $W^*$ is the largest (bounded) set satisfying this condition, and the condition is in fact satisfied with equality. Conversely, it is easy to show that any (bounded) set satisfying the self-generation condition is contained in the equilibrium payoff set $W^*$.

This provides a simple and powerful characterization of equilibria, which is an essential tool to prove the folk theorem in the imperfect public monitoring case. The folk theorem shows that, despite the imperfection of monitoring, we can achieve any feasible and individually rational payoff profile under a certain set of conditions. Before presenting a formal statement, let me sketch the basic ideas behind the folk theorem. When monitoring is imperfect, players have to be punished when a ‘bad’ signal outcome $\omega$ is observed, and this may happen with a positive probability even if no one defects. For example, in the joint project game, the project may fail even though everyone works hard.

A crucial difference between the perfect and imperfect monitoring cases is that, in the latter, punishment occurs \textit{on the equilibrium path}. The resulting welfare loss, however, can be negligible under certain conditions.

Consider a two-player game, where the probability distribution of the signal $\omega \in \Omega = \{\omega^1, \ldots, \omega^K\}$, when no one defects, is given by $P^* = (p^*(\omega^1), \ldots, p^*(\omega^K))$ in Figure 1. Suppose that each player’s defection changes the probability distribution to exactly the same point $P'$. Then, there is absolutely no way to tell which player deviates, so that the only way to deter a defection is to \textit{punish all players simultaneously}, when a ‘bad’ outcome emerges. This means that surplus is thrown away, and we are bound to have substantial welfare loss. Now consider a case where different players’ actions affect the signal asymmetrically: player 1’s defection leads to point $P'$, while the defection by player 2 leads to $P''$. In this asymmetric case, one can \textit{transfer} future payoff from player 1 to 2 when player 1’s defection is suspected. Under such a transfer, surplus is never thrown away, and this enables us to achieve efficiency.

Figure 1
More precisely, consider the normal vector $\mathbf{x}$ of the hyperplane separating $P'$ and $P''$ in the figure, and let $w_1 = \mathbf{x}$ and $w_2 = -\mathbf{x}$ be the continuation payoffs of player 1 and player 2 respectively. Figure 1 indicates that player 1’s expected continuation payoff $P' \cdot w_1 = P' \cdot \mathbf{x}$ is reduced by her own defection $(P' \cdot \mathbf{x} < P'' \cdot \mathbf{x})$. Similarly, player 2’s defection reduces her expected continuation payoffs $(P'' \cdot (-\mathbf{x}) > P'' \cdot (-\mathbf{x}))$. Note that this asymmetric punishment scheme does not reduce the joint payoff, because by construction $w_1 + w_2$ is identically equal to 0. This is an essential idea behind the folk theorem under imperfect public monitoring: When different players’ deviations are statistically distinguished, asymmetric punishment deters defections without welfare loss.

When can we say that different players’ deviations are statistically distinguished? Note well that the above construction is impossible when $P''$ is exactly in between $P'$ and $P'$ (that is, when $P''$ is a convex combination of $P'$ and $P'$). Such a case can be avoided if $P^*, P'$ and $P''$ are linearly independent. The linear independence of the equilibrium signal distribution ($P^*$) and the distributions associated with the players' unilateral deviations ($P'$ and $P''$), is a precise formulation of what it means when the signal ‘statistically distinguishes different players’ deviations’.

Let us now generalize this observation. Given an action profile (for simplicity of exposition, assume it is pure) to be sustained, there is an associated signal distribution $P^*$. Consider any pair of players $i$ and $j$, and let $|A_i|$ be the number of player $k$'s actions ($k = i, j$) in the stage game. Since each player $k = i, j$ has $|A_k| - 1$ ways to deviate, we have $|A_i| + |A_j| - 2$ signal distributions associated with their unilateral deviations. If those distributions and the equilibrium distribution $P^*$, altogether $|A_i| + |A_j| - 1$ vectors, are linearly independent, we say that the signal can discriminate between deviations by $i$ and deviations by $j$. This is called the pairwise full rank condition. This holds only when the dimension of the signal space ($|\Omega|$, the number of signal outcomes) is larger than the number of those vectors (that is, $|\Omega| \geq |A_i| + |A_j| - 1$). Conversely, if this inequality is satisfied, the pairwise full rank condition holds ‘generically’ (that is, it holds unless the signal distributions have a very special structure, such as exact symmetry). This leads us to the folk theorem under imperfect public monitoring (this is a restatement of Fudenberg, Levine and Maskin, 1994, in terms of genericity):

**Folk theorem under imperfect public monitoring:** Suppose that the signal space is large enough in the sense that $|\Omega| \geq |A_i| + |A_j| - 1$ holds for each pair of players $i$ and $j$. Then, for a generic choice of the signal distributions and the stage game, any feasible and individually rational payoff profile $\nu \in V^*$ can be asymptotically achieved by a sequential equilibrium as the discount factor $\delta$ tends to 1.

In contrast to the perfect monitoring case, the proof is non-constructive. Rather than explicitly constructing equilibrium strategies, the theorem is proved by showing that any smooth subset of $V^*$ is self-generating. In fact, the exact structure of the equilibrium strategy profile to sustain, for example, an efficient point is not so well understood. Sannikov (2005) shows that detailed structure of equilibrium strategies can be obtained if the model is formulated in continuous time.

**Imperfect private monitoring**

Now consider the case where all players receive a private signal about their opponents’ actions. Although this has a number of important applications (a leading example is the secret
price cutting model), this part of research is still in its infancy. Hence, rather than just summarizing definitive results as in the previous subsections, I explain in somewhat more technical detail the source of difficulties and the nature of existing approaches.

The difficulties come from a subtle but crucial difference from the perfect or public monitoring case. I explain below the difference from three viewpoints, in the increasing order of technicality.

1. In the perfect or public monitoring case, players share a mutual understanding about when and whom to punish. They can cooperate to implement a specific punishment, and, more importantly, they can mutually provide the incentives to carry out the punishment. This convenient feature is lost when players have diverse private information about each other's actions.

2. In the perfect or public monitoring case, public information directly tells the opponents' future action plans. In the private monitoring case, however, each player has to draw statistical inferences about the history of the opponents' private signals to estimate what they are going to do. The inferences quickly become complicated over time, even if players adopt relatively simple strategies.

3. In the perfect or public monitoring case, the set of equilibria has a recursive structure, in the sense that a Nash equilibrium of the repeated game is always played after any history. Now consider a Nash equilibrium of, for example, the repeated Prisoner's Dilemma with imperfect private monitoring. After the equilibrium actions in the first period, say (C,C), players condition their action plans on their private signals $\omega_1$ and $\omega_2$. Hence the continuation play is a correlated equilibrium, where it is common knowledge that the probability distribution of the correlation device $(\omega_1, \omega_2)$ is given by $p(\omega_1, \omega_2 | C, C)$. When player 1 deviates to D in the first period, however, the distribution of correlation device is not common knowledge: player 1 knows that it is $p(\omega_1, \omega_2 | D, C)$, while player 2 keeps the equilibrium expectation $p(\omega_1, \omega_2 | C, C)$. Hence, after a deviation, the continuation play is no longer a correlated equilibrium in the usual sense. In addition, the space of the correlation device (the history of private signals) becomes increasingly rich over time. Therefore, the equilibria in the private monitoring case do not have a compact recursive structure; a continuation play is chosen from a different set, depending on the history.

One way to get around these problems is to allow communication (Compte, 1998; Kandori and Matsushima, 1998). In their equilibrium, players truthfully communicate their private signal outcomes in each period. The equilibrium is constructed in such a way that each player's report of her signal is utilized to discipline other players and does not affect one's own continuation payoff. This implies that each player is indifferent about what to report, and therefore truth telling is a best reply. Such an equilibrium, which depends on the history of publicly observable messages, works in much the same way as the equilibria in the public monitoring case. Hence, with communication, the folk theorem is obtained in the private monitoring case.

The remaining issue is to characterize the equilibria in the private monitoring case without communication. From the viewpoint of potential applications, this is important, because collusion or cartel enforcement is a major applied area of repeated games, where communication is explicitly prohibited by the antitrust law.

One may expect that, when players' private information admits sufficient positive correlation, an equilibrium can be constructed in a similar way to the public monitoring case. Sekiguchi (1997) is the first to construct a non-trivial (and nearly efficient) equilibrium in the private monitoring game without communication, and his construction is basically built on such an idea. Strong correlation of private information is, however, not assumed in his model but is derived endogenously. He assumes that private signals provide nearly perfect observability and considered mixed strategies. In such a situation, the privately observed random variables, the action-signal pairs, are strongly correlated (because a player's random action is strongly correlated with another player's signal under nearly perfect observability). Mailath and Morris (2002) show that, in general, there is ‘continuity’ between the public and private but sufficiently correlated monitoring cases, in the sense that any strategy with a finite memory works in either case.

Those papers are examples of the belief-based approach, which directly addresses the statistical inference problem (see point 2. above). Some other papers follow this approach, and they provide judiciously constructed strategies in rather specific examples, where the inference problem becomes tractable. Aside from the case with near perfect correlation, however, we are yet to have generally applicable results or techniques from this approach.

More successful has been the belief-free approach, where an equilibrium is constructed in such a way that the inference problem becomes irrelevant. As a leading example, here I explain Ely and Valimaki's work (2002) on the repeated Prisoner's Dilemma with imperfect private monitoring. Each player's strategy is a Markov chain with two states, R (reward) and P (punishment). A specific action is played in each state (C in R, and D in P), and the transition probabilities between the states depend on the realization of the player's private signal. Choose those transition probabilities in such a way that the opponent is always indifferent between C and D no matter which state the player is in. This requirement can be expressed as a simple system of dynamic programming equations, which has a solution when the discount factor is close to 1 and the private signal is not too uninformative. By construction, any action choice is optimal against this strategy after any history, and in particular this strategy is a best reply to itself (so that it constitutes an equilibrium). Note that one's incentives do not depend on the opponent's state, and therefore one does not have to draw the statistical inferences about the history of the opponent's private signals.

There are certain difficulties, however, in obtaining the folk theorem with such a class of equilibria. First, players may be punished simultaneously in this construction, and our discussion about the public monitoring case shows that some welfare loss is inevitable (unless monitoring is nearly perfect). Second, even if we restrict our attention to the nearly perfect monitoring case, there is a certain set of restrictions imposed on the action profiles that can be sustained by such a belief-free approach.
Those difficulties can be resolved when we consider block strategies. Block strategies treat the stage games in $T$ consecutive periods as if they were a single stage game, or a block stage game, and applies the belief-free approach with respect to those block stage games. It is now known that, by using the block strategies, the folk theorem under private monitoring holds in the nearly perfect monitoring case (Hörner and Olszewski, 2006) and for some two-player games where monitoring is far from perfect (Matsushima, 2004). In the former, the block structure of the stage game helps to satisfy the restrictions imposed on the sustainable actions in belief-free equilibria. In the latter, an equilibrium is constructed where players choose constant actions in each block. This means that players have $T$ samples of private signals for the constant actions, so that the observability practically becomes nearly perfect when $T$ is large. With this increased observability and some restrictions on payoff functions, the folk theorem is obtained. For this construction to be feasible, the signals have to satisfy certain strong conditions, such as independence (across players).

The general folk theorem, or a general characterization of equilibria, for the private monitoring case is yet to be obtained, and it remains an important open question in economic theory. A comprehensive technical exposition of the perfect monitoring, imperfect public monitoring, and private monitoring cases can be found in Mailath and Samuelson (2006).

Bibliography

**How to cite this article**

We explain what reputation effects are, how they arise and the factors that limit or strengthen them.

Keywords

collusion; complete information games; conflicting interest games; extensive form games; imperfect monitoring; incomplete information games; industrial organization; Jensen's inequality; Markov equilibria; martingales; prisoner's dilemma; repeated games; reputation; signalling; tit-for-tat; uncertainty

In a dynamic setting signals sent now may affect the current and future behaviour of other players; thus, signals can have effects unrelated to their current costs and benefits. It is the interplay between signals and their long-run consequences that is studied in the literature on reputation.

The literature on reputation has two main themes. The first is that introducing a small amount of incomplete information in a dynamic game can dramatically change the set of equilibrium payoffs: introducing something to signal can have big implications in a dynamic model. These kinds of result can also be interpreted as providing a robustness check. Dynamic and repeated games typically have many equilibria, and reputation results allow us to determine which equilibria continue to be played when a game is ‘close’ to complete information. The second theme of the literature on reputations is that introducing incomplete information in a dynamic game may introduce new and important signalling dynamics in the players' strategies. Thus reputation effects tell us something about behaviour. This theme is particularly important in applications to macroeconomics and to industrial organization, for example. For either of these themes to be relevant it is necessary to have a dynamic game with incomplete information, so work on reputation has been influenced by, and influences, the larger literature on repeated and dynamic games of incomplete information. An excellent detailed treatment of reputation can be found in Mailath and Samuelson (2006).

An example

Most of the results below will be described in the context of a simple infinitely repeated trading game. The row player is a seller who can produce high or low quality. The column player is a buyer. Producing high quality is always expensive for the seller, so she would rather produce low quality; the buyer, however, wants to buy only a high-quality product. The only non-standard element is that the buyer regrets not buying a high-quality product. The trading game (Figure 1) has a unique equilibrium (L, N).

Figure 1
A trading game
Let us record some facts about this game. The set

\[ V = \{ (x, y) : x > 0, y > -1/3, y \leq x \text{ and } y \leq 3 - 2x \} \subset \mathbb{R}^2, \]

illustrated in Figure 2, is the set of feasible and strictly individually rational payoffs for the trading game. The axes are drawn through the minmax payoffs to make \( V \) clear. If the seller could commit to a pure strategy, she would prefer to choose \( H \) as the buyer's best response to this is \( B \). However, she could do even better by committing to a mixed strategy; playing \((3/4, 1/4)\) for example would also ensure the buyer played \( B \) and give the seller a bigger payoff. Reputation arguments can provide ways for these commitment payoffs to be achieved by sellers who are not actually committed to anything.

Figure 2
Sets of equilibrium payoffs and reputation bounds
The trading game is played in each of the periods $t=1,2,\ldots$ with perfect monitoring; at the end of the period the players get to observe all payoffs and the pure action taken by their opponent. If both players' discount factors, $\delta < 1$, were sufficiently large, any point in $V$ could be sustained as an equilibrium payoff. If the seller is long lived but faces an infinite sequence of buyers who each live one period, then any point on the line segment joining $(0,0)$ to $(1,1)$ is an equilibrium payoff. (No seller payoff above 1 is achievable if mixed actions are not observable; see Fudenberg, Kreps and Maskin, 1990.)
reputation: The New Palgrave Dictionary of Economics

The stage is now set. To understand how reputation works we will need to introduce something for the seller to signal. Its commitment to high quality? Its low cost of high quality? Its commitment to always ripping off customers…? At this stage it is unnecessary to be specific, and we will concentrate on the general issues of learning. There are two types of sellers, ‘strong’ and ‘normal’, that the buyer may face in a game. The seller is told their type by nature at time $t=0$. The buyer, however, is unaware of nature’s selection and spends the rest of the game looking at the seller’s behaviour and trying to figure out what type she is. The normal seller plays action $a \in \{H, L\}$ with probability $\hat{\sigma}^t(a)$ at time $t$, and the strong seller plays $a$ with probability $\hat{\sigma}^t(a)$ at time $t$. Everything we say in the section below applies to the case where normal and strong sellers follow history-dependent strategies. (These behaviour strategies do depend on the – public – history of play before time $t$, but let us keep this out of our notation.) An initially uninformed buyer attaches probability $p^t$ to the strong type and $1-p^t$ to the normal type at time $t$; again this depends on the observed history. Our buyer expects the seller to play $a$ with probability $\tilde{\sigma}^t(a) = p^t \hat{\sigma}^t(a) + (1-p^t) \hat{\sigma}^t(a)$, and as time passes the buyers observe the outcomes of this strategy and revise their prior accordingly.

**Tricks with Bayes’s rule and martingales**

Now we generate three properties of learning that are extensively used in the reputation literature. We will call them the ‘merging’ property, the ‘right ballpark’ property and the ‘finite surprises’ property. These properties are based on some simple facts about how Bayesian agents revise their beliefs, that is, how uncertainty about the seller’s type is processed by the buyers or any other observer of its behaviour. A more advanced treatment of these results can be found in Sorin (1999). We defer any derivation of reputation results to the next section, so a reader could skip this section.

How does the buyer revise his or her beliefs in the light of an observed action $a^t$? A plain application of Bayes’ rule tells us

$$p^{t+1} = \frac{Pr(a^t \cap \text{Strong})}{Pr(a^t)} = \frac{p^t \hat{\sigma}^t(a^t)}{\tilde{\sigma}^t(a^t)}.$$

Or, in terms of the change in the beliefs

$$p^{t+1} - p^t = \frac{p^t(\hat{\sigma}^t(a^t) - \tilde{\sigma}^t(a^t))}{\tilde{\sigma}^t(a^t)} = \frac{p^t(1-p^t)(\hat{\sigma}^t(a^t) - \tilde{\sigma}^t(a^t))}{\tilde{\sigma}^t(a^t)}.$$

These equalities are powerful tools when combined with the properties of the priors.

**Merging property.** This tells us exactly how the long-run behaviour of the sellers is related to the buyer’s long run beliefs. Either $p^t(1-p^t) \to 0$ and the buyer eventually learns the type of the seller and can perfectly predict their actions, or all types of the seller end up behaving in the same way $\hat{\sigma}^t(a^t) - \tilde{\sigma}^t(a^t) \to 0$ and again the buyer can perfectly predict their actions. Nothing else can happen!

The stochastic process $\{p^t\}$ is a martingale on $[0,1]$ with respect to public histories. To see this there is a simple calculation we can do.

$$E(p^{t+1} \mid \eta_t) - \sum_{a^t} Pr(a^t) p^{t+1} = \sum_{a^t} \tilde{\sigma}^t(a^t) - \frac{p^t \sigma^t(a^t)}{\tilde{\sigma}^t(a^t)} - p^t.$$
(The expectation $E(\cdot)$ is taken with respect to the buyer's beliefs about future play.) Bounded martingales converge almost surely (see Williams, 1991, for example), which implies $|p^{t+1} - p^t| \to 0$ almost surely. Applying this to the second equality above (noting that $|\sigma'(a')| \leq 1$), we get

$$p'(1 - p') \sigma'(a') - \sigma'(a') \to 0, \quad (Merging)$$

almost surely. This kind of result is extensively used in Hart (1985) and the literature that stems from his work.

Right ballpark property. The strong seller knows that the future will evolve according to the strategy $\hat{\sigma}$ (we use $\hat{\Pr}(\cdot)$ and $\hat{E}(\cdot)$ to denote her probability measure and its expectation). This seller might ask, as she plays out an equilibrium, how little probability the buyers can attach to the strong seller, or how low $p'$ could get when she plays $\hat{\sigma}$. Of course, when the seller is in fact the strong type it is very unlikely that $p'$ becomes low – beliefs must stay in the right ballpark. (For example, if $\sigma'$ was actually a pure strategy the strong seller cannot ever believe $p'$ will decrease. As she plays $\hat{\sigma}$ there will be periods in which the normal type of seller could have done something different, so observing the actions of $\hat{\sigma}$ will cause buyers to revise $p'$ upwards.)

From the perspective of the strong seller, the likelihood ratio is a martingale:

$$E\left(\frac{1 - p^{t+1}}{p^{t+1}} \mid \mathcal{F}_t\right) - \frac{1 - p'}{p'}.$$

(The calculation is just like the earlier one for $p'$, where we use $\hat{\Pr}(\cdot) = \hat{\sigma}(a')$.) Let $\tau$ be the first time, $s$ say, that $\mathcal{F}_s \leq \nu$ and let $C^\tau$ be the event that $\tau \leq t$. That is, sometime in the first $t$ periods $\mathcal{F}_s < \nu$. Then the martingale property combined with the optional stopping theorem (for example, Williams, 1991) implies

$$\frac{1 - p^0}{p^0} - \hat{\Pr}(C^\tau) E\left(\frac{1 - p^\tau}{p^\tau} \mid C^\tau\right) \equiv \hat{\Pr}(C^\tau) \frac{1 - \nu}{\nu}.$$

The above gives an upper bound on $\hat{\Pr}(C^\tau)$ that is independent of $t$. Thus it also bounds the probability that $p_t$ is ever below $\nu$:

$$\hat{\Pr}(\exists s \in \tau \mid p_t < \nu) \leq \frac{\nu}{p^0}. \quad (Right \ Balloarp)$$

Hence, the strong seller knows that it is very unlikely that the buyer's posterior will ever be close to certain she is actually the normal seller.

Finite surprises property. The strong seller might also ask how many times (as she plays $\hat{\sigma}$) the uninformed buyers will make a big mistake in predicting her strategy, that is, how
many periods does \( \| \hat{\sigma}^t - \bar{\sigma}^t \| > \nu \) occur when the seller actually plays \( \hat{\sigma} \). Here we are helped by the fact that our seller has only two actions, so the variation distance between the mixed actions is just twice the difference in probability of the realized action \( \| \hat{\sigma}^t - \bar{\sigma}^t \| = 2|\hat{\sigma}^t(a') - \bar{\sigma}^t(a')| \). Let \( M_N \) be the event that there are more than \( N \) mistakes, \( \| \hat{\sigma}^t - \bar{\sigma}^t \| > \nu \), before time \( T \). The finite surprises property is that independently of the equilibrium \( \hat{\Pr}(M_N) \to 0 \) as \( T, N \to \infty \). Thus, it is very unlikely that there are many periods in which the buyers do not think the seller will play as the strong type if the seller is indeed this type.

Jensen’s inequality applied to the likelihood ratio above implies that the prior is a submartingale, that is, \( \hat{\mathbb{E}}(p^{t+1} | h_t) \geq p^t \). There is a second property of martingales we can now use: they cannot move around very much: \( \sum_{t=1}^{T} \hat{\mathbb{E}}((p^{t+1} - p^t)^2) \leq 1 \). (A proof of this fact follows from \( \hat{\mathbb{E}}((p^{t+1} - p^t)^2) \leq \hat{\mathbb{E}}((p^{t+1})^2 - (p^t)^2) \).) A substitution from the first Bayes’ rule equality above then tells us

\[
1 \geq \sum_{t=1}^{T} \hat{\mathbb{E}}((p^{t+1} - p^t)^2).
\]

It is obvious that only a few of the (non-negative) terms in the sum above can be much above zero, otherwise the upper bound will be violated. The right ballpark property tells us it is very unlikely that \( p^t < \nu \). On the event \( \{p^t \geq \nu \text{ } \forall \text{ } t \} \cap M_N \), the \( p^t \) in the above expectation is greater than \( \nu \) and there are at least \( N \) differences that are bigger than \( \nu / 2 \), so the sum is at least \( N\nu (\nu / 2)^2 \), hence

\[
1 \geq \sum_{t=1}^{T} \hat{\mathbb{E}}((p^{t+1} - p^t)^2) \geq \hat{\Pr}(\{p^t \geq \nu \text{ } \forall \text{ } t \} \cap M_N) \frac{N\nu^3}{4}.
\]

Using the fact that \( \Pr(A \cap B) \geq \Pr(B) - \Pr(A^c) \) we now have an upper bound on \( \hat{\Pr}(M_N) \).

\[
\frac{4}{N\nu^3} + \hat{\Pr}(\exists \text{ } t \text{ such that } p_t < \nu) \geq \hat{\Pr}(M_N).
\]

The right ballpark property gives us

\[
\hat{\Pr}(M_N) \leq \frac{\nu}{p_0} + \frac{4}{N\nu^3}. \text{ (Finite Surprises)}
\]

As the size of the surprises becomes small \( \nu \to 0 \) and the number of surprises becomes large \( N\nu^3 \to \infty \), the strong seller must attach smaller and smaller probability to \( M_N \). Fudenberg and Levine (1989; 1992), for example, invoke this property.

Basic reputation results: behaviour

The three tools above are sufficient to establish most well-known reputation results. The arguments below are entirely general, and are widely applied, but we use them only in the trading game. To make things simple, suppose that for some reason the strong seller is committed to playing \((b, 1−b)\), that is, in every period \(t\) the strong buyer provides high quality with probability \(b\). We reserve the discussion of more complicated types of reputations for a later section.

From the perspective of the buyer, any equilibrium will consist of two phases: an initial phase when there is learning and signalling about the seller's type (this is sometimes called reputation building, although often reputation destruction is what occurs), and a terminal phase when the learning has virtually settled down. It is the merging property that tells us there must be this latter phase. The play in the game moves into this second phase either because the buyer is almost sure he knows the type of the seller (reputation considerations have vanished) or because the sellers are playing in the same way. Thus the equilibria of dynamic signalling games are inherently non-stationary, which is in contrast to much of the work on repeated games. Of course, Markovian equilibria can be calculated but these too will exhibit the two phases of play. The initial learning, when reputation builds or is destroyed, depends on the particular equilibrium and the game being studied. This phase may last only one period (if a once and for all revealing action is taken by a seller) but frequently it is long and has a random duration (if both types of seller randomize, for example).

Let us first examine reputation destruction in the case where \(b ≈ 1\), so the strong seller is committed to high quality and only very occasionally slips up. There is an equilibrium of this game where the normal type of seller will offer low quality more often than the strong type, and thereby gradually reveal her type (destroy her reputation for being good).

Nevertheless, as this occurs she will enjoy heightened payoffs. The trade-offs our normal seller experiences in this game are what drive the reputation destruction. A seller offering low quality today enjoys the benefit of a higher payoff now, but the observation of low quality typically leads the buyers to revise downwards their probability of the strong seller and buy less in the future, whereas a seller offering high quality will lead the buyer's posterior on the strong seller to be revised upwards and an increased likelihood of buying in the future. Exactly how the normal seller chooses to trade off long-run benefits and short-run costs is unclear. It is possible that pooling dominates and that future buying is so strong that the normal seller prefers to offer high quality even if it costs something in the short run. However, in this equilibrium the normal seller perceives the long-run benefits to be relatively small and prefers to offer low quality today. The normal seller can be thought of as exploiting, or cashing in, the value of her accumulated reputation. We also know, from the finite surprises property, that there will be finite opportunities for the normal seller to do this. Relatively soon there will come a time where the buyers know the seller is normal and purchase accordingly.

Reputation building (as opposed to destruction) is more likely in a world where there is the possibility that one is thought to be bad, for example, if the strong type is committed to ripping customers off and only occasionally produces a good product \((b ≈ 0)\). In such a world the normal seller wants to tell buyers she is not this type, because by playing as the strong type she is doomed to never trade. She is building a reputation for not being the strong type. To do this the normal type will have to incur the cost of repeatedly offering high quality, even if the buyer is not buying. This is expensive and will drag down the normal seller's equilibrium payoff. But, as above, it will increase the likelihood of future buying by decreasing the likelihood of a strong seller. In contrast to the reputation destruction case, there are short-run costs borne by the normal type to achieve long-run gains. Again, the nature of these costs and benefits rely on the buyers' uncertainty about the seller's type.

Basic reputation results: payoffs

Reputation issues can have an extreme effect on payoffs, and this is what first came to the attention of economists. The general question of how the presence of something to signal in the repeated game affects the equilibrium payoffs could be answered in a number of ways. One way would be to calculate equilibria explicitly. This is usually difficult and would not establish results that hold for all equilibria.

Instead, a different approach is taken that is described in the following recipe:

1. If the seller is strong, then in finite time the buyers will believe they face a seller who plays arbitrarily close to \((b, 1−b)\) for ever.
2. Figure out what the buyers will do when the seller is strong.
3. Use step 2 to evaluate the normal seller's payoff if she pretends to be strong for ever.
4. At a Nash equilibrium the answer to step 3 is a lower bound on the normal seller's equilibrium payoff.

Step 1 is independent of the model and is a result of our earlier calculations. The right ballpark property tells us that \(p^t\) does not tend to zero when the seller is strong. The merging property then implies either \(p^t \to 1\), or eventually all remaining normal types of buyer are also playing arbitrarily close to \((b, 1−b)\). In either of these cases, at a large but finite time the buyers believe that they face a seller who will always play \((b, 1−b)\).

Before proceeding to apply this recipe, we illustrate its power with the remarkable results we expect to get. Let us first consider a world where buyers are short run. We will show that...
introducing an arbitrarily small probability that there is a strong seller places a lower bound on the normal seller's equilibrium payoffs of $2 - b$ (when $b > 1/3$). Thus for $b$ close to $1/3$ the equilibrium payoffs in the complete information game (the segment joining (0,0) and (1,1)) and the incomplete information game are disjoint! Moreover, the normal seller can get almost his maximum feasible payoff at every equilibrium. In the second case, where buyers are also long run, we will get less strong conclusions; nevertheless, we will show that the normal type of seller must get at least $2/3 - b$ when $b > 1/3$. These payoffs are illustrated in Figure 2.

The really difficult part of our recipe is step 2, because we have to understand how the buyers will behave in equilibrium. We therefore need to consider as separate cases what happens if buyers are short run or long run. Also, the amount of discounting that the sellers do affects the answer to step 3, so we need to consider different arguments for different amounts of discounting. The following catalog moves from simple to more elaborate arguments and from stronger to weaker reputation effects.

### Reputation without discounting: short-term buyers

When a buyer lives only one period he plays a best response to the seller's current action. By step 1 in the very long run this will be $B$ if $b > 1/3$ and $N$ if $b > 1/3$. Step 3 is simple; by playing $B$ for ever the normal seller knows that in a large but finite time she can ensure the buyer will behave as above and so she will receive a stage game payoff approximately $R^*(b)$, where

$$
R^*(b) = \begin{cases} 
2 - b & b > 1/3, \\
-b & b < 1/3.
\end{cases}
$$

If there is no discounting, and limits are correctly taken, $R^*(b)$ will equal the normal type's payoff from playing $\bar{\sigma}$ for ever. Thus, at step 4, at any Nash equilibrium the normal type must get at least $R^*(b)$.

In a general game $R^*$ is equal to the seller's payoff from playing the strong type's stage game strategy when the buyer plays his or her unique best response. (If the best response is not unique this is not correct.)

### Reputation with discounting: short-term buyers

Step 2 is as above – we still have short-term buyers. When the normal seller discounts payoffs, however, playing $\hat{\sigma}$ and eventually getting $R^*(b)$ every period does not tell us what her payoff discounted to time zero will be. There is an order of limits issue; as the discounting of the seller becomes weaker ($\nu \to 1$), it could be that the equilibria change and there are more and more periods where the seller is not getting $R^*(b)$. It is now that the finite surprises property plays an important role. First notice that, when $\nu$ is chosen appropriately and $||\bar{\sigma} - \hat{\sigma}|| < \nu$, then playing a best response to $\bar{\sigma}$ is the same as playing a best response to $\hat{\sigma}$. Hence, it is only when a surprise occurs that the normal seller is not getting $R^*(b)$ from playing $\hat{\sigma}$. But the probability of more than $N$ surprises can be made very small independently of the discounting. So, as the discounting becomes weak and $N$ periods have a small effect on total discounted payoff, there is a small probability of the normal seller of getting anything less than $R^*(b)$ when she plays $\bar{\sigma}$. Any Nash equilibrium, therefore, gives the normal seller at least $R^*(b)$. This is the kind of argument first made in specific cases by Kreps and Wilson (1982) and Milgrom and Roberts (1982), and generalized in Fudenberg and Levine (1989; 1992).

### Reputation without discounting: one long-run buyer

If the buyer lives for many periods, he will not necessarily play a short-run best response to $(b, 1-b)$ even if he expects it to be played for ever. We can, however, use some weaker information. At an equilibrium the buyer must on average get at least $1/3$ (his minmax payoff) against $(b, 1-b)$. This implies that the buyer has to buy with at least probability $1/3$ when $b > 1/3$ and buy with at most probability $1/3$ when $b < 1/3$. Thus, if the buyer buys with probability greater than $1/3$, she expects to receive a payoff of at least $2/3 - b$.

If the buyer buys with at most probability $1/3$, she expects to get at least $-b$. The seller is not discounting, so what she gets in the long run from playing $\hat{\sigma}$ is also what she expects to
get at time zero. Our answer to step 3, therefore, is

\[ R^\dagger(b) = \begin{cases} \frac{2}{3} - b & b > 1/3 \\ -b & b < 1/3 \end{cases} \]

and we have a weaker lower bound on the normal type's payoff.

In an arbitrary game \( R^\dagger \) is equal to the seller's worst payoff from playing as the strong type when the buyer plays a response that gives him more than his minmax payoff. In certain cases this can be a very strong restriction – for example, if the seller has a pure strategy that minmaxed the buyer and there is a unique response for the buyer that ensured he received his minmax payoff. Certain games, known as games of conflicting interests, have the property that the best action for the seller to commit to is pure and minmaxes the buyer. \( R^\dagger \) is a very tight bound for such games.

**Reputation with discounting: one long-run buyer**

This final case combines most of the above issues. If the seller discounts the future much less than the buyer, then in the long run the seller must get \( R^\dagger(b) \) from playing \( \tilde{\sigma} \). If a normal seller pretends to be strong, the buyers think there are at most \( N \) periods when the strong strategy is not played. Imagine now we have a buyer who cares only about what happens in the next \( t' \) periods. Such a buyer can think there are at most \( t' \) \( N \) periods in which \( \tilde{\sigma} \) is not played for the next \( t' \) periods. (This kind of argument is due to Schmidt, 1993.) As the seller becomes very patient \( N \) periods become of vanishing importance and the normal seller's payoff is bounded below by \( R^\dagger(b) \). If the seller and buyer discount equally, however, reputation effects cannot be found except in some very special cases.

**Imperfect monitoring: temporary and bad reputation**

The analysis of reputation given above presupposes perfect monitoring by the buyers and sellers of each others' actions. In many dynamic and repeated games this is not likely. To what extent do the above results continue to hold when the players are not able to see exactly what their opponent did in any one period? Perhaps reputations are harder to establish if the observed behaviour is noisy? On the other hand, perhaps deviations from the strong type's action is harder to detect and so reputations last longer and are more valuable.

The merging, right ballpark and finite surprises properties all hold true under imperfect monitoring, with a suitable redefinition, provided there is enough statistical information for the buyer to eventually identify the seller's behaviour. (This is a full-rank condition on the players' signals.) As a result, the bounds on payoffs given in the previous section continue to hold.

Under imperfect monitoring with adequate statistical information there is one new behavioural feature of these games – reputation is almost always temporary, that is, the buyer will eventually get to know the seller's type. To see why this is so, let us amend the game in Figure 1 by restricting the buyer to imperfectly observe the seller's action. With probability \( 1 - \epsilon \) the buyer observes the seller's true action in the current period, but with probability \( \epsilon \) he observes the reverse action. (We must also assume the buyer does not see his own payoffs, otherwise he can deduce the seller's action from his payoff.) Consider a game where the seller always provides high quality (\( b=0 \)) and suppose that reputation is permanent in such a game. Then \( p \) would, at least some of the time, converge to a number that is not zero or one. (Remember beliefs have to converge.) The merging property tells us that, in this case where the limit of beliefs is between zero and one, the buyer will be certain the normal seller is always providing high quality. Such buyers will ignore the occasional low-quality product as just unlucky outcomes, and there will be no loss of seller reputation if the buyer ever receives low quality. The normal type of seller can, therefore, deviate from always providing high quality, gain one unit of profit, and not face any costs in terms of loss of reputation. This cannot be an equilibrium. The initial claim that reputation is permanent has to be false as a result of this contradiction. The details of this argument can be found in Cripps, Mailath and Samuelson (2004).

When the monitoring is not statistically informative, 'bad reputation', due to Ely and Valimaki (2003), is a possibility. Uninformative monitoring is a particular problem in repeated extensive form games, because players do not get to see the actions their opponent would have taken on other branches of the game tree. Bad reputation may arise in our example if the buyer could take an action (such as not to buy) that stopped the seller being able to signal her type. Then, the normal seller might find herself permanently stuck in a situation where she cannot sell. This is not particularly surprising if the buyers were strongly convinced they faced a strong seller that almost always provided low quality. However, in certain circumstances this problem is much more severe: even if the buyers were almost certain the seller were normal, every equilibrium has trade ending in a bounded and finite time. Thus, it is possible that introducing something for the seller to signal has huge negative costs for her equilibrium payoffs. To illustrate this, suppose the seller were a restaurant with
imperfect control over quality, although it does have a strategy (for example, doubling the butter and salt content!) that makes it more likely the buyer will think the meal he received is good — but is actually damaging to the buyer. When play has reached the position where just one more bad meal will lead the buyer to permanently avoid the restaurant, then the restaurant will choose to use this unhealthy strategy. Knowing this, the buyer will choose to go elsewhere for his last but one meal too, and there is an unravelling of the putative equilibrium. Buyers eat at the restaurant only if they get very few bad meals, because they know they are in for clogged arteries and high blood pressure after that. Bad reputation arises because the seller cannot resist the temptation of taking actions that are actually unfavourable to the buyer in an effort to regain his good opinion. They actually have the reverse effect of ultimately driving the buyers away.

Reputation for what?

In our discussion we consider a strong type of seller who is committed to playing a particular fixed (random) action in each period. Is this form of uncertainty the only relevant one, or are there other potential types of strong seller that may do even better for our normal seller? There are two alternatives to consider: the strong seller is committed to playing a history-dependent strategy, or the strong player is equipped with a payoff function and her strategy is determined by an equilibrium. If the seller faces a sequence of short-term buyers, then committing to a fixed stage game action is the best she could ever do, because each buyer's optimization focuses on what the seller does in the current period — the future is irrelevant. Even when the buyers are long lived, there are circumstances where committing to play a fixed action imparts a strategic advantage in repeated play, for example in most coordination or common interest games. However, there are other repeated games, such as the Prisoner's Dilemma, and dynamic games where committing to a fixed stage action is worthless. What the seller would like to do is to commit to a strategy, such as tit-for-tat, which would persuade a sufficiently patient buyer to cooperate with the strong type. Provided some rather strong conditions are satisfied, this is possible. Our recipe for reputation results will break down when we consider strong sellers with payoffs rather than actions; nevertheless, reputation results are possible. For example, if the strong seller had payoffs of 2 for high quality and zero for low quality he would be strategically identical to a seller who always provided high quality.

Many players: social reputation and other considerations

Thus far we have resolutely stuck to a model of two players, but it is clear that reputation is a pervasive social and competitive phenomenon. Here we sketch some of the issues in many-player reputation. The literature on this area is in its infancy; very little can be said with much certainty now. The easiest case to deal with is what happens as the number of uninformed players (the buyers in our example) increases. Here the benefit to the seller of building a reputation for high quality increases, as providing a good product today means the seller is more likely to trade with many buyers tomorrow. In a way, increasing the number of buyers is like making the seller more patient, and so we would expect the seller to be more inclined to build a reputation in this case. A second case would be where there are very large numbers of informed buyers trying to acquire reputations for individual or group characteristics. Models of career concerns are similar to reputation models and have many workers trying to acquire reputations for individual characteristics. Also, there are models of group reputation, such as Tirole (1996), where a particular class of individuals behaves in a particular way to perpetuate the 'group's' reputation. In both these types of model the large numbers assumption allows one individual's reputation decision to be treated as virtually independent of others. Thus they can be analysed using quite simple tools. A final case is where a few informed agents are in competition or collusion with each other. Collusion in team reputation obviously introduces a public goods issue. If one player contributes to the good name of the group, he or she does not get to enjoy the full benefits of the contribution. Typically, therefore, reputations for such teams are harder to establish. One might conjecture that competition appears to drive a player towards excessive investment in reputation, but there are many effects at work that we do not completely understand. For example, competitors may also act to undermine their rival's reputation and to interfere with its development. This is a fertile region for applied and theoretical investigations.

How to cite this article

Resale markets seem necessary to correct misallocations of assets, where misallocations may be the result of mistakes in initial purchasing decisions, or more generally of changes in the state of the economy. For the sake of illustration, a car owner may after a while find it desirable to buy a new car, and he may be willing to resell his old car on the second-hand market. A manager of a firm holding a Universal Mobile Telephone System (UMTS) licence may be willing to resell her licence to another firm if she realizes that the firm is unable to cover its cost (generated by the licence acquisition). A homeowner may need to resell his house if he has to move to another country or jurisdiction.

A question of primary interest is whether such resale markets are good for the economy. Or, to put it differently, whether, when and how should such resale markets be regulated? This article starts with the laissez-faire viewpoint on this issue; it then proceeds to show how asymmetric information and commitment issues mitigate that viewpoint.
The laissez-faire viewpoint

The classical neoliberal viewpoint as represented by the Chicago School would favour laissez-faire. Within the present context, this would imply that resale markets should not be regulated. The premise of this line of thought is that resale markets give the right flexibility so that assets can be allocated to the right agents at any point in time. This view has important consequences for the theory of mechanism and market design. Indeed, it implies that the initial allocation of property rights is irrelevant, as resale markets should be able to correct any misallocations (this is one version of the so-called Coase Theorem – Coase, 1960). Thus, according to this view, a government interested in maximizing economic efficiency should worry neither about the method of privatization nor about how to allocate licences for operating public services. It should simply allow for well-functioning resale markets.

Of course, very few economists truly believe that real resale markets can achieve such a fantastic job of always allocating assets to the right agents at the right time. On the academic side, Akerlof (1970) provides an early theoretical example of market failure in the context of the market for used cars (more on this below). Coase himself argues that transaction costs which are numerous are likely to invalidate the above angelic view about resale markets. On the ‘real world’ side, it seems implausible that the method of privatization or the allocation of licences for the use of public services is irrelevant for economic efficiency. In fact, recent years have seen a rapid growth of auction methods to allocate licences or privatize publicly owned firms, suggesting an interest on the part of practitioners in market design. It is worth pointing out that, in the case of licence auctions, most governments have chosen not to allow for resale markets, suggesting some distrust towards their functioning.

In the tradition of Coase, the words ‘transaction costs’ will be interpreted to mean any reason why inefficiencies may arise in transactions. Of course, some of the reasons need not be related to the intuitive notion of transaction costs, and one could alternatively use the more neutral terminology of ‘market imperfections’. The rest of this article will review how theoretical insights from the mechanism design literature and the bargaining literature help identify significant sources of transaction costs. The review will abstract from transferability issues, which is a legitimate idealization for transactions that are not too big for the financial capabilities of the parties. The theoretical insights will then be used to shed some light on whether and how to regulate resale markets.

The role of private information

It is relatively intuitive to see why private information may be a source of inefficiency in transactions. A seller who privately knows her valuation for the object for sale has an incentive to pretend that she values the object more than she really does, in the hope that this will lead the buyer to increase his purchasing price. Similarly, a buyer has an incentive to pretend that he values the good less than he really does, in the hope that he will obtain a lower selling price. But such distortions inevitably induce inefficiencies whenever the gains of trade are not large enough. This intuition has been formalized in the work of Myerson and Satterthwaite (1983), who show that, if the distributions of valuations are independently distributed between a seller and a buyer, and if it is not known who values the good more, inefficiencies must arise in any bargaining game in which no outside money is given to the bargaining parties. One of the strengths of Myerson and Satterthwaite's work is that it applies to any bargaining
game, including protocols in which a broker could help improve the bargaining outcome and protocols allowing for several stages of bargaining. The result is obtained by relying on the so-called revelation principle, which allows for the derivation of constraints that should be satisfied in any Nash–Bayes equilibrium of any game (whether static or dynamic): these constraints are the so-called incentive constraints – an agent with valuation $\nu$ should find his own strategy no worse than the strategy of the same agent with valuation $\nu'$ – and the participation constraints – an agent should get at least what he could get by staying outside the game. Myerson and Satterthwaite then proceed to show that these constraints together with the constraint that the bargaining parties receive no outside money cannot be simultaneously satisfied unless there are inefficiencies (see Milgrom, 2004, for an exposition of this and other impossibility results).

The above buyer–seller set-up assumes that agents know how valuable the good is to them. This is referred to as a ‘private values set-up’. Akerlof (1970) identifies another source of bargaining inefficiency in set-ups in which the value to the buyer is a function of the information held by the seller – this is sometimes called an informational externality and referred to as an ‘interdependent values set-up’. For example, a seller of a used car may know the quality of his or her car, and the quality of the car obviously affects the valuation of both the seller and the buyer. In an elegant example, in which the buyer is known to value the good $\alpha$ times as much as the seller with $2 > \alpha > 1$ and the quality (identified here with the valuation of the seller) is distributed uniformly on $[0,1]$, Akerlof shows that there can be no trade. The no-trade result arises because a selling price of $p$ would be acceptable to the seller only if the quality is below $p$, resulting in an average quality of $p/2$. But such an average quality does not justify buying the good at price $p$ for the buyer, as $\alpha p / 2 - p < 0$. One of the beauties in Akerlof's example is that it illustrates that, even in situations in which it is common knowledge that the buyer values the good more than the seller, there is no trade in equilibrium. Even though Akerlof restricts his analysis to special trading mechanisms, the inefficiency he identifies can be shown to arise in any equilibrium of any bargaining game, with the use of the same mechanism design techniques as those of Myerson and Satterthwaite. It also extends (even though not in the extreme form of no trade) to other classes of problems with interdependent values (see Samuelson, 1984).

In the above bargaining set-ups, a specific form of property rights was assumed. Within the same examples, other efficiency conclusions would arise with alternative property right structures, thereby illustrating how the initial allocation of property rights may affect efficiency in the presence of informational asymmetries. Obviously, in Akerlof's interdependent values example, if the person valuing the good more is initially the owner of the good there is no inefficiency, which thereby offers a simple illustration of this idea. (See Jehiel and Pauzner, 2006, for further elaboration.) In the private values situation considered by Myerson and Satterthwaite, if the two parties are ex ante symmetric and initially own 50 per cent shares of the object, a double auction (in which the party quoting the highest price would buy the 50 per cent shares of the other party at a selling price in between the two quoted prices) would result in an efficient allocation of property rights. Cramton, Gibbons and Klemperer (1987) generalize the latter insight by showing that mixed ownership is economically superior in partnership dissolution problems with private values.

The above bargaining inefficiencies implicitly assume that no outside money can be introduced on to the bargaining table. Otherwise, with large enough subsidies, efficiency could be obtained in the above bargaining set-ups, thereby suggesting that an appropriate public intervention may eliminate the...
inefficiency due to asymmetric information. However, in interdependent values situations in which agents hold multidimensional signals that are independently distributed across agents, Jehiel and Moldovanu (2001) show that the sole incentive constraints make it generically impossible to achieve the first-best allocation no matter how much money is introduced on to the bargaining table. This result is especially relevant in transactions involving several items because then private information is naturally multidimensional. The result then implies that no public intervention can eliminate the bargaining inefficiencies. (A similar conclusion arises even with one-dimensional private information if the single crossing condition is violated; see Maskin, 1992.)

The above results assume that there is no correlation in the private information held by the various agents. Whenever there are correlations, incentive constraints are less severe because the report made by agent i can be used to deter misreports by agent j. The works of Crémer and McLean (1985; 1988) and Johnson, Pratt and Zeckhauser (1990) (see also Myerson, 1981) suggest that inefficiencies can be totally eliminated even under moderate correlations if agents are risk neutral and transfers can be arbitrarily large. However, limited liability and risk aversion (which seem plausible, especially if very large transfers are involved) ensure that the qualitative insights obtained for the case without correlation continue to hold with moderate correlation (see Robert, 1991). Hence, inefficiencies due to asymmetric information continue to hold even in the correlated case, as long as correlation is not too large. (See also Compte and Jehiel, 2006, who argue within Myerson and Satterthwaite's private values set-up that inefficiencies may arise even with large correlation whenever agents have the option to leave the bargaining table at any time, thereby obtaining their reservation utility.)

As already mentioned, the above inefficiencies hold even if multiple stages of bargaining are allowed, as long as the only inferences of the players come from the equilibrium play of the other parties and not from the release of new hard information (either in an exogenous manner or through endogenous information acquisition). If new information becomes available, the situation is different. Obviously, if the private information held by the various agents become public at some stage, then at this stage bargaining parties with full commitment abilities should be able to implement an efficient agreement. This is because, if inefficiencies were to arise at that stage, a party could propose a Pareto improvement with no further move, keeping the generated surplus for herself: this can be viewed as an application of the Coase Theorem. But, even if one adopts the view that eventually private information becomes publicly available, a critical issue is about how long this takes. If it takes very long, inefficiencies are still likely to be significant because the transitory phase is long. If it does not take long and full commitments are possible, efficiency can be expected.

The role of commitment

The above reported results assume full commitment abilities on the part of the bargaining parties. Another major source of inefficiencies is the limited commitment abilities of the agents. From the viewpoint of mechanism design, the relaxation of commitment abilities of the proposing party (sometimes called Principal) is generally thought of as a bad thing. But one should be cautious here about the criterion used to assess what ‘good’ or ‘bad’ means. Clearly, from the viewpoint of the Principal limited commitment ability is a bad thing because it puts additional constraints on the Principal's maximization exercise. However, from the viewpoint of society (as measured by social...
resale markets: The New Palgrave Dictionary of Economics

welfare), the conclusion is far from clear. For example, Coase's conjecture suggests that a monopolist with no commitment ability may end up pricing his good efficiently if consumers are forward-looking (they anticipate the distribution of future prices correctly) and patient enough. In a similar vein, the commitment ability of an auctioneer may allow him to use inefficient reserve prices, which he might be unable to exploit under weaker commitment scenarios. (See McAfee and Vincent, 1997, for a formal approach, and Zheng, 2002, for an optimal auction model in which, even though the seller can commit not to lower his reservation price if there is no interested buyer, buyers can resell the object if they wish.) Clearly, more work is required to understand the pros and the cons of commitment from a mechanism design perspective with non-benevolent principals.

In a number of transactions, the transacting parties impose a cost or benefit on third parties: think of the sale of pollution rights or the sale of technologies through patents in imperfectly competitive markets. From the viewpoint of the transaction, this corresponds to an externality in the sense that the trade between a subset of agents affects the payoffs of other agents (see Jehiel, Moldovanu and Stacchetti, 1996). Abstracting from informational asymmetries, Jehiel and Moldovanu (1999) in a one-object environment and Gomes and Jehiel (2005) in a general multi-object environment study resale markets in such set-ups with allocative externalities. They establish that the lack of commitment ability may induce long-run inefficiencies in resale markets whenever there are allocative externalities and agents are patient and forward-looking. Furthermore, if we take as given the legal constraints governing how goods can be exchanged, the initial allocation of property rights is shown to have no effect on the long-run properties of the equilibrium pattern of sales in such markets, as long as parties are forward-looking and patient enough. Thus, in such a complete information world, the lack of commitment ability induces inefficiencies in the presence of allocative externalities and at the same time makes it irrelevant how the initial property rights are allocated.

Practical implications

What are the lessons to be drawn from these theoretical observations? What do these results imply for the desirability of resale markets?

A first category of problems concerns those situations in which private information is persistent. Then the above inefficiency results show that in most scenarios, no matter how exchanges are organized, no matter whether or not resales are permitted, and no matter how well resale markets work, inefficiencies are inevitable. In interdependent value situations with multidimensional signals, even subsidies may not be enough to eliminate the inefficiencies.

Full commitments including controls over resales would seem desirable from a mechanism design viewpoint, as long as the proposing parties seek to maximize total welfare. However, with non-benevolent agents there is no reason in general to expect the full commitment scenario to be preferable to weaker commitment scenarios whenever private information is persistent.

A second category of problems concerns those situations with vanishing private information that will be identified with complete information. Then resale markets permit an efficient allocation of goods whenever agents care solely about their own allocation (that is, when there are no externalities). However, when there are allocative externalities in the sense that the allocation of agent \( i \) directly influences the well-being of agent \( j \), resale markets do not allow parties with limited commitment...
abilities to reach an efficient state of the economy. Yet, even when there are allocative externalities, the efficiency of the economy is unaffected by the initial allocation of property rights, suggesting that in such situations the only role for government interventions is through the legal framework, not the allocation of property rights. For example, it may be desirable from this perspective to require by law that the transacting parties compensate those agents suffering from the transaction.

In complete information situations, it would seem that full commitments including controls over resales should improve efficiency. However, that view ignores the reality of a changing environment, which is one of the basic rationales for the existence of resale markets. Because the economy is changing, resale markets are necessary. The complete contracting scenario implicitly assumed by the full commitment idea is impractical in that it might involve agents that are not even present in the economy (think of a future homeowner who may not yet be born and whose future possession already exists). From a practical viewpoint, the main issue is about understanding the effect of the legal framework that governs resale markets on the overall efficiency of the economy. Some insights about how the legal framework might improve the economic performance of resale markets have been suggested above (see the idea of compensating those agents who suffer from the transaction). Admittedly, more work on both the theoretical and empirical sides is required to understand this as well as the additional effect of persistent private information on resale markets.

monopolist when demands are interdependent. *Econometrica* 53, 345–62.

A research joint venture (RJV) is an agreement between two or more partners to perform research and development (R&D). RJVs provide a mechanism to bridge the divide between the optimal public R&D policy – free dissemination of knowledge – and private incentives to invest in R&D – appropriation of returns to investments. Three important issues related to appropriation of returns to R&D condition the private incentives to form a RJV: coordination of R&D investments between RJV partners, free-riding inside and outside the RJV, and information sharing between RJV partners.

Article
A research joint venture (RJV) is an agreement between two or more partners to perform research and development (R&D), where each partner has an active role in the generation of new knowledge and technology. As such, a RJV is distinct from the ex ante or ex post agreement to acquire knowledge or technology as in R&D contracting or the licensing of technology respectively. Many times RJV and R&D cooperation are used as synonyms in the literature.

Two features distinguish R&D from ordinary capital investments. First, R&D is a public good (Arrow, 1962). The use by one firm of the information produced by its R&D investments does not diminish the amount of information available to other firms. Second, and related to its public good nature, R&D investment is plagued by an externality problem. Firms investing in R&D typically cannot fully
appropriate the returns to their own R&D investments. This tends to reduce the incentive to invest in R&D when firms act non-cooperatively (Spence, 1984; d'Aspremont and Jacquemin, 1988). Both of these characteristics of R&D investments have a profound impact on the optimal way of organizing R&D, as they affect the incentives to invest in R&D. From a welfare perspective the optimal economy-wide organization would involve the free distribution of the knowledge produced by these R&D investments. However, such a policy would provide little incentive for private investment in R&D in the first place. RJVs provide a mechanism to bridge this divide between public policy and private incentive.

Incentives to form RJVs

Given the public-good nature of R&D, firms do have an incentive to jointly develop technology and share the costs and risk of these projects. Mariti and Smiley (1983) provide evidence for the importance of cost and risk-sharing for the success of R&D cooperation. Developing new technology from scratch implies incurring a high (fixed) cost. Transferring and sharing knowledge that is already developed has a low (marginal) cost. Therefore, firms with complementary products (Röller, Tombak and Siebert, 1997) or complementary knowledge (Sakakibara, 1997) have an incentive to form RJVs to share knowledge for the development of new products. Furthermore, from a transaction costs perspective R&D collaboration allows access to specialized and complementary know-how, while at the same time allowing for a transfer of technology at lower transaction costs than with arm's length arrangements. As a result the total cost of developing new knowledge through a RJV is reduced (Pisano, 1990; Oxley, 1997).

While knowledge transfer and cost sharing provide the most common and trivial incentive for the formation of RJVs, the industrial organization literature emphasizes competitive motives for engaging in R&D cooperation and RJVs. R&D is imperfectly appropriable and R&D results, therefore, leak out involuntarily to rival firms. These models concentrate on horizontal R&D cooperation among rival companies as a mechanism to internalize these spillovers. The R&D process is represented as a two-stage, non-tournament model where in a first stage firms make R&D investments that (strategically) affect second-stage output market decisions through either a cost-reducing or a demand-enhancing effect. Firms can cooperate – form an RJV – in the R&D stage, but may continue to compete in the product market (for example, Katz, 1986; d'Aspremont and Jacquemin, 1988; Kamien, Müller and Zang, 1992; Suzumura, 1992; Leahy and Neary, 1997). From this literature we discern three important issues conditioning the interrelation between the profitability of RJVs and spillovers: coordination, free-riding and information sharing.

Coordination

Cooperation in these models is typically industry-wide and takes the form of firms coordinating R&D choices in order to maximize joint profits. As a result investment in R&D in an RJV is increasing in the level of the spillover as the firms internalize the positive effect these spillovers have on their partners. In addition, when spillovers are high enough – that is, above a critical level – coordination in R&D will result in higher R&D investment than in non-coordinating firms. At the critical spillover level, the
profitability of cooperative and non-cooperative R&D strategies coincides. (When goods are substitutes, the level of product differentiation and the number of rivals are important parameters that determine the critical spillover level; de Bondt, Slaets and Cassiman, 1992.)

Coordination through joint profit maximization without incurring any explicit costs to R&D cooperation increases the firms' profitability in these models. But, more importantly, spillovers increase the profitability of cooperation in R&D. Furthermore, for spillovers above the critical level, firms have an increasing incentive to engage in R&D coordination (De Bondt and Veugelers, 1991). This means that, when spillovers are high enough, firms have an increasing incentive to engage in R&D coordination. Such cooperation would furthermore enhance welfare as R&D investment and market output increase.

F reeriding

Most models focus on the welfare and profitability of R&D cooperation, ignoring the stability of such cooperation. The stability of RJVs can be threatened by free riding of non-participating companies on the output of the venture, or by free riding by partners who may conceal their technological expertise while trying to absorb as much as possible of the partner's knowledge (Shapiro and Willig, 1990). Kesteloot and Veugelers (1994) find that cooperative agreements that are profitable, and at the same time also stable, require involuntary – outgoing – spillover levels that are not too high. (Using a repeated game, cheating can be prevented by grim-trigger strategies specifying an eternal dissolution of an industry-wide venture. An alternative approach to solve the internal stability problem is through the organizational design of the venture. Perez-Castrillo and Sandonis, 1996, characterize incentive compatible and individually rational contracts that lead to disclosure of knowledge and, hence, the formation of profitable research joint ventures.) Hence, although higher spillover levels increase the profits from cooperation through coordination, they also increase the profits from cheating by a partner and from free riding by an outsider to the cooperative agreement. Therefore, cooperative ventures become more profitable the more able firms are to restrict outgoing spillovers by protecting their information while selectively sharing information with partners.

I nformation sharing

Some models take into account the fact that firms can indeed manage spillovers by voluntarily increasing the spillovers among cooperating partners. Such information sharing is found to further increase the profitability of cooperation in R&D. In addition, information sharing not only increases the profitability of R&D cooperation; it also makes such agreements more stable. Eaton and Eswaran (1997) show that, when technology trading cartels are not necessarily industry-wide, information sharing is an even stronger stabilizing force. In this case a much stronger punishment can be specified, namely, the ejection of the cheating firm from a technology-trading coalition, followed by the continuation of information sharing by the non-cheating members. Similarly, De Bondt and Wu (1997) find that information sharing produces larger coalition sizes that are both internally and externally stable. Katsoulacos and Ulph (1998) explicitly model the choice of spillovers by cooperating and non-cooperating firms, and find that RJVs will always share at least as much information as non-cooperating firms because the former maximize joint profits. When firms act non-cooperatively, however, one would
expect that the aim is to minimize the creation of spillovers – the outgoing spillovers – through the use of effective legal and strategic protection measures while at the same time to maximize the incoming spillovers. Kamien and Zang (2000) show that firms that coordinate their R&D expenditures maximize information flows – their incoming spillovers – through the choice of very broad research directions for the RJV. If the firms cannot coordinate their R&D expenditures, they are more concerned about managing their outgoing spillovers by choosing a more narrow research approach. This result emphasizes a potential dual role of spillovers: outgoing spillovers which might jeopardize the cooperative agreement, and incoming spillovers which increase the attractiveness of the cooperative agreement. In an empirical paper Cassiman and Veugelers (2002) indeed show that incoming spillovers and appropriability have important and separately identifiable effects: firms with higher incoming spillovers and better appropriation have a higher probability of cooperating in R&D.

RJVs and social welfare

When firms are allowed to form RJVs, R&D investments increase with the level of spillovers, exceeding the non-cooperative investment level when the spillovers are substantial (d’Aspremont and Jacquemin, 1988). Competing firms that cooperate in R&D might thus increase not only profits but also welfare when the spillovers are substantial. Policywise, a case can then be made for allowing RJVs to form when spillovers are high. However, when spillovers are low firms acting non-cooperatively with respect to R&D bring about higher welfare than when allowed to form an RJV (Suzumura, 1992). The only effect of a RJV in this case is to reduce R&D competition, which in turn decreases welfare (Katz, 1986). (It has often been suggested that RJVs might also facilitate collusion in the output market. A necessary condition for a RJV to be welfare improving in this case is that total R&D investments increase. Martin, 1997, analyses the increased potential for tacit collusion in RJVs, while Yi, 1995, looks at the welfare effects of product market collusion by an industry-wide RJV. Greenlee and Cassiman, 1999, discuss the effects of collusion in the output market on RJV formation.) This theoretical finding has fuelled the debate on the issue of relaxing antitrust regulation with respect to RJVs. In evaluating cooperative R&D, regulators often use the same ‘rule of reason’ as in the case of mergers. Given the dynamic nature of R&D, insensitive application of static merger guidelines may lead to undesirable outcomes (Ordover and Willig, 1985). Appropriate standards for evaluating RJVs should be developed. Jorde and Teece (1990) propose the creation of an administrative procedure for evaluating and possibly certifying cooperative R&D agreements in order to establish a safe harbour from antitrust litigation. But Shapiro and Willig (1990) argue that this would provide too much protection to RJVs, especially because the regulator needs a great deal of information to evaluate a RJV, and much of this information might be proprietary. Policymakers have attempted to address these issues. In the USA firms can register their RJVs under the National Cooperative Research Act (NCRA). By registering under the NCRA, firms become exempt from treble damages under antitrust regulation. However, cooperative R&D ventures need not register under the NCRA. In that case, they are liable under the usual antitrust regulation. Scott (1988) actually notes that cooperative research registered under the NCRA predominantly falls into industries without severe appropriability problems, while supposedly welfare-enhancing RJVs do not seem to register, leading to a suspicion of adverse selection of RJVs under the NCRA (Cassiman, 2000).
In Europe the 1986 Single European Act amendments to the Treaty of Rome gave the Community specific responsibility for strengthening ‘the scientific and technological basis of European industry’. In addition to the EEC block exemption of Article 85(1) of the EC treaty for cooperative ventures in R&D, a variety of programmes were initiated, many of which explicitly fostered inter-firm cooperation tied to Community funding for part of the R&D costs of the proposed projects (Martin, 1996). Nevertheless, the debate on the exact implementation of these policies is still ongoing and has initiated a broader debate on the interaction between innovation policy and competition policy.

Conclusion

While the industrial organization models of RJVs have focused on imperfect appropriation among competitors, several areas for research on RJVs remain thoroughly unexplored. First, empirical work has indicated that most RJVs are formed with customers, suppliers or research organizations rather than with competitors. Recent empirical work has started to tackle the issue of different types of partners for the RJVs, but little theoretical work has followed (Fritsch and Lukas, 2001; Belderbos, Carree and Lokshin, 2004; Veugelers and Cassiman, 2005).

Second, and related, we still know very little about the actual effect of engaging in RJVs on firm (innovation) performance. Brandstetter and Sakakibara (1998) find some evidence of the formation of RJVs on research productivity, and Belderbos, Carree and Lokshin (2004) show that cooperation in R&D leads firms to generate more sales from products that are new to the market. But most empirical studies interpret R&D cooperation as an indirect indication of RJV’s profitability. To really uncover the incentives to engage in RJVs, we need to understand how RJVs improve the innovation performance of firms relative to alternative organizational forms.

Finally, little progress has been made yet in understanding the organization of RJVs from a theory of the firm perspective. Why would firms make joint investments in R&D and share property rights and decision rights over the outcome of future research outcomes? When is this efficient or when does it enhance the competitiveness of firms?

The simplest example of a reservation price is that price below which an owner will refuse to sell a particular object in an auction. Since the owner could always, in principle, enforce such a price by outbidding everyone else, this leads immediately to the more general concept of a reservation price as that price at which the owner of a fixed stock will choose to retain some given amount from that stock, rather than supply more, and of the amount retained as the owner's 'reservation demand' at the price in question. Considering alternative hypothetical prices, one sees that the owner's supply curve of the commodity can equally well be described as an 'own (reservation) demand' curve, where 'supply' and 'own demand' sum identically to the given stock. The same is naturally true of the market supply curve. Thus consider the standard example of the determination of the price of first-edition copies of a certain old book. A demand curve may be drawn up for those who at present own no copies. Taking account of each present owner's reservation price (or prices for those who possess more than one copy), we may also draw up a supply curve. (Of course ‘supply’ by present owners may be negative at low prices.) Confrontation of the demand and supply curves will then show the market-clearing price. Equally, however, we could have drawn up the ‘reservation demand’ curve of present owners, summed it with the demand curve of non-owners and then confronted the ‘total’ demand curve with the given stock. Since ‘supply’ and ‘reservation demand’ sum identically to total stock, at every price, the alternative diagram inevitably shows the same market-clearing price as does the first; it does not show the number of books traded, however.

It will be clear that an agent's reservation price for any type of commodity can be expected to depend on one or more of the following considerations: the scope for direct 'own use' of the commodity; the agent's present need for liquidity; the agent's other resources; the perishability of the commodity and thus the various elements of storage costs (including interest costs); expectations about future prices,
there being always a speculative element in the reservation price of any commodity which is not immediately perishable. These considerations all emerge in theories of ‘factor supply’, for example in the theory of household labour supply. Since ‘labour time’ is instantly perishable, there is no strictly speculative element to take into account (although someone seeking work may refuse a particular job offer because the wage offered is below a ‘reservation wage’ based on expectations as to the wage that can be obtained after further job searching). The conventional theory is, however, firmly based on viewing labour supply in terms of the ‘reservation demand’ for time not spent in market employment, and it is this that leads to the familiar argument that the income effect of a ‘wage’ change can both be large and contrary to the substitution effect, with the result that labour supply may be either positively or negatively related to the level of the ‘wage’. Analogous arguments bear on the supply of land services by landowners who have an ‘own use’ for their land, on the supply of agricultural products, and so on. The reservation price concept is also useful in the context of privately owned natural resources, a context which introduces two further determinants of reservation price. The lowest price at which a natural resource owner will be prepared to extract the resource will naturally depend on extraction costs, both the present extraction costs and those expected in the future; it will also depend on the expected growth rate, if any, of the resource. It is to be noted that the ‘neoclassical rule of free goods’ would never have to be applied to primary inputs for which (a) there was a positive price below which supply would be zero, and (b) demand at a zero price would be positive (both conditions holding for all prices of other commodities).

It was noted above, in connection with the market for first-edition copies of a book, that the ‘total’ demand curve diagram gives the same information with respect to price, and less information with respect to quantity, than does the more conventional supply and demand diagram. How then could P.H. Wicksteed – whose name is so strongly associated with the concept of a supply curve being merely a ‘reversed demand curve’ – have been so insistent that the former diagram is actually superior to the conventional one? (See Wicksteed, 1910, Book II, Ch. IV, and 1914.) Because the ‘total’ demand curve diagram emphasizes the idea that essentially the same kind of forces underlie the conventional supply curve as underlie the usual demand curve, thus breaking down the idea that there is an asymmetry in market forces, with subjective factors being dominant on the ‘demand side’ and objective ones on the ‘supply side’. The diagram in which a single demand curve (inclusive of reservation demand) confronts a fixed supply is at once congenial to any author both seeking to stress the subjective elements of the economic process and upholding the opportunity cost doctrine as against the real cost doctrine. While acknowledging that the demand and supply curves diagram illuminates the process through which the market clearing price is discovered, therefore, Wicksteed insisted that the other diagram brings out far more clearly the fundamental determinants of that price, namely, subjective marginal valuations and given supplies. With reference to continuously produced commodities, as opposed to first-edition copies, maintenance of this viewpoint would presumably require that the ‘given stocks’ referred to should be those of primary inputs. Here it may be noted that, even in the course of denouncing the conventional supply curve, Wicksteed admitted that ‘as we recede from the market and deal with long periods … cases may arise in which something like a “supply curve” seems legitimate’ and that nature does not have ‘reserve prices in which she expresses her own demand!’ (1914, p. 16, n.1).

Residential real estate is a major asset for most households. This article focuses on three issues relating to housing as an investment. (a) Are returns to housing investment predictable? (b) What is the optimal fraction of real estate in an investment portfolio? (c) How important are borrowing constraints, and how do they influence housing prices? It concludes that housing risks are difficult to hedge in practice and that developing suitable derivative markets would fulfil an important function.

Article

Residential real estate is in any definition a major asset class. The average Swedish household invests three-quarters of its net wealth in its own home. Yet it was not until after 1990 that central questions in finance were asked about real estate. Is the market for real estate informationally efficient? What is the optimal fraction of real estate in a household portfolio? What role do financial constraints play in the pricing of real estate? These are particularly challenging questions in view of the special nature of residential real estate assets: properties are heterogeneous, transactions are infrequent, the trading parties are typically amateurs, and the market is best characterized as a search market where identical properties may trade at quite different prices. For all these reasons the data problems are of a different order of magnitude from those in the core areas of finance. Naturally, progress has been slow and we should not expect answers ever to be as sharp as for assets like stocks and bonds.

This article is organized around the questions posed above. Other areas, in particular the important field of mortgages and mortgage-backed securities, are not discussed.
Market efficiency

Standard theories of portfolio choice and asset pricing presume that markets are informationally efficient in the sense that it is impossible to make profits from trading strategies based on publicly available information, such as past returns. There is ample evidence indicating that real estate markets are not efficient in this sense. Time series studies of real estate returns typically find a strong pattern of positive autocorrelation on quarterly or yearly data (Case and Shiller, 1989; Englund and Ioannides, 1996). Such a pattern could in principle reflect time-varying risk premia, but this interpretation appears implausible. A problem with most studies of housing returns is that they measure only the time variation in the capital-gains part of returns and ignore the value of housing services (the implicit rent). An exception is Meese and Wallace (1994), which is based on micro evidence on unregulated rents. They confirm, for the San Francisco Bay Area, that returns on owner-occupied homes are indeed predictable based on past returns, but they also show that the profits involved are not sufficient to cover realistic transaction costs for a round-trip trade. There is no money to be made by shifting between renting and owning, with housing consumption fixed, but it may be profitable to time moves according to predicted returns. A general conclusion is that transaction costs in a broad sense are important in understanding real estate markets.

Portfolio choice

Research on portfolio choice has been hampered by a lack of reliable high-frequency data. Much recent research has been stimulated by the repeat-sales indexes for US metropolitan areas developed and analysed by Case and Shiller (1989). Goetzmann (1993) uses the Case–Shiller indexes to compute optimal portfolios (efficient frontiers) in mean-variance space, taking into account the idiosyncratic component of housing return, that is, the added risk of an individual home above the general return risk captured by a price index. He finds optimum housing shares to be on the order of 10–50 per cent of household net wealth depending on risk attitudes. It is well known from portfolio analysis of other assets that calculated portfolio shares are quite sensitive to input data, particularly expected return, and hence should be treated with caution. Nevertheless, later studies using data for European countries (using hedonic indexes not available in the United States) have obtained similar results (see, for example, Englund, Hwang and Quigley, 2002, for Stockholm; le Blanc and Lagarenne, 2004, for Paris; and Iacoviello and Ortalo-Magné, 2004, for London). The discrepancy between computed optimal portfolio shares and real world numbers, often in the order of several hundred per cent, is striking and has provided a challenge for further research. The standard mean-variance analysis is obviously oversimplified in several ways. First, it is static. Grossman and Laroque (1990) consider lifetime portfolio choice when utility is derived from a durable good (housing), which can only be traded at a cost (proportional to house value). Housing trades are determined in analogy with Ss-models from inventory theory, and optimal portfolios are shown to be mean-variance efficient like in the static case. Second, the standard analysis does not account for housing services as a consumption good separate from non-durable goods. Flavin and Yamashita (2002) analyse a two-good version of the Grossman and Laroque model with a stochastic relative price of housing. Based on correlations calculated from Case–
Shiller indexes, their model indicates that the optimal fraction of financial assets going into stocks is inversely related to the fraction invested in housing, and hence should increase with age, consistent with empirical observations. More recently some authors have analysed models with finite lifetimes, using numerical solution techniques. A key factor in determining the attractiveness of investing in housing is the correlation between labour income and the returns to housing: the stronger the correlation, the smaller is the optimal housing portfolio share.

Third, we have so far assumed housing to be consumed by owning, disregarding the alternative of renting. The issue of tenure choice is a classic one in the housing literature; see Henderson and Ioannides (1983) for a two-period model that brings out some of the basic features. Only rarely have issues of risk been included in the analysis. Among the exceptions are Rosen, Rosen and Holtz-Eakin (1984) and Turner (2003), who find that volatile house prices deter young households from entering into owner-occupancy. These studies do not explicitly measure the relative risks of owning compared with renting. More recently, Sinai and Souleles (2005) have emphasized that owning one's home is a way of hedging the risk associated with stochastic variations in the cost of renting. This is a particularly important aspect for households with a long expected stay in the same dwelling or the same housing market. Empirically, Sinai and Souleles confirm, for US households, that the probability of homeownership is indeed an increasing function of rent risk.

For most households, net wealth falls far short of the value of the house they demand for consumption purposes. Hence, any portfolio study that includes housing has to take a stand on the availability of borrowing. In fact, most households are constrained in their access to borrowing, at least when young, and financial constraints exert an important influence on savings and housing choices over the life cycle; see King (1980) for an early study emphasizing borrowing constraints. Integrating down-payment constraints into models of dynamic portfolio and tenure choice remains an important topic for future study.

Asset pricing and financing constraints

The standard approach to real estate price determination (as in Poterba, 1984) is explicitly couched in asset pricing terms: the price is the discounted value of the housing services generated by the property net of operating and maintenance costs. In principle, housing services could be valued based on market rents for comparable dwellings. In applying this approach, lip service is often paid to risk-adjusting the discount rate. It is fair to say, however, that there is no established theory or pragmatic consensus on the choice of discount rate. In recent years there has been a surge of interest in integrating housing into the standard asset-pricing paradigm. So far, however, interest has focused on the impact on financial asset prices of introducing housing collateral rather than on pricing real estate assets.

More attention has been paid to the direct impact of financial constraints on pricing. If the representative homebuyer is constrained by borrowing opportunities rather than by lifetime resources, then wealth shocks have a direct impact on housing demand. This implies that a shock to the demand and supply of housing services will be reinforced through its impact on financing constraints. An income shock, for example, will increase demand and housing prices, thereby releasing borrowing constraints. This will in turn give an extra boost to demand and prices. There will be a ‘financial multiplier’: the more important financial constraints are, the more sensitive prices will be to shocks to underlying fundamentals. This
view of real estate pricing was formulated by Stein (1995) and has been inserted into an overlapping-generations framework with demographic fluctuations by Ortalo-Magné and Rady (2006). Its empirical validity has been investigated in some studies. As an example, Lamont and Stein (1999) show that variations in the sensitivity of house prices to income shocks across US states can be explained by differences in loan-to-value ratios. Financial constraints may also explain the strong impact of variations in house prices on consumption observed in many studies; see, for example, Case, Quigley and Shiller (2005) for the United States and internationally.

Historically, mortgage lending has been further restricted by regulations in virtually all countries. Dismantling these regulations has in many cases caused price booms. But borrowing constraints remain important facts of life even in unregulated market environments, and there are large differences across countries even today, reflecting history and legal institutions. Chiuri and Jappelli (2003) show that average downpayment ratios vary from close to 50 per cent in Italy to a little above 10 per cent in Sweden and United Kingdom. They find that these differences, which they largely ascribe to legal tradition – relating to foreclosure, for example – explain differences in homeownership rates across countries, in particular the age when young households enter into owner occupancy.

The future

Not only has the area of real estate economics been lagging in its adoption of new analytical frameworks from finance, markets have also been slow in adopting new financial instruments and contracts to handle better the important risks many household confront in relation to their housing investment. While households have access to a wide variety of mortgage instruments, markets remain seriously incomplete and fail to offer flexible and liquid contracts related to housing price risks. As Robert Shiller (2003) has forcefully argued, this is one of the macro risks in society that remain uninsurable despite their fundamental importance for individual welfare. Options or futures on relevant housing price indexes could go a long way towards providing such insurance. It remains to be seen how long it will take to develop liquid markets in such instruments.

residential segregation

Jacob L. Vigdor
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Housing market equilibria display residential segregation when there are systematic disparities in the physical location of households belonging to different racial, ethnic, socio-economic, or other social groups. Historically, segregation has often been enforced through non-market processes such as legal restrictions. Modern segregation, by contrast, is largely driven by cross-group differences in willingness to pay for housing in group enclaves. Segregation often generates social concern, particularly when the segregated group is of low socio-economic status. Empirical studies, including a few based on randomized mobility experiments, suggest that there are negative consequences of growing up in an enclave neighbourhood.

Article

The term ‘residential segregation’ describes a housing market equilibrium marked by systematic disparities in the physical location of households belonging to different racial, ethnic, socio-economic, or other social groups. While history is replete with examples of groups forced to live in complete isolation from the remainder of society, residential segregation is not inherently a dichotomous phenomenon. Rather, housing markets may exhibit varying degrees of segregation; social scientists have endeavoured to quantify this variation for the better part of a century. The term ‘ghetto’ is often ascribed to social groups experiencing segregation that exceeds a loosely defined threshold.

Residential segregation may be the outcome of a past residential sorting process wherein centralized authorities restricted some agents' location choices. Very simple economic theory, and an increasing amount of empirical evidence, however, point to the conclusion that modern-day residential segregation is driven primarily by the operation of decentralized market forces.

Even if residential segregation is a pure market phenomenon, many observers harbour concerns that segregated housing market equilibria are suboptimal from a social welfare perspective. Some debate exists as to whether segregated housing markets are inefficient. Arguments hinge on whether households are fully informed at the time they make location decisions, or whether they face borrowing constraints. It is a less controversial observation that residential segregation has important implications for distributional equity. In segregated equilibria, for example, wealthy households have the opportunity to avoid subsidizing the local public good consumption of poorer households. Over the past several decades, there have been many attempts to estimate the relationship between residential segregation and inequality between groups, in both the short term and the long term.

Here, basic evidence is provided on the existence and magnitude of contemporary residential segregation. This evidence draws heavily on the experience of racial and immigrant groups in the United States; the measurement of segregation in other nations is limited in scope and often confined to very recent observations. As discussed below, this is more a reflection of data limitations than any genuine lack of interest. The basic economic theory of why segregation exists is then outlined, and empirical evidence that has been brought to bear on the issue discussed. The concluding discussion considers the potential implications of segregation on socio-economic outcomes and human capital investment.
Measuring segregation

There are many ways to measure segregation (Massey and Denton, 1988). The metrics most commonly used in sociology and economics require the existence of neighbourhood-level data on the distribution of groups in a city or region. Some measures, including the spectral segregation index (Echenique and Fryer, 2005), require additional data on the physical location of these neighbourhoods and, in some cases, their land area. A central challenge to the systematic measurement of segregation is the lack of comparable neighbourhood-level data across nations, or even cities within nations, and over time. The United States, for example, has collected data on the race of its inhabitants since 1790, but did not report race at a consistently defined neighbourhood level until 1940. The United Kingdom did not systematically collect information on the ethnic identity of its inhabitants until the 1991 Census.

Given the existence of required data, the most commonly used segregation indices classify the residential separation of any particular group between two extremes: perfect segregation, where group members never share a neighbourhood with individuals not belonging to the group, and perfect integration, where group members form an equal share of the population in all neighbourhoods. The dissimilarity index (Duncan and Duncan, 1955), records groups on the scale from 0 (perfectly integrated) to 1 (perfectly segregated) using the following formula:

\[
D = \frac{1}{2} \sum_{i} \left| \frac{A_i}{A} - \frac{B_i}{B} \right|
\]

where \(i\) indexes neighborhoods, \(A_i\) and \(B_i\) represent the number of group members and others in neighborhood \(i\), respectively, and \(A\) and \(B\) represent the total population of group members and others in the city or region. The dissimilarity index has a relatively intuitive interpretation: it is the share of group members, or others, who would have to switch neighbourhoods in order to achieve perfect integration. While many demographers state a preference for other indices based on various criteria, the dissimilarity index is most commonly used in existing literature.

Stylized facts

The absence of neighbourhood-level data makes it difficult to gauge the contemporary level of segregation in many cities, let alone historical levels. The most comprehensive historical data pertain to American cities. Cutler, Glaeser and Vigdor (1999; 2005) use these data to compute long-term trends in dissimilarity for African-Americans and foreign-born individuals, respectively. Figure 1 plots weighted averages of these measures across cities, with weights equal to the population of the group in question in each city. Immigrant segregation is computed separately for each country-of-origin group in each city; the immigrant time series represents the weighted average of these data.

Figure 1
Dissimilarity of African-Americans and immigrants in the United States, 1890–2000
As the relatively low initial levels of black–white dissimilarity indicate, urban ghetto neighbourhoods were relatively uncommon in the United States at the turn of the 20th century. The birth of the African-American ghetto coincided with the so-called Great Migration of blacks from the southern part of the United States to northern cities between the First World War and 1965. Segregation reached its peak at the end of this period of migration. In 1970 dissimilarity levels in some areas, chiefly large industrial cities of the north-eastern and mid-western United States, were at or near 0.90. Since that time, segregation has fallen pervasively throughout the nation but most acutely in rapidly growing cities in the southern and western parts of the country.

Immigrant segregation, quite strikingly, displays the opposite trend to racial segregation in the United States. Immigrant dissimilarity remained stable at relatively low levels through the first half of the century, then rose steadily. Thus, even as racial ghettos have declined over the past few decades, immigrant segregation has risen. Cutler, Glaeser and Vigdor (2005) present further data indicating that the rise in average segregation can be attributed primarily to the growth of groups that have always experienced high segregation, rather than to the increasing segregation of individual groups. The growing, highly segregated groups generally originate in less developed countries and gravitate toward the largest cities in the United States. The limited amount of data available from other nations supports the general trend found in the United States: individual racial and ethnic group are experiencing
stable or declining segregation in most parts of the world.
Socio-economic segregation, or the degree to which households in poverty tend to cluster together in neighbourhoods, increased in the United States in the 1970s and 1980s, but showed some evidence of lessening in the 1990s.
Table 1 presents some representative dissimilarity index values for groups in some of the world's largest cities, using recently available data.

Why are groups segregated?

Theories of racial segregation can be classified into two types. The first type permits some form of discrimination in housing markets. The second models segregation as the equilibrium outcome of a fully competitive market. A potential third class of models explains one form of segregation as the direct consequence of a second form – for example, it explains racial segregation as a consequence of economic segregation. This third class is of less interest to attempts to explain segregation more generally.

In a discrimination-based model, location choices are constrained for members of one group, defined by race, ethnicity, or other observable characteristic. The constraints on location choice might include explicit legal barriers or implicit patterns of ‘steering’ households towards certain locations. Historical examples of explicit legal barriers abound. In a few cases, governments have attempted to restrict location choices as a matter of public law, have enforced contracts between private parties restricting racial ownership or occupancy of property, or have adopted policies that had the effect of limiting the residential options of certain groups. In the United States, federal legislation had made most explicit forms of housing market discrimination illegal by the end of the 1960s.

While few observers would argue that explicit racial or ethnic barriers to location choice persist in the developed world, the existence and prevalence of implicit discriminatory patterns is a subject of continuing debate. Government policies such as zoning laws, which local governments use to regulate the density and nature of residential development within their borders, may implicitly perpetuate segregation. Housing audit studies provide evidence of discriminatory behaviour among real estate agents, mortgage brokers, or landlords. In these studies, auditors of different races present carefully matched, fictionalized credentials to housing market agents. The behaviour of these agents is then analysed to uncover any systematic differences in treatment by race. Recent studies, such as Ondrich, Ross and Yinger (2003), find evidence of significant racial disparities in treatment in the United States.

While disparities in treatment of housing market auditors can be interpreted as evidence of continued racism, such behaviour can also be consistent with unbiased, profit-maximizing motives. As in models of statistical discrimination in labour markets or other settings, agent behaviour could be motivated by accurate perceptions of differences in average preferences across racial groups.
residential segregation: The New Palgrave Dictionary of Economics

Such an interpretation is consistent with the second type of racial segregation theory, which posits that segregated housing market equilibria are fully consistent with decentralized, unconstrained household choices. Preference-based theories of segregation owe some intellectual debt to Tiebout's (1956) vision of residential sorting, but evolve most clearly from Schelling's (1978) simulation of residential sorting in the presence of very slight preferences for neighbours of one's own group. Schelling's simulations show that a small initial concentration of same-group neighbours can rapidly evolve into a vast enclave community. This process of ‘tipping’ is driven by group members' heightened willingness to pay for locations in close proximity to the initial cluster. As the enclave grows in size, it becomes disproportionately more attractive to group members than to others. So long as the segregated group in question maintains a steady population share in the entire market, the enclave is very unlikely to dissipate.

Much anecdotal evidence supports the Schelling model. The neighbourhood integration that has taken place in the United States since 1970, for example, has left most African-American enclaves untouched. Rather, integration has occurred either in newly developed neighbourhoods on the fringe of urban areas or in locations marked by significant demolition and redevelopment.

While intuitively appealing and supported by anecdotal observation, true empirical tests of preference-based theories are rendered difficult by the unobservability of household preferences. Econometric models associated with the measurement of willingness to pay, such as discrete choice models, often assume away the existence of housing market discrimination (for example, Bayer, McMillan and Rueben, 2004). Survey-based methods of eliciting preferences are valid only to the extent that respondents can accurately separate their valuation of neighbourhood racial composition from all other attributes, and truthfully reveal this valuation. What survey evidence that exists supports the notion that groups harbour preferences for same-group neighbours (Vigdor, 2003).

Why might individuals care about the racial or ethnic composition of their neighbourhoods? Group members may prefer to congregate in enclaves in order to take advantage of scale economies enabling the supply of group-specific community institutions or consumer goods. Individuals may also seek to limit exposure to other groups on the basis of stereotyped perceptions of inferiority, greater criminality, or other characteristics. It is also possible that individuals care, not about the race of their neighbors directly, but about characteristics correlated with race, such as socio-economic status. These varying hypotheses have dramatically different implications for the social value of segregation. Unfortunately, these various explanations are observationally equivalent. Each predicts that segregation occurs in equilibrium because willingness to pay for housing in a group enclave is relatively higher among group members.

While there is currently no consensus on the importance of housing market discrimination in perpetuating segregation, Cutler, Glaeser and Vigdor (1999) present evidence that any such importance has declined. In 1940, at a time when many forms of housing market discrimination were legal – and in some cases practised by government itself – restrictions on African-American location choice had the impact of increasing equilibrium prices in segregated areas. By 1970 that premium had disappeared, suggesting that these artificial barriers to mobility had been removed.

**Does segregation influence economic outcomes?**

A number of hypothesized causal mechanisms link segregation to socio-economic outcomes. The ‘spatial mismatch’ hypothesis contends that segregation reduces the average income of certain groups to the extent that their residential enclaves are located at some distance from growing employment centres (Kain, 1968). Segregation may also lead to differences in education quality across racial or ethnic groups, to the extent that schooling is tied to residential location. Finally, there may be other localized factors that differ across neighbourhoods and have the net impact of leading to different human capital investment trajectories. For example, children growing up in different neighbourhoods may develop different consumption or investment preferences by being exposed to different types of role models.

Numerous attempts have been made to empirically estimate the impact of segregation on outcomes, whether operating immediately through spatial mismatch-type mechanisms or developmentally. Much of this empirical literature is plagued by a fundamental endogeneity problem: since individuals choose their own neighbourhoods, any correlation between neighbourhood characteristics and individual outcomes might reflect selection rather than any causal effect of the former on the latter. Researchers have implemented three strategies for circumventing these selection problems. The first is to focus on the outcomes of young adults, whose location choices are presumably determined by their parents rather than themselves. Vigdor (2002) points out that the strategy of studying young adults is suspect in the presence of inter-generational transmission of economic outcomes. A second basic strategy for identifying the impact of segregation on outcomes in the presence of selective migration is to model location choice and socio-economic outcomes simultaneously. Some research in this vein makes use of individual data-sets with detailed geographic identification, recently made available by the US Census Bureau. A simultaneous equation model can uncover the true causal impact of segregation on outcomes if it employs an instrumental variable – a factor that affects location choice but otherwise bears no correlation to individual outcomes. In practice, identifying a valid instrumental variable is very difficult.

Recently, researchers have addressed selective migration concerns by turning their attention to randomized mobility experiments, in which a ‘treatment’ group is offered a voucher redeemable for housing only in certain neighbourhoods, while a ‘control’ group is offered no such aid. While these experiments generally do not permit examination of the causal impact of segregation per se, they do allow a more general study of the potential importance of neighbourhood characteristics in determining outcomes. In general, studies find little impact of neighbourhood factors on the socio-economic outcomes of adults. There is more evidence in favour of developmental impacts on youth. Orr et al. (2003) present an overview of research results stemming from one such randomized mobility experiment, the Moving to Opportunity demonstration programme.

Reswitching of technique is the property whereby, when multiple production techniques are available in a wage–profit economy, the same technique may be optimal at different levels of the rate of interest. This means that a virtual movement of the rate of interest in a given direction might make it rational to use techniques that had been previously excluded, so that the rate of interest cannot provide an unambiguous ranking of techniques. This possibility is rooted in the complex interactions (movements of relative prices) that occur in a production economy with different proportions between labour and intermediate inputs.

Keywords

capital deepening; capital intensity; factor-price frontiers; intermediate products; recurrence of technique; reswitching of technique; technical choice

Article

Reswitching of technique refers to the virtual adoption of production techniques, either by the individual producer or by the economic system as a whole. Standard economic theory treats technical adoption on the assumption that there is a multiplicity of techniques for producing any given good, and that the producer, as a rational decision maker, will switch from one technique to another according to a certain hypothetical sequence as the prices of productive factors are changed. This sequence would depend on the ranking of techniques in terms of capital per man or ‘capital intensity’, so that a lower rate of interest (which is equal to the rate of profit in equilibrium) would be associated with the ‘adoption’ of a technique characterized by higher capital per man. This process is known as capital deepening.

The development of discrete production models in the 1950s led to the discovery that this view of ‘rational’ technical adoption is not necessarily well founded. David Champernowne (1953) and Joan Robinson (1956) pointed out that a movement of the rate of interest in a given direction might make it optimal once again to use techniques that had been previously excluded. This phenomenon is known as reswitching of technique.

The original discovery was associated with the belief that reswitching was nothing more than a ‘curiosum’, which could not be left out on grounds of pure logic but was nevertheless unlikely to happen. The discussion of this phenomenon by Piero Sraffa (1960) showed that reswitching is the normal outcome of a situation in which the various production processes are characterized by different proportions between ‘direct’ labour and the quantity of ‘past’ labour. (This latter is the quantity of labour that is indirectly required in a production process, being required in producing its intermediate inputs.) Sraffa’s analysis also provides a clear insight into the reasons for technical reswitching along the hypothetical sequence associated with changes in the rate of profit. It is worthwhile considering his example in some detail.

The pure products’ case

It is useful to start with the consideration of a special category of commodities, which we might call of the pure product type. These are commodities that are never used as productive inputs, so that their price reflects production cost, but cost is never influenced by the variation of their particular prices.

Let a and b be commodities of that type, and let them be produced with different proportions of direct labour to past labour. (This structure of labour requirements is representative of
the differences in the proportions between labour and intermediate inputs in the production processes of the two commodities.)

Let \( a \) require more labour than \( b \) if we consider labour applied eight years before the year in which the product is ready, whereas \( b \) requires more labour than \( a \) in the cases of labour applied in the current year and 25 years earlier. This situation may be represented as follows (\( n \) is the date at which labour is applied):

\[
\begin{align*}
\text{n} & = 8 \\
\text{l}_a(8) & = \nu + 20 \\
\text{(i)} & \\
\text{n} & = 0 \\
\text{l}_a(0) & = x \\
\text{n} & = 25 \\
\text{l}_a(25) & = \nu \\
\text{2. (ii)} & \\
\text{n} & = 0 \\
\text{l}_b(0) & = x + 19 \\
\text{n} & = 25 \\
\text{l}_b(25) & = \nu + 1 \\
\text{3. (iii)} & \\
\end{align*}
\]

We are now in a position to examine in which way the cost difference between the two products may vary if the rate of profit is raised from 0 to a maximum value of 25 per cent. (An increase of the rate of profit is equivalent to a change in the weight of the different labour terms in each cost equation.)

The cost difference is expressed by the following equation:

\[
\rho_a - \rho_b = 20w(1 + r)^8 - \left[19w + w(1 + r)^{25}\right].
\]

(1)

On the assumption that the wage rate \( w \) is inversely related to the rate of profit according to the following expression:

\[
w = 1 - \frac{r}{25\%},
\]

the cost difference equation will be represented by the curve in Figure 1.

Figure 1
The cost of \( a \) rises relatively to \( b \) as \( r \) increases between zero and nine per cent. The reason for this is that the change of \( r \) leaves the value of current labour unaffected, whereas the 'excess labour' of date 8 is much greater than the excess labour of date 25. The increase in the value of \( I_{lb(25)} \) is more than offset by the increase in the value of \( I_{la(8)} \) and the compound effect of these two variations is an increase in the cost difference. Beyond \( r = 22\% \), since at this particular level of the rate of profit the decline of the wage rate starts offsetting the increase in the value of remote labour terms due to a higher \( r \).

The above argument has straightforward implications for technical choice in the case of commodities of the pure product type. For in this case we can take for granted that the price of each commodity reflects its cost of production, whereas this price has no influence at all on the cost. Under such conditions, eq. (1) permits us to examine in which way the relative profitability of two techniques is varied as \( r \) goes from 0 to \( r \) (max). In fact, we may take eq. (1) to illustrate the difference between the unit costs of production of the same commodity produced with two alternative techniques. (For reasons of symmetry with the previous argument we call such alternative techniques \( a \) and \( b \) respectively.) Figure 1 can be
applied to this particular case. An immediate shortcoming would be that a change in the price of direct to ‘dated’ labour, as reflected in an increasing \( r \), is associated with a positive excess of unit cost \( p_a \) over unit cost \( p_b \) until the curve intersects the horizontal axis for the first time. This involves that, over this interval, technique \( b \) is more profitable than technique \( a \). A further increase of \( r \) (until \( r(\text{max}) \)) is associated with a negative difference \((p_b - p_a)\), so that technique \( a \) is more profitable than technique \( b \). However, the same figure shows that the reduction of the cost difference stops at \( r = 22\% \). For any \( r \) such that \( 22\% < r < r(\text{max}) \), the cost difference is increasing once again. This increase stops at \( r = 25\% \) when techniques \( a \) and \( b \) become equally profitable.

The movement of the cost difference when \( r \) is increasing shows that the relative profitability of techniques \( a \) and \( b \) is subject to fluctuations which depend on the particular interval within which \( r \) is changed. The relative profitability of technique \( a \) with respect to technique \( b \) is initially decreasing, then increasing, finally decreasing again. These fluctuations show that the ‘unevenness’ of the input structure may bring about multiple switches between the two techniques as we consider a steadily increasing \( r \): the same technique might be adopted at low and high rates of profit, with the alternative technique being adopted at intermediate levels of \( r \).

The ‘intermediate products’ case

It might appear that the above picture gets greatly complicated when we consider the more general case of products that are used as productive inputs either of themselves or of other commodities. For in this new situation the price of a commodity reflects its production cost, but this cost might itself be influenced by that price. (Directly in the case of a product used in its own production, indirectly in the case of a product that is, at some stage, a necessary means of production for at least one of its inputs.) An immediate consequence of the consideration of interdependence between production processes is that inspection of the cost difference equation is no longer sufficient in order to assess the relative profitability of alternative techniques. The mutual influence between prices and production costs brings about the need of comparing systems of interrelated techniques (production technologies) rather than individual techniques. This requires consideration of the price system that will be associated with each technology at any given distribution of income between wages and profits.

The analysis of the ‘intermediate products’ case can be carried out by examining a simple model with two alternative two-good technologies A and B, in which all products are used as inputs of themselves and of the other commodity. We shall also assume that the two technologies differ only in the technique used to produce commodity 1.

The two price systems may be written as follows:

\[
(a_{11}p_1 + a_{21}p_2)(1 + r) + l_1(a)w = p_1
\]

\[
(a_{12}p_1 + a_{22}p_2)(1 + r) + l_2(a)w = p_2,
\]

\[
(b_{11}p_1 + b_{21}p_2)(1 + r) + l_1(b)w = p_1
\]

\[
(b_{12}p_1 + b_{22}p_2)(1 + r) + l_2(b)w = p_2,
\]
where \( a_{ij} \) and \( b_{ij} \) are the quantities of commodity \( i \) required to produce one unit of commodity \( j \) with technologies A and B respectively, \( l_i(a) \) and \( l_i(b) \) are the quantities of labour entering one unit of commodity \( i \) with technologies A and B respectively, \( p_i \) is the price of product \( i \), \( w \) is the unit wage and \( r \) the rate of profit. The quantities \( a_{ij}, b_{ij}, l_i(a) \) and \( l_i(b) \) are known, whereas \( r, w, p_i \) are unknown.

Either product is common to both systems. We may thus choose either commodity 1 or 2 as the common standard of prices (numéraire) in both systems. If we put the price of commodity 1 equal to unity, commodity 1 becomes the common numéraire of price systems (2.1) and (2.2). At this stage, it is found convenient to assess the relative profitability of alternative technologies by considering the functional relationship between \( r \) and \( w \) for each technology.

The systems of eqs. (2.1) and (2.2) would each be associated with a particular relation between the rate of profit and the unit wage. The wage–profit relationships for the two systems would respectively be given by the following expressions:

\[
\begin{align*}
W_A &= \frac{1 - (a_{22} + a_{11})(1 + r) + (a_{11}a_{22} - a_{21}a_{12})(1 + r)^2}{(1 + r)[a_{22}l_2(a) - a_{21}l_1(a)] + l_1(a)} \\
W_B &= \frac{1 - (b_{22} + b_{11})(1 + r) + (b_{11}b_{22} - b_{21}b_{12})(1 + r)^2}{(1 + r)[b_{22}l_2(b) - b_{21}l_1(b)] + l_1(b)}
\end{align*}
\]

It may be immediately noted that \( w \) is always a decreasing function of \( r \), independently of the sign of the second order derivative (see also Morishima, 1966, p. 521). We may also note that the unit wage is expressed in terms of the same numéraire in (3.1) and (3.2). This suggests that the relationships between \( r \) and \( w \) (also known as factor-price frontiers) can be plotted as negatively sloped curves on the same diagram.

The intersections between the two curves occur at those levels of the rate of profit which are associated with the same unit wage in both technologies. The number of intersections can be obtained by equating \( w \) in eqs. (3.1) and (3.2) and solving for \( r \). The resulting equation will generally have more than one positive solution (Bruno, Burmeister and Sheshinski, 1966, p. 534). In the case of technologies such that each product is a necessary input for all commodities including itself (all products are basic commodities), the maximum number of intersections is given by the number of distinct commodities in the two alternative systems of production (Bharadwaj, 1970). This implies that, in the two-good technologies of our example, there will be at most two intersections. Figure 2 represents a case in which there are two intersections in the positive quadrant.
Technologies A and B can now be compared, on grounds of profitability, by considering which technology yields the higher rate of profit for any given wage. (Or, alternatively, which technology yields the higher wage rate for any given rate of profit.) Figure 2 makes clear that the relative profitability of the two technologies is subject to fluctuation as \( r \) increases from 0 to \( r^*(B) \) (the maximum rate of profit with technology B). At a low level of the rate of profit \( (r < r_1) \), technology A is more profitable (‘cheaper’) than B. At \( r = r_1 = r_2 \), A and B are equally profitable. At levels of \( r \) between \( r_1 \) and \( r_2 \), B is more profitable than A. But at any rate of profit higher than \( r_2 \), A is again more profitable than B.
Reswitching of technique may be shown to be possible between complete production systems as well as between individual techniques. Shortly after the identification of the reswitching possibility by Champernowne (1953) and Robinson (1956), and its subsequent analysis by Sraffa (1960), Morishima (1964) and Hicks (1965), David Levhari (1966) proposed the argument that reswitching between production systems is possible only in the case of a ‘reducible’ or ‘decomposable’ technology matrix, so that reswitching would not occur with technologies producing only basic commodities (‘irreducible’ or ‘indecomposable’ technologies). Levhari’s argument was disproved by Pasinetti and others (Pasinetti, 1966; Morishima, 1966; Garegnani, 1966). It was also acknowledged to be false by Levhari and Samuelson (Levhari and Samuelson, 1966; Samuelson, 1966). Conditions excluding reswitching were then discovered by Bruno, Burmeister and Sheshinski (1966) and other authors (Starrett, 1969). Their outstanding feature is the introduction of technological assumptions that eliminate those ‘complicated patterns of price-movement with several ups and downs’ (Sraffa, 1960, p. 37) on which the very possibility of reswitching is founded. As shown above, the possibility of reswitching in the comparison between alternative states of the economy is associated with differences in the proportions between labour and intermediate inputs for any given pair of production techniques. This implies that reswitching can be observed only if the economic system is represented in such a way as to bring in view the ‘ups and downs’ of relative prices. This property was implicitly recognized by John Hicks (1973), when he noted that the possibility of reswitching arises when techniques are ‘no longer capable of being distinguished by a single parameter’, so that any switch along the technological frontier ‘will be a matter of balance between advantages and disadvantages, a balance which itself is affected by prices’ (Hicks, 1973, pp. 44–5). This consideration is at the basis of Hicks’s ‘simple profile’, in which any given technique is described by a single parameter (the ratio of construction labour to utilization labour) and reswitching is excluded (Hicks, 1973, pp. 44–6). Joseph Stiglitz took a different view when he distinguished between reswitching as a possibility relative to the comparison among steady states, and ‘recurrence of techniques’ as an outcome for an economy ‘on its optimal development trajectory’ (Stiglitz, 1973, p. 138). In particular, Stiglitz noted that ‘recurrence of techniques may occur in technologies which do not allow reswitching’, and that ‘in technologies in which there is reswitching there may be no recurrences’ (Stiglitz, 1973, p. 139). John Wright (1975, p. 22) examined a related issue showing that reswitching can be avoided if one assumes an appropriate ‘rate of fall of discount rate through time’. A few years later, Edwin Burmeister and Peter Hammond (1977) explored a related issue, and suggested that reswitching can be excluded as soon as we allow economies to ‘jump’ over intermediate states (techniques) along a given optimal adjustment path. Recent literature has examined the likelihood of reswitching from the computational or the empirical point of view. In particular, Stefano Zambelli (2004) has shown that a discrete production model is significantly likely to (computationally) generate a reswitching economy, whereas Zonghie Han and Bertram Schefold (2006) have found the empirical likelihood of reswitching to be significant but not very high. Another strand of literature investigated the relationship between the possibility of reswitching and the stability of optimal paths. In this connection, John Barkley Rosser further explored the problem set-up examined in Burmeister and Hammond (1977) and noted the existence of a trade off between the observability of reswitching and the smoothness of optimal adjustment paths (Rosser, 1983; 2000). More recently, Michael Mandler (2005) and Bertram Schefold (2005) have discussed alternative conditions under which reswitching may or may not be associated with unstable economic dynamics.

Synthesis and appraisal

The capital controversy of the 1960s has conclusively shown that the logical possibility of reswitching is of a general nature. Disagreement about the implications of reswitching for economic theory as a whole does not conceal the fact that a crucial discovery in the theory of technical choice was made. In particular it was shown that choice of technique is related to income distribution in a much more complex way than it was once thought to be, and that the rate of interest (or the rate of profit) cannot provide an unambiguous ranking of different technical alternatives as the distribution of income is varied. The discussion of reswitching called attention to a paradox that had long been overlooked. This is that rational choice, in its classical formulation, presupposes not only agents capable to rank alternatives in a consistent way, but also objective states of the world making such a consistent ranking feasible (see Urmson, 1950, pp. 154–9; Scazzieri, 1982). The reswitching debate has shown that a ‘granular’ representation of production techniques leads to a complex pattern of interaction such that any given technique may be associated with two or more different positions on the profitability ranking of techniques (see above). This discovery was made possible by the consideration of price movements in a capital-using economy (see above). Its most immediate implication has been to cast doubt upon the representation of capital structure in terms of simple aggregate parables. However, reswitching also called attention to another, perhaps more fundamental, feature of technical choice. This is the dual nature of the grading procedure associated with choice. For grading situations express not only the agent’s ability to rank states of the world in a consistent way, but also the possibility to rank those states in terms of ‘objective’ characteristics independent of the agent’s preferences and choices. The reswitching debate has proved that the latter prerequisite may be a will-o’-the-wisp as soon as we consider the complex interactions that take place in a production economy.

The common-sense definition of retirement is leaving employment of a substantial nature by a worker in his or her fifties, sixties or older with no intention of returning to work. However, this definition has no empirical counterpart because we do not observe intentions in the data. Rather, empirical work typically measures retirement in one of two ways. First, a worker is said to retire when he or she leaves the labour force in his or her fifties or older for a ‘considerable’ period of time. The ‘considerable’ period may be limited by the length of the observation period in panel data, but it is meant to distinguish retirement from normal job change by workers in their fifties or sixties. The second definition is an affirmation by the worker that he is retired. This definition aims to address right-censoring in panel data by using the individual’s own assessment of retirement status. Because many workers state that they are retired after they have left a career job yet continue to work, this definition often adds the requirement of departure from the labour force. Which definition should be preferred will depend on the empirical analysis and the objective of the research. For some research questions, the definition can make a substantial difference, for example in the study of ‘unretirement’. In this article I think of retirement as the transition from being in the labour force to not being in the labour force by people in their fifties or older.

Historical trends in labour force participation

In 1957 the labour force participation rate of men aged 60–64 in the United States was about 83 per cent; by 1987 it had fallen to 55 per cent, and since then has risen to about 58 per cent. The participation rate of women aged 60–64 rose over this time period because of the historical increase in the participation rate of women of younger ages: an increasing rate of retirement by older women was offset by an increasing number of women reaching age 60 and still in the labour force. Although the levels and rates of decline are somewhat different, participation rates of older men fell sharply in nine European countries and Canada. What caused these very large declines? In the United States and in many European countries the generosity of the public pension system increased sharply in the late 1960s and 1970s. For example, a good measure of the generosity of the system in the United States is the monthly Social Security benefit for men were they to retire at age 65. The average of those Social Security benefits was $307 in 1957 and $649 in 1987 (both in 1987 dollars).
for an annual growth rate of 2.5 per cent. Since 1987 the real growth rate has been just 1.1 per cent and that growth has been due to wage growth, not to changes in the programme rules which have been stable. The coincidence of the decline in labour force participation with the increase in Social Security benefits suggests that Social Security was at least partly responsible for the decline, but there were changes in other determinants of labour supply as well. The private pension system expanded, and real household income increased both because of a rise in earnings and an increase in dual earner households. One objective of research on retirement has been to quantify the contributions of these and other sources to the decline in labour force participation, to predict the future course of labour force participation of the older population, and to understand the response to policy change such as alterations in the structure and generosity of Social Security.

The leading edge of the baby-boom generation will begin to retire in substantial numbers in about 2008, leading to a worsening of the financial health of the Social Security and Medicare systems in the United States. For example, the ratio of the population 65 or over to the working age population (ages 20–64) is a commonly used measure of demographic aging. In 2000 this ratio was 0.21; it is forecast to increase to 0.36 by 2030, an increase of 72 per cent. The retirement of the baby-boom generation will affect the Social Security and Medicare trust funds, requiring adjustments to those programmes. What will be the effect of those changes on retirement? In particular could policy delay retirement without unduly harming workers while improving fiscal balance? To make a good assessment of the effects of policy requires a model of retirement behaviour.

Data

Since the 1970s the most important advance in our ability to study retirement behaviour has been the development of the Health and Retirement Study (HRS). The HRS is a longitudinal data collection on about 20,000 people aged 51 or over in the United States. The HRS was fielded in 1992 with the express purpose of providing data with which to study retirement and health, and their interactions. As such it contains data on all the relevant economic variables that affect retirement, many health variables and many other non-economic variables that have additional effects. The HRS is a biennial longitudinal survey, and as of 2006 it had fielded eight waves. The original cohort was initially 51–61, so that by wave 8 it was 65–75 and had mostly retired. New cohorts aged 51–61 were added in 1998 and in 2004, and they were re-interviewed in successive waves. Based on the success of the HRS, the English Longitudinal Study of Ageing was modelled on HRS and was fielded in England in 2002. It is also a biennial panel. The Survey of Health, Ageing and Retirement in Europe was fielded in 2004 in 11 European countries, and a second wave with an expanded roster of countries followed in 2006. It is modelled on the HRS and ELSA with the aim of providing data that will permit international comparative studies.

Economic models of retirement

Retirement is an aspect of labour supply, and so the same general framework applies. However, in a number of ways it is easier to study retirement than hours worked: most of the retirement incentives are well measured; typically (although not always) retirement can be freely chosen whereas the choice of hours may be constrained by the demands of employers. As a consequence the response of retirement to incentives is substantial whereas the response of hours to the wage rate, at least among males, is small. Although some models of retirement are very complex, many of the ideas can be illustrated with a simplified version of a retirement model which, nonetheless, incorporates most of the important aspects of economic model of retirement.

Retirement must be placed in a life-cycle context because the gain from additional work is an addition to lifetime economic resources, and its value depends on life expectancy. Consider a worker who will live another N years and who is contemplating whether to retire. Should he work another year he would lose a year of leisure which has utility of U and which initially I assume is constant no matter what the age of the worker. He would gain a year's income which he could add to his stock of wealth. The increase in utility from the income is V = wage: the marginal utility of wealth multiplied by the annual wage. To maximize utility the worker should not work when \( U > V \times wage \). Under the universal assumption that the marginal utility of consumption declines in consumption, \( V \) will be smaller at older ages with wealth held constant: at older ages the fixed amount of wealth would have to be consumed over fewer years so that per period consumption would be greater than at younger ages. Greater consumption would cause the marginal utility of consumption to be lower and therefore the marginal utility of wealth to be lower. At some age \( V \) declines enough that \( V \times wage < U \), and at that age the worker would leave the labour force.

In a complete life-cycle model, consumption and, therefore, saving would be chosen by the worker as well as retirement. Yet we would like to think of a ‘wealth’ effect on retirement. Variation in wealth across workers and the accompanying variation in retirement ages can be generated by variation in wages to which the worker reacts both in the choice of consumption and the retirement age. In this example, wealth is endogenous; but we might think of some variation in wealth that is exogenous to the model. Examples would be variation in initial wealth or through inheritances, variation in rates of return on assets or variation in required expenditures during the working life such as the number of children. Having in mind some exogenous variation in wealth across individuals, I will speak of a ‘wealth effect’ on retirement, but it should be understood that its estimation is difficult because it is endogenous in a complete life-cycle model of retirement behaviour.

These ideas are illustrated in a model of retirement choice. In this model the worker's problem is to choose the retirement age \( R \) and consumption level \( c \) to maximize lifetime utility
where $c$ is consumption which is assumed to be constant. (In this model with fixed lifespan, consumption will be constant if the interest rate and the subjective time rate of discount are the same.) $L$ is baseline utility from leisure and $U$ is the additional utility from leisure that someone gets when retired. The lifetime budget constraint is $N = R$ where $w$ is the fixed wage. A corner solution is possible when someone places little value on leisure: he will work his entire life. But in the more usual case of retirement before age $N$, the solution satisfies the lifetime budget constraint and the first-order condition

$$u'(t) = u' \frac{w}{w}$$

where $u'$ is marginal utility. Then some manipulation will show that $\frac{dR}{dU} < 0$, and $\frac{dc}{dU} < 0$: an increased value of leisure in retirement will reduce the retirement age and the budget constraint will require a reduction in consumption. Also, $\frac{dR}{dN} > 0$: increases in life expectancy will increase the retirement age. Because those in good health have greater life expectancy, healthy people will work longer, independent of any health effect on productivity or on the disutility of work.

An increase in the wage will increase consumption: $\frac{dc}{dw} > 0$. The effect of $w$ on $R$ is indeterminate because of the income and substitution effects whose relative magnitudes depend on the utility function. For example, if utility is constant relative risk aversion so that $u'(t) = C^{-\gamma}$, then $\frac{dR}{dw} > 0$ if $\gamma < 1$ and $\frac{dR}{dw} < 0$ if $\gamma > 1$.

In the context of this model and other models that allow consumption to be chosen, wealth will be an object of choice. We can observe co-variation in wealth and $R$ across individuals due to variation in $w$, but that co-variation will not show how $R$ would change were we to add additional wealth to someone's wealth holdings. In this model such an addition would reduce $R$ whereas the observed variation in assets at retirement associated with variation in $R$ could either be positive or negative depending on the details of the utility function. Because $u'$ is constant in age, the model predicts that once retired, no one will 'unretire'.

### The retirement hazard

A common object of study in retirement research is the retirement hazard: the probability of retirement at age $t$ given working at $t$. The retirement hazard can be found from the simple retirement model by considering only the part of the population still working at age $t$. Among those workers find those who will chose $R = t + 1$; the ratio of the number of those workers to the number of workers at $t$ is the retirement hazard.

Estimation of a hazard model requires panel data where the hazard would be expressed in discrete time: the probability of retirement between $t$ and $t+1$ conditional on working at $t$.

Retirement hazard models are a rather natural way to think about the retirement process particularly in the context of time-varying covariates such as the wage rate or health – just as in the simple model, an increase in wealth will increase the retirement hazard because of the reduction in $V$. The model does not make a prediction about the variation in the retirement hazard with age, which will depend on the rate at which $V$ declines with wealth.

Other predictions depend on whether we are thinking of long-run comparisons across individuals, or short-run reactions by an individual to a change in the environment. For example, if we compare the retirement behaviour of two individuals, one who has a high wage rate and one who has a low wage rate, we cannot predict who will retire earlier because their saving rates would have been different and so their wealth levels would be different: in the comparison of $U$ with $u^r w, u^r$ and $w$ move in opposite directions.

A good deal of the work on retirement comes from extensions of this simple model to take account of complexities in the budget set, changes in $U$ with age and uncertainty about the future. A leading example is the study of the effects of private pensions on retirement. Private pensions are either defined contribution (DC) pensions or defined benefit (DB) pensions. In a DC plan, the employer and/or the employee puts money as specified by the plan into an investment account usually at each pay period. The amount is a small fraction of pay (say, six per cent) which implicitly increases the wage by a small per cent. The account grows at the rate determined by the portfolio held in the account. At retirement the funds are available to the retired worker typically to spend as he wishes. Thus the plan is defined by the contribution rules (hence, DC). What the worker actually receives will depend on the performance of the portfolio.

In a DB plan the worker will receive a pension or annuity at retirement which is based on the years of service with the employer, on the age at retirement and on a measure of earnings in the last few years of employment. Thus the pension plan is defined by the benefit that a worker will receive on retirement. Most DB plans have the curious feature that the benefit
will depend on the age of retirement in a highly nonlinear way. If $PV_a$ is the expected present value of lifetime pension benefits (pension wealth) conditional on retiring at $a$,  
$PV_{a+1} - PV_a$ is the addition to pension wealth (additional compensation) from working from $a$ to $a+1$. DB plans often have a critical age, say $A$, at which a full or unreduced pension benefit is paid to a worker who retires at that age. Workers who retire before $A$ may have their pension benefit reduced substantially. Then the apparent compensation from working from $A-1$ to $A$ is the wage plus $PV_A - PV_{A-1}$. It is not hard to find examples where the total compensation is more than twice the wage. Said differently, the pension is reduced sufficiently for early retirement so that the gain in pension wealth from a year's work exceeds the wage. Furthermore, often pensions are not adjusted upward if a worker retires past $A$ even though for a given pension level the expected present value declines with age. For example, for a single male aged 60 under the assumption that the pension is not indexed and that the nominal interest rate is five per cent, the pension should increase by about eight per cent per year of delayed retirement after age 60 to keep pension wealth constant. If the pension is not adjusted upward at all, the implicit wealth loss from delaying retirement for a year would be about eight per cent of the expected present value of the pension. Assuming the pension replaces 50 per cent of the pre-retirement wage and assessing pension wealth at 12.2 times annual pension income (which is $PV_A$ in this example) means that the loss in pension wealth from delaying retirement is about 50 per cent of the wage. Said differently, the worker would be working for just half of the apparent wage.

The large gain before age 60 in pension wealth creates a large gain in compensation for working from 59 to 60, and the large loss reduces compensation substantially should the worker not retire at 60. These changes in DB pension wealth modify the money wage to produce net compensation. Net compensation for working from age 59 to 60 would be large and net compensation for working from 60 to 61 would be small. It is likely that a worker aged 59 would calculate that $U>V \times wage$ because the money wage would be large. A worker aged 60 would calculate $U>V \times wage$ because the money wage would be small. Thus we would observe many retirements at age 60. More generally spikes in compensation induced by DB plans cause correspondingly large spikes in the retirement hazard at critical ages such as $A$. An important part of research on retirement is to obtain data on the details of DB plans so as to relate retirement to these spikes.

DC plans matter, but mainly as an addition to wealth. Typically DC plans do not have special ages at which the implicit compensation is very large or small: rather they add a small percentage to the implicit wage. (However, DC plans can have early withdrawal penalties which may affect retirement among those who have no private savings.) This simple model of retirement has a number of advantages: estimation would show the effect of changing the net wage or changing wealth on the retirement hazard, and the estimations follow in a straightforward way from what is directly observable in data. It is clear what variation in the data produces the results. The model has considerable flexibility: the retirement hazards can be age specific so that the wage and wealth effects are different for each age. Because the estimation only requires the net wage and wealth at $t$ and the retirement outcome at $t+1$, just two waves of panel data are needed. Data far out of sample are not needed: for example, to study the retirement hazard of 59 year-olds, one does not need data on what their wage would be should they work until, say, 65.

However, the simple model has a number of disadvantages. Sometimes DB pensions can induce non-convexities in the lifetime budget constraint as shown in Figure 1. In that figure the vertical axis is lifetime earnings on an arbitrary scale, and the horizontal axis is age at retirement, inverted to show increasing years of retirement. The lifetime budget constraint has a slope equal to the net wage. In our example the large implicit net wage from working while 59 causes the slope of the budget constraint to steepen, and the small implicit net wage from working while 60 causes it to flatten. We would expect that normal shaped indifference curves would cause large numbers to retire at age 60, and, indeed, this is what is observed in data when we have good information about DB plans. The simple model would replicate this clustering at 60. But the simple model would not replicate the prediction that very few would retire at 58: the apparent gain from working while 57 is about the same as the gain from working at 55, 56 and 58, so the simple model would predict that about the same number would retire at each of those ages. But workers can foresee that if they work until they are 59 they will have the option of working from age 59 to age 60, resulting in considerable financial gain. Of course the reason the simple model would not replicate the data is that it makes only a two period comparison: retirement at $t$ compared with retirement at $t+1$. It does not make global utility comparisons.

Figure 1
Lifetime earnings and stylized indifference curve
The simple model does not take account of uncertainty. For example, if a possible decline into bad health will require considerable health care expenditures at some future date, a worker may consider retiring later to build up precautionary saving. In this simple model any such tendency would show up in other estimated parameters.

A second type of model is designed to handle non-convexities in the budget set. It is the option value model. In a simplified form it specifies a utility function in which utility depends on years of leisure and on lifetime earnings (Stock and Wise, 1990). A worker will choose the retirement that maximizes utility which is shown at age 60 in the figure. A worker aged 58 would observe that the gain from working another year would be relatively modest, but that the gain from working two more years would be substantial. He would work another year so as to have the option of working the year after that.

The main advantage of the option value model over the simple model is that it can account for non-convexities in the budget set. If properly specified and estimated, it can simulate a greater range of policy options than the simple model. For example, an expansion of the budget set at age 63 by the introduction of a work bonus could only locally affect predicted retirement in the simple model: a worker would have to remain in employment until age 63 in the absence of the alteration. But in the option value model workers who had been contemplating retirement at 60, 61 or 62 could be affected.

A disadvantage of the option value model is that it is dependent on the specification of the utility function. Also it requires the construction of the budget set even at ages where the worker is not observed to work. In the extreme, it requires the construction of the budget set for all future ages. For example, if a worker continues to work at age 57, it may be that he has strong tastes for work or it may be that he has a DB plan with a large incentive to work until age 60. To study his retirement behaviour at age 57 we have to construct the budget set that he perceives at age 57.

In the same way as the simple model, the option value model does not account for uncertainty. This creates some tension because the model assumes that at age \( t \) the worker uses information about the environment at \( t \) and has expectations about what the environment will be at \( t+1 \), at \( t+2 \), at \( t+3 \) and so forth. Based on this information he may decide to retire at, say, \( t+4 \). At \( t+1 \) he will use information about the environment at \( t+1 \) which will usually be different from the information that was used at \( t \) about the environment at \( t+1 \). This new information along with new expectations about the future environment may cause an alteration in the intended retirement age. Yet the model does not allow the decision at \( t \) to be influenced by the knowledge that new information will be arriving and that the (tentative) decision could be changed.

**Social Security and retirement**

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_A000225&goto=B&result_number=1459
Social Security, the public pension system in the United States, is a DB pension but it differs from private (employer provided) pensions in at least two ways. First, it is almost universal so that its empirical effects on retirement are difficult to study due to the lack of programme variation across individuals. Second, at critical retirement ages Social Security is approximately actuarially fair; that is, $PV_{a+1} - PV_a \approx 0$ for most workers so that it does not generate the strong retirement incentives of private DB plans. Nonetheless, it is clear that Social Security has an important influence on retirement. First, the retirement hazard is much greater at 62 than at 61 or at 63, as illustrated in Figure 2. Age 62 is the age at which a worker can first claim Social Security benefits, and there is no other explanation for the elevated hazard. Until year 2003, 65 was the normal retirement age under Social Security, and, in addition, the age of entitlement to Medicare, the health care insurance plan for the elderly. Second, this pattern is found in international comparisons where there is programme variation that can help identify programme effects (Gruber and Wise, 1999).

**Figure 2**
Stylized labour force participation and retirement hazard rates

Despite the empirical evidence of the effect of Social Security on retirement, its influence is difficult to explain in an economic model: why should a worker retire at 62 and claim Social Security benefits rather than at some other age, when there are no economic gains from doing so? One possible explanation is based on a liquidity constraint: low-wage workers have been forced by the Social Security system to save more than they would desire and so they do not engage in any private saving. Thus they reach their early sixties with greater-than-desired retirement resources but access to those resources is conditional on retirement. As a consequence, they retire at 62 when they are first able to access them. A difficulty with this explanation is that many workers who have wealth (demonstrating that they were not forced to over-save by the Social Security system) also retire at 62. A second possible explanation concerns the rate of return (about three per cent real) used in the calculation of $PV_{a+1} - PV_a$. If some individuals believe they can obtain a higher rate on their investments, they can increase their lifetime resources by taking Social Security payments and investing them at a higher rate of return than the implicit rate associated with delayed
claiming. It is difficult to evaluate this explanation because we do not know the rates of return people expect. A third explanation is that most people believe their life expectancies to be less than average; in that case they are better off taking Social Security benefits early because they may die before they have received substantial benefits. While individual variation in subjective survival may explain the desire of some to retire and claim Social Security benefits at 62, the average subjective survival as measured by subjective survival in the HRS is close to life-table survival rates. Thus, these factors may explain some (small) part of the excessive retirements at age 62, but they are inadequate for explaining the major part of the excess.

We expect that greater wealth will lead to earlier retirement, and, indeed a contributory factor to the decline in labour force participation in the older population is probably increases in wealth. However, a wealth effect is difficult to show empirically, for several reasons. Wealth is measured with substantial error, and this tends to reduce any estimated effects.

Taste variation for retirement can mean that observed wealth is not causative for retirement but rather the result of a desired retirement age. For example, those who place little value on leisure will want to retire late in life and so will save at a low rate. Thus when they reach normal retirement age they will be observed to have low wealth and not to retire. But the delay in retirement is not the result of the lack of wealth: rather the lack of wealth is the result of wanting to retire late. In this model it is necessary to find an instrumental variable to correct for the endogeneity and observation error of wealth. As always this is difficult.

The wage rate measures the price of leisure. In the simple model which says that retirement will occur when $u > V \times \text{wage}$ an increase in the wage would lead to delayed retirement. It is, of course, necessary to control for wealth in an estimation aimed at finding a wage effect: those with high wages in the past will have accumulated more wealth, reducing $V$, the marginal utility of wealth. If we do not account for wealth, we may observe little relationship between the wage and retirement in data.

Health

The HRS as well as the international data gathering efforts collected many non-economic variables that are likely to influence retirement. The leading class of additional variables measures health. In the evaluation of whether $u > V \times \text{wage}$, $u$ is understood as the utility of leisure relative to the utility of working. It is likely that worsening health increases $u$ because it reduces the utility of working more than it reduces the utility from leisure. Thus a first-order effect of poor health is earlier retirement, both in cross-person comparisons (comparing those in poor health with those in good health) and within person comparisons (comparing those suffering a decline in health with those having stable health). If health declines on average with age, the retirement hazard will tend to increase in age. However, health also influences $V$, the marginal utility of wealth, although the direction of that influence is not solidly established. If the institutional setting exposes individuals to considerable health spending risk, $V$ will be higher among those in poor health because of the high productivity of (private) spending on health. If individuals are fully insured against health spending risk, $V$ may be lower among those in worse health: health could prevent individuals from fully enjoying what money can purchase. Of course, in simple cross-person comparisons other influences on retirement vary systematically with health and they must be controlled. For example, those in worse health have less wealth, causing $V$ to be larger; they have reduced life expectancy, which reduces $V$; and they have lower wages. Thus the relationship between health and $V \times \text{wage}$ is ambiguous. However, as an empirical matter, we observe in panel data that those in worse health retire earlier than those in better health.

The response to an unexpected decline in health (a health shock) is easier to understand because some factors that vary across persons are constant. If exposure to health care expenditure risk is relatively small, $V$ would decline because of reduced life expectancy and (possibly) because of a reduced ability to spend wealth. If, in addition, the health shock caused a decline in the wage, $V \times \text{wage}$ would decline leading to an increased likelihood of retirement. Indeed, empirically health shocks such as a heart attack are associated with elevated retirement hazard rates.

The availability of health insurance on the job and of employer-sponsored retiree health insurance should affect retirement before the age of 65 because it will change both the expected value of out-of-pocket health care costs and the variance in those costs (Blau and Gilleskie, 2001; 2006). For couples the situation is more complex because in retirement one spouse can be covered by the health insurance of the other. This variation in the provision of health spending insurance provides opportunities for the identification of an insurance effect on retirement.

Accounting for uncertainty

The effects of uncertainty are put in sharpest perspective under the assumption that it is costly to return to work once retired. If it is not costly, an individual can simply return to work as new information arrives in the future, buffering the effects of any negative shocks. This means the decision to ‘retire’ has less consequence. It is undoubtedly true that it is costly to return to work once retired, although the magnitude of the cost varies substantially across persons because of differences in specific human capital by occupation.

A worker contemplating retirement should be thinking about uncertainties that he would face should he continue to work and uncertainties should he retire. The first type would include wage growth, the likelihood of job displacement, the likelihood of a health event that would limit work, the evolution of his pension entitlement and other job characteristics. Remaining on the job gives an option to experience these outcomes both positive and negative. Retiring means both forgoing these options and forgoing the option of continuing to work both in the coming year and in subsequent years. The second type of uncertainty, that associated with the state of retirement, includes the rates of return on assets, health
retirement: The New Palgrave Dictionary of Economics

Expenditures in the health insurance environment associated with retirement, survival or life expectancy, uncertainty about one's own utility function especially about one's ability to enjoy wealth, and the utility associated with full-time, uninterrupted leisure.

It is obvious that decision-making under these kinds of uncertainty is difficult. For example, economic resources have to last for many years on average; yet a typical survival curve shows that there are significant chances of dying shortly following retirement and significant chances of dying many years after retirement. In 2003 a 65-year-old man had a life expectancy of 16.8 years, or, stated differently, he could expect to die at age 81.8. However, he had an 11 per cent chance of dying before age 70 and an 11 per cent chance of surviving to age 93. To find the optimal or even satisfactory consumption path is difficult: on the one side he would need to guard against running out of resources should he survive to 93; on the other side excessively low consumption is likely to lead to his dying with considerable wealth, which, if he has no bequest motive, is wasted.

The market solution to this problem is annuities. However, the private purchase of annuities is minimal: among 65–69-year-olds just three per cent receive any income from privately purchased annuities; among those aged 70–74, six per cent receive income from annuities. There are a number of possible explanations for the lack of privately purchased annuities. The rate of return is low because of the profit of the sellers. The price of annuities is actuarially unfair to most people because the typical purchaser lives longer than average, which increases the seller's break-even price. Finally, some people may have a bequest motive: complete annuitization would eliminate any bequests.

In my view, none of these explanations is adequate to explain the lack of annuitization. Profits are not unusually high compared with profit margins in other financial products. While annuities are actuarially unfair for many people, they are not unfair for people who expect to be long lived; yet, annuity purchase is low among such people. Even people with a bequest motive should find it advantageous to annuitize partially. A possible explanation that has been little explored concerns the actual insurance that annuities provide. Privately purchased annuities are not indexed, so people will be concerned about the real value of consumption an annuity would be able to finance at advanced old age. Even a fairly moderate level of inflation will reduce substantially the real value of an annuity over 25 years. Also, the appropriate time horizon is 25–30 years: what is the probability the annuity provider will still be in business?

Estimation of the effects of uncertainty on retirement is conducted in the context of a dynamic programming (DP) model (Rust and Phelan, 1997). The model will specify all possible future states of the world and assign utilities to them conditional on economic resources. Then by well-established backward solution methods the algorithms will find the expected utility associated with continued work and associated with retiring, where the expectation is taken with respect to the joint distribution of stochastic elements in the model. Thus, the analyst will supply the probability distribution of the age of death, the probability distributions of rates of return on assets, the probability distribution of health shocks and associated spending, and so forth. The model predicts continued work when the expected utility from work is greater than the expected utility from retiring, and it predicts retirement at the age when the reverse becomes true. For the reasons discussed in the context of the certainty retirement model, expected utility associated with continued work declines with age and expected utility associated with retirement increases with age, so a worker will eventually be predicted to retire. The model is adjusted with respect to parameters and specification until the anticipated retirement ages match most closely those observed in the data.

The data requirements of such a DP model are immense: the analyst needs to assign probabilities to all future exogenous outcomes such as mortality, asset returns and so forth, but the probabilities are not observable. The appropriate probabilities are subjective probabilities: those used by the respondent when making the retirement decision under uncertainty. In particular, the probabilities need not be the same as any observable probabilities of the corresponding events. For example, a population life table displays an estimate of the population mortality risk at each age. Even if the population subjective survival probabilities match those in the life table, individuals should have subjective survival probabilities that deviate from the life table because each person has risk factors that will alter the objective survival probabilities. People with above-average health will survive longer than people with below-average health; people with less education die earlier than people with more education. However, the subjective survival probabilities of people with those characteristics need not correspond even to the objective survival probabilities conditional on those observable characteristics. First, people undoubtedly have private information about their true survival probabilities. Second, they may well have biased subjective survival probabilities in the sense that the probabilities on which people base their retirement decisions are not good predictors of their actual survival. In a similar manner, people have subjective probability distributions over rates of return on assets that may not correspond at all to historic market rates of return or to rates of return predicted by any model based on rational expectations. In this situation, there are no objective data from which the analyst can find the probabilities of the stochastic events required by the dynamic programming model.

Because subjective probabilities are so important in the study of intertemporal decision making, including retirement, the HRS asks respondents to state their probabilistic beliefs about important stochastic events such as survival. Although the model requires survival probabilities to each future age, knowing even the subjective survival probability to a single age is a considerable improvement over using life tables: based on a model of the relationship between subjective survival, actual survival and a life table, one can estimate individualized subjective survival curves (Gan, Hurd and McFadden, 2005).

The advantages of DP models are that they incorporate uncertainty in a formal manner and in principle they can provide an estimate of the effects of uncertainty on retirement. For example, they could predict the response to a mean-preserving spread in survival such as a 20 per cent change of dying before age 70 and a 20 per cent change of surviving to age 93. DP models produce estimates of utility function parameters and so they are capable of out-of-sample prediction. For example, they could predict retirement patterns were the normal retirement age under Social Security increased to age 70.

The disadvantages of dynamic programming models of retirement include the data requirements. Because of the complexity and data requirements, dynamic programming models of retirement are able to account for only a limited number of stochastic events. A significant problem is that the data are not subject to validation: thus a model failure could be due to an incorrectly specified model or to invalid data, particularly the probability distributions of the stochastic events. A second disadvantage is that it is difficult to understand what in the
Joint retirement

Most people are married when they reach retirement age, and, because of increases in the labour force participation of wives, often both spouses work. Among working husbands aged 55–59 in 2004, 74 per cent of their wives also work. On average, husbands are about three years older than their wives, so that, when the husbands reach age 62, their wives will be about 59. A husband may be influenced by his Social Security benefits to retire but it may be disadvantageous for the wife to retire at 59. Nonetheless, we observe in data some coordination of retirement dates; that is, the probability a wife will retire given the retirement of the husband is greater than the unconditional probability that a wife will retire, and similarly for the conditional probability a husband will retire (Blau, 1998; Gustman and Steinmeier, 2000). A way to model this is to assume a household utility function in which the value of leisure of one spouse is increased by the leisure of the other spouse. That is, their leisures are complements. In a reduced form, the retirement of the husband will be influenced by the incentives he faces such as his wage rate and pension provisions, but also by the incentives his wife faces. Notice that these effects are in addition to any operating through the lifetime budget constraint: if their leisures are not complements, we should observe the early retirement of the husband balanced by the late retirement of the wife in compensation for the loss of earnings of the husband.

Joint retirement offers an arena for the study of household decision-making when there may be conflict between husband and wife as in a collective model of household utility. A typical empirical implementation of the collective model studies the demand for various purchased goods; but it is difficult to know which spouse benefits from a particular purchase. For example, suppose we observe that in households where the husband earns substantially more than the wife the household spends relatively little on clothing. Is this evidence that the power allocation in the household is related to relative earnings? The answer would depend on the assumption that wives benefit more from clothing purchases than husbands. In the case of early retirement, however, we observe who the primary beneficiary of the leisure is, providing sharper identification of the collective model versus the unitary model.

We should anticipate that models of joint retirement will become more important and useful. First, an increasing number of wives reach traditional retirement ages while working, so the quantitative importance of joint retirement will increase. Second, the strong influence of DB pension plans on retirement incentives has made the cost of coordinating retirement high when there are conflicts between optimal retirement dates induced by the plans. With the shift to DC plans, these conflicts will become quantitatively less important in the population because DC plans do not have the sharp retirement incentives of DB plans. We should expect an increase in the amount of coordinated retirements.

Behavioural economics and retirement

The discussion of the determination of retirement has assumed rational decision-making in the context of the life-cycle model: individuals and couples are assumed to maximize expected lifetime utility conditional on beliefs about the probabilities of future events. In that set-up we are still very far from testing important aspects of the model because of our limited measures of those beliefs; an apparent failure of the model could be due to its being an incorrect characterization of decision-making but it could also be due to our lack of valid measures of those beliefs. Nonetheless, there is evidence at least in saving behaviour that the forward-looking model does not apply to all people. Some people strongly prefer the present to the future; they lack the ability to process relevant information; they apparently use rules of thumb; they are heavily influenced by defaults; they do not take actions that would result in fairly large financial gains even though the cost of those actions seems to be small. These examples are about saving behaviour and portfolio choice. It is more difficult to find evidence of non-optimizing behaviour in retirement choice, possibly because it is more difficult to understand what the optimal decision is. For example, job characteristics including distaste for work, perceived discrimination, health and how it interacts with job characteristics could all have large influences on retirement; yet they are mostly unobserved.

In view of these difficulties it is worthwhile asking what would constitute evidence against the rational retirement model. One type of evidence would be an empirically important ‘normative’ retirement age: a high rate of retirement at an age that may be economically disadvantageous (or at least not economically advantageous) where that age is determined by social norms or convention. Thus, a substantial number of individuals who retire at that age would have better economic outcomes had they retired at some other age. However, to find this empirically faces considerable difficulty. At the population level in the United States excessive retirements occur at 62 and 65, ages of importance under Social Security and Medicare. To be certain that these retirements are due to convention rather than to rational economic choice, we need a great deal of information about expectations and personal tastes, and we need to have confidence that our models are complete. In my view we are not in a position to assert that individuals are making a mistake when they retire at those ages. A somewhat different category of evidence concerns economic preparation for retirement. Do we observe large numbers of workers retiring with inadequate resources to finance their consumption in retirement? If the answer is ‘yes’, retirement is suboptimal in the sense that the marginal utility of wealth is too high for the retirement age chosen. While there is controversy in the literature about the empirical facts concerning preparation for retirement, the main assertion in the literature about a lack of maximizing behaviour has been that saving is suboptimal, not that retirement is suboptimal. Abstracting from spending on health shocks, this argument has considerable validity because saving is under the control of the individual whereas the individual has somewhat less control over retirement. For example, unemployment often leads to retirement because of the difficulty for older workers to find re-employment. Or unmeasured job characteristics such as discrimination against older workers may make continued employment uncomfortable.

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_A000225&goto=B&result_number=1459(第 9/11 页)2009-1-3 0:09:21
The economic models of retirement that have been discussed here and estimated in the literature assume that the decision to work at a given wage is made by the worker. Yet, there is a large literature on the desire of employers to shed older workers; furthermore, there is unemployment at older ages, implying that sometimes retirement is not completely voluntary. Although there are laws against age discrimination in employment, it is likely that employers are able to put some pressure on older workers to retire. However, this observation about the demand side of the labour market for older workers has been formed during an era of increasing number of workers in their forties and fifties when firms may, indeed, have felt they had too many older workers. But as the baby-boom generation begins to retire, the attitude of firms towards older workers should change: firms will want to retain them. Thus, an important research question concerns the evolution of the demand side. How will employers accommodate older workers who may not want to work full time or with the intensity of younger workers? Connected to this question is the long-run productivity of older workers. Apparently firms have wanted to shed older workers because their productivity relative to their costs (including the cost of health care) declined with age. With changing technological requirements on the job, will this unfavourable age-related decline in productivity worsen or improve over time?

We have witnessed a long-run improvement in the health of the older population both in terms of life expectancy and in terms of disability. According to economic theory, increased longevity should cause an increase in the retirement age because of the necessity of financing increased years in retirement. A decline in disabilities will allow more workers to remain in the workforce, and better health is likely to lead to greater productivity at any given age. An important research objective is to quantify these effects and to forecast how changes in retirement will affect important policy concerns. For example, in the United States working past age 65 reduces Medicare expenditures because employer-provided health insurance pays for health care before Medicare. Should enough workers remain in the labour force, the financing difficulties with Medicare will be partially solved, requiring less vigorous policy intervention.

Research on the interaction between health and retirement will likely increase in importance. For example, the sanguine scenario of later retirement because of a reduction in the rate of disability depends on continuing improvements in health. Yet there is considerable uncertainty in forecasts of health, particularly because of the high levels of obesity in the working-age population. We do not have a good understanding of how obesity leads to disability. Although we have made some progress in our understanding of intertemporal decision-making, a great deal remains to be done. We need to understand how people make such decisions, what information they use, what expectations or probability distributions they have and how they form them, how those expectations evolve as they approach retirement, and so forth. These investigations would be helped were we to have methods of estimating at the individual level preference parameters such as risk aversion and the subjective time rate of discount independently of actual choices. A good example is portfolio choice, where we would like to estimate risk aversion. Lacking data on expected rates of return, we have to make assumptions about those expectations so that risk aversion is conditional on those assumptions. If we knew something about risk aversion we could estimate beliefs about expected rates of return.

These objectives will likely lead to a greater use of subjective data combined with objective data. For example, rather than just studying the determinants of actual retirement, we can study the determinants of the subjective probability of retirement at some target age, say, 62. In panel data, this method can control for unobserved heterogeneity in a straightforward way because we can observe the change in the subjective probability of retirement as the environment changes (Chan and Stevens, 2004).

Because of the continued evolution in survey methods and the ongoing data collection by the HRS, we will have greater sample sizes with which to estimate retirement models. We should be able to observe the effects of natural experiments that can help identify our models. For example, the HRS was in the field in 2002 for the beginning of the natural experiment of the increase in the normal retirement age under Social Security. We will be able to find directly any movement in the retirement spike associated with that age. The continued data collection, natural experiments, innovations in survey design, and the greater use of subjective data should lead to considerable progress in modelling and retirement decision and in quantifying the determinants of retirement.

returns to scale measurement

Susanto Basu
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

If output grows faster than inputs, holding technology constant, the production function exhibits increasing returns to scale. Increasing returns in the aggregate production function may be due to overhead (fixed) costs, diminishing marginal cost, positive spillovers from aggregate activity, the entry of new varieties of inputs or changes in the distribution of inputs across heterogeneous firms. Each channel has significant implications for models of growth, trade and business cycles. Returns to scale are hard to estimate and even difficult to define, since the definition may depend on the degree of aggregation and the time horizon under study.

Article

Knowing the degree of returns to scale (RTS) in a firm, or its average in an industry or economy, is important for a variety of economic questions. First, it is important for assessing the plausibility of models of endogenous growth, which typically require at least constant returns to reproducible inputs, and thus increasing returns overall. Second, the size of scale economies is an important determinant of the gains from trade. Third, knowing the RTS is important for assessing the plausibility of certain business-cycle models, which often rely on the existence of substantial increasing returns to scale (IRS). Fourth, the RTS is a lower bound on the size of the markup of price over marginal cost, which is a quantity of great interest in industrial organization. Finally, a basic tenet of productive efficiency requires that the value marginal product of an input be equalized across the uses to which that input could be devoted. Knowing the RTS in each use is important for checking that this condition holds. Assume that firms have a production function for gross output:

$$Y = F(\tilde{K}, \tilde{L}, M, T). \tag{1}$$

Firms use capital services $\tilde{K}$, labour services $\tilde{L}$ and intermediate inputs of materials and energy, $M$, $T$ indexes ‘technology’, not directly observed, which is defined to include any inputs that affect firm-level production but are not compensated by the firm (including, for example, Marshallian externalities as well as exogenous technical
returns to scale measurement: The New Palgrave Dictionary of Economics

change). All variables are functions of time.

Assume $\bar{L} = EHN$, where the number of employees, $N$, and hours worked per employee, $H$, are observed, but the effort of each employee, $E$, is unobserved. Capital services are the product of the observed capital stock, $K$, and its unobserved utilization rate, $Z$ (for example, the number of shifts the machine is operated): $\bar{K} = ZK$. The capital stock and the number of employees may be quasi-fixed (costly to adjust). The adjustment cost can be modelled explicitly in the production function (see Berndt, 1986).

$F$ is (locally) homogeneous of arbitrary degree $\gamma$ in the priced inputs. Constant returns implies $\gamma = 1$. RTS equals the sum of output elasticities:

$$
\gamma = \frac{F_1 \bar{K}}{\gamma} + \frac{F_2 \bar{L}}{\gamma} + \frac{F_3 M}{\gamma},
$$

where $F_j$ is the marginal product of input $J$. Assuming firms minimize cost, we can denote the firm's cost function by $C(\gamma)$. $\gamma$ also equals the inverse of the elasticity of cost with respect to output:

$$
\gamma(\gamma) = \frac{C(\gamma)}{\gamma C'(\gamma)} = \frac{C(\gamma) / \gamma}{C'(\gamma)} = \frac{AC}{MC'},
$$

where $AC$ equals average cost and $MC$ equals marginal cost. IRS may reflect overhead (fixed) costs or decreasing marginal cost; both imply that average cost exceeds marginal cost. If increasing returns take the form of overhead costs, then $\gamma(\gamma)$ is not a constant structural parameter, but depends on the level of output the firm produces.

To make this point more clear, consider a special case of (1):

$$
\gamma = G(K, L, M, T) - \Phi,
$$

where $\Phi$ is a flow (per-period) fixed cost and $G$ is homogeneous of degree $\rho$ in $K, L$ and $M$. In this case, $\gamma = \rho(\gamma + \Phi) / \gamma$. Thus, RTS, $\gamma$, may strictly exceed $\rho$. Some papers use empirical estimates of $\gamma$ to calibrate $\rho$. Since this procedure is not generally correct, some of the results in these papers (for example, the existence of sunspot equilibria), do not follow from the existence of IRS per se. Indeed, IRS is compatible with increasing marginal costs ($\rho < 1$), as in the standard Chamberlinian model of imperfect competition.

Even if firms are identical, the RTS of the aggregate production function (either of an industry or an economy) is not necessarily the $\gamma$ of every firm; it also depends on the dynamics of firm entry and exit. Suppose that in the long run all changes in aggregate output are accommodated by changes in the number of firms, with firm-level output remaining constant. Then the aggregate production function has constant returns to scale in the long run, but increasing returns when the number of firms is fixed in the short run. (However, if the new firms produce new varieties of goods, then the aggregate function may exhibit a form of increasing returns through a 'love of variety' in production, as in Ethier, 1982.)

Firms may charge a price $P$ with a markup, $\mu$, where $\mu = P / MC$. RTS is a technical property of the production function, whereas the markup is a behavioural parameter.
However, from (3), the two are linked:

$$\gamma = \frac{C(Y)}{YC'(Y)} = \frac{p}{C'_r(Y)} \frac{C(Y)}{P_Y} = \mu(1 - s\pi),$$

where $s\pi$ is the share of pure economic profit in gross revenue. As long as pure economic profits are small, as most estimates suggest, eq. (5) shows that $\mu$ approximately equals $\gamma$. Large markups thus require large increasing returns. Since most studies estimate low profit rates, and since $\mu \geq 1$, eq. (5) shows that firm-level RTS must either be approximately constant or increasing. Internal IRS also requires that firms charge a markup, to avoid losses.

One can estimate RTS from either the production function or the cost function, using the implications of eq. (2) or eq. (3) (see Berndt, 1986, for an exposition of the cost approach). The two literatures have developed to have different aims. The cost-function literature typically takes second-order approximations to the underlying production function, which allows it to estimate elasticities of substitution between inputs, but pays little attention to the issue that observed factor prices may not be allocative, especially at high frequencies. The production-function literature takes first-order approximations, but devotes more attention to correcting biases from unobserved right-hand side variables (the quantity analogue of unobserved true factor prices). Neither literature has found a good solution for dealing with issues of endogenous regressors (for example, the presence of output in the firm cost function when one allows for non-constant returns to scale).

Taking logs of both sides of (1) and differentiating with respect to time gives:

$$dY = \frac{F_1K}{Y} d\tilde{k} + \frac{F_2L}{Y} d\tilde{l} + \frac{F_3M}{Y} dm + dt.$$  

Small letters denote growth rates (so $dY$, for example, equals $\dot{Y}/Y$); the output elasticity with respect to technology is normalized to one.

Cost minimization puts additional structure on (6). (The advantage of the cost minimization framework is that it is unnecessary to specify the potentially very complicated, dynamic profit maximization problem that gives rise to $P$ or $\mu$.) Suppose that firms take the price of all $J$ inputs, $P_j$, as given by competitive markets. The first-order conditions for cost-minimization then imply that

$$PF_j = \mu P_j.$$  

If firms make pure economic profits, these appear in the data as factor payments (most often to capital, sometimes to labour). In order for (7) to hold, the prices of capital and labour must be defined as the rental price (or shadow rental price) of capital and the competitive wage rate for labour. The relationship still holds if some factors are quasi-fixed (costly to adjust), as long as we define the input price of the quasi-fixed factors as the appropriate shadow prices, or implicit rental rates.

Using eqs (5) and (7), we can write each output elasticity as the product of RTS multiplied by total expenditure on each input divided by total cost (not revenue). Thus, for example,
\[
\frac{F_1ZK}{Y} = \frac{p_KK}{\sum p_I} = \gamma c_k
\]

(8)

c_j are the cost shares of each type of input, and sum to 1.

Substitute these output elasticities into (6) and use the definition of input services:

\[
d\gamma = \gamma [\epsilon_K dK + \epsilon_L dL + \epsilon_M dm] + dt = \gamma [\epsilon_K (dk + dz) + \epsilon_L (dn + dh + de) + \epsilon_M dm] + dt = \gamma [\epsilon_K dk + \epsilon_L dn + dh + de] + \gamma [\epsilon_M dm] + dt = \gamma dx + \gamma du + dt
\]

(9)

Defining \(dx\) as a share-weighted average of conventional (observed) input growth, and \(du\) as a weighted average of unobserved variation in capital utilization and effort, we obtain our basic estimating equation for \(\gamma\), the last line of (9). Note that to create the cost shares \(c_j\) one needs to construct an estimate of pure profits, as in Hall (1990). Alternatively, one can assume zero economic profit on average and use the observed revenue shares.

Regarding (9) as an estimating equation, one immediately faces three issues. First, the econometrician usually does not observe utilization \(du\) directly. In this case, the regression suffers from measurement error. Unlike classical measurement error, variations in utilization \(du\) are likely to be (positively) correlated with changes in the measured inputs \(dx\), leading to an upward bias in the estimated \(\gamma\). Second, should one take the output elasticities as constant (appropriate for a Cobb–Douglas production function or for a first-order log-linear approximation), or time-varying? That is, should one allow \(\gamma\) and the share-weights in (9) to change over time? If the elasticities are not truly constant over time, then treating them as constant may introduce bias. Third, even if the output elasticities are constant and all inputs are observable, one faces the ‘transmission problem’: The technical change term, \(dt\), is likely to be correlated with a firm’s input choices, leading to biased OLS estimates of \(\gamma\). In principle, one can solve this problem by instrumenting the right-hand-side variables, or by using a proxy for \(dt\), following Olley and Pakes (1996).

Approaches to controlling for \(du\) also involve the use of proxies. One method builds on the intuition that firms view all inputs (whether observed by the econometrician or not) identically. For example, a firm should equate the marginal cost of obtaining more services from the observed intensive margin (for example, working current workers longer hours) and from the unobserved intensive margin (working them harder each hour). If the costs of increasing hours and effort are convex, firms will choose to use both margins. Thus, changes in an observed input – for example, hours per worker – provide a measure of unobserved changes in the intensity of work. This suggests a regression of the form:

\[
d\gamma = \gamma dh + \kappa dh + dt
\]

(10)

where \(dh\) is the growth rate of hours per worker. Basu and Fernald (2001) summarize research showing that regression (10) controls for variable effort. In addition, if the cost of varying the workweek of capital takes the form of a shift premium – for example, one needs to pay workers more to work at night – then this regression corrects for variations in utilization of capital as well as labour. (If the cost of varying capital’s workweek is ‘wear and tear’ – that is, capital depreciates in use – then the regression is somewhat more complicated, but theory still suggests appropriate proxies.)
In principle, allowing for time-varying factor shares in an estimating equation like (10) is always preferable to having constant shares, since using time-varying shares approximates the true function to a second order. However, attempting to estimate the time-varying shares requires observing (or estimating) the true shadow cost of inputs at each point in time. If observed factor payments at each point in time do not correspond to the factor's true cost each period – for example, if firms smooth wage payments by offering workers insurance through an implicit contract – then treating the observed prices as allocative may introduce larger biases (see also Carlton, 1983, on intermediate goods prices).

Since one is unlikely to observe allocative factor prices period-by-period, one probably should take a first-order approximation and assume constant, not time-varying, elasticities. For estimating the RTS a first-order approximation may suffice, and it will be accurate as long as the true average factor price is the mean of the observed prices over the sample period.

So far, the discussion has concerned the estimation of internal returns to scale. However, a number of interesting models assume the existence of spillovers between competitive firms with internal constant returns, leading to external increasing returns in the aggregate production function. The empirical literature searching for such spillovers follows two sharply divergent tracks. The search for high-frequency spillovers is usually atheoretical, and amounts to augmenting disaggregated estimating equations like (10) with measures of aggregate activity. However, since most such exercises do not attempt to control for unobserved changes in utilization (omitting, for example, the $\kappa \, dh$ term in (10)), they are vulnerable to the charge that the putative externalities are actually proxies for unobserved changes in internal inputs. Furthermore, Basu (1995) presents a model where apparent external effects are actually driven by a different economic mechanism, and shows that his model can be distinguished from true technological spillovers by examining gross-output data, as opposed to the commonly used value-added data. Performing the test, apparent externalities are found in value-added but not in gross output, suggesting they are not true spillovers.

However, the search for long-run external effects is based firmly on the economic insight that knowledge creation has built-in increasing returns, since knowledge is non-rival. Thus, there is a long tradition of searching for externalities to R&D, summarized by Griliches (1998). R&D spillovers appear to be a fact, but their exact magnitude is still an issue subject to debate. And there is no consensus at all on whether the magnitude of the spillover is large enough to permit fully endogenous long-run growth.

So far, the discussion has been couched in terms of firm-level output, or aggregation over identical firms. For some applications, one wants to know the RTS for an industry or a sector but allow – plausibly – for the possibility that firms have heterogeneous characteristics, including different $\gamma$'s. It turns out that, in this realistic scenario, there is not even an unambiguous definition of increasing returns to scale. Basu and Fernald (1997) show that industry output growth equals:

$$d \bar{Y} = \gamma d \bar{X} + d \bar{U} + R + dt,$$

(11)

$\bar{Y}$ is the average RTS across firms; $d \bar{Y}$, $d \bar{X}$, and $d \bar{U}$ are appropriately – weighted averages of firm-level output and input growths; $R$ represents various reallocation (or aggregation) effects; and $dt$ is an appropriately – weighted average of firm-level technology.

The intuition for ‘$R$’ is that $\gamma$ need not be the same across firms within an industry (or the economy). Output growth therefore depends on the distribution of input growth as well as on its mean: if inputs grow faster in firms where they have above-average marginal products ($\gamma$ is higher), industry output grows more rapidly as well. Thus, aggregate productivity growth is not just firm-level productivity growth writ large; comparing eqs (9) and (11) shows that there are qualitatively new effects at the aggregate level. Is the RTS of an industry just the average of firm-level RTS, $\bar{Y}$, or does it include the aggregation effects, $R$, which are also the result of deviations from constant returns and perfect competition? The answer will depend on the economic question being asked (see Basu and Fernald, 1997, section V), but empirically the magnitudes are often quite different.

returns to scale

John Eatwell
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
constant returns; decreasing returns; dynamic increasing returns; increasing returns; indivisibilities; returns to scale; substitution; technical change

Article

The technique of production of a commodity \( y \) may be characterized as a function of the required inputs \( x_i \):

\[
y = f (x_1, x_2, ..., x_n)
\]

If all inputs are multiplied by a positive scalar, \( t \), and the consequent output represented as \( t^s y \), then the value of \( s \) may be said to indicate the magnitude of returns to scale.
If \( s=1 \), then there are constant returns to scale: any proportionate change in all input results in an equiproportionate change in output. If \( s>1 \), there are increasing returns to scale. If \( s<1 \) (though not less than zero, given the possibility of free disposal) then there are decreasing returns to scale.
These mathematical definitions suggest a symmetry between the three classifications of returns to scale. This appearance of symmetry is entirely spurious.
The original arguments from which is derived the economic rationale underlying the various categories of returns to scale are to be found in the works of the classical economists. Yet there, as Sraffa (1925) pointed out, each category is derived from quite different economic phenomena. Increasing returns derived from the process of accumulation and technological change, associated as they were with the division of labour attendant upon the extension of the market. Decreasing returns were held to derive from the limited availability of land, and were an important component of the theory of income distribution, being the foundation of the theory of rent.
Yet it was from these disparate origins that Marshall (1890) attempted to formulate a unified, symmetric, analysis of returns to scale which would provide the rationale for the construction of the supply curve of a competitive industry, derived in turn from the equilibria of the firms within the industry. Marshall himself recognized the incompatibility of the assumption of competition and presence of increasing returns (1890, Appendix H). Piero Sraffa (1925; 1926) exposed the entire exercise as ill-founded by demonstrating that neither increasing nor decreasing returns to scale are compatible with the assumption of perfect competition in the theory of the firm or of the partial-equilibrium industry supply curve – a result which, although prominently published and debated, has apparently escaped the notice of those who still draw that bogus U-shaped cost curve whilst purporting to analyse the equilibrium of the competitive firm.

The difficulties identified by Sraffa rest upon the economic rationales for variable returns to scale. The idea of constant returns to scale derives essentially from the proposition that a given set of production conditions may be replicated so long as all the requisite inputs may be varied in the same proportion. Indivisibilities in the production process may limit exact replication to particular levels of output. But the concept, though less precise, is not in any way diminished by the presence of indivisibilities, particularly if the optimal scale of operation of a given technique is small relative to the overall level of output.

The presence of decreasing returns to scale would suggest that replication is, for some reason, impossible. Yet if all inputs are correctly enumerated and all increased in the same proportion, then, barring indivisibilities, there can be no barrier to replication. Decreasing returns can derive only from a fixed input (or an input which cannot be increased in the same proportion as others) which prevents replication. In other words, there is no such thing as decreasing returns to scale. Decreasing returns derives from substitution, from the necessity of changing input proportions.

Whilst decreasing returns to scale do not exist, increasing returns to scale are typically based on propositions so general as to defy precise clarification. There are some examples in which outputs are an increasing function of inputs for purely technical reasons. The capacity of a pipeline, for example, is defined by the area of its cross-section, $\pi r^2$ whereas the circumference of that cross-section is equal to $2\pi r$. If it were possible to increase capacity merely by increasing the circumference (if the walls of the pipe did not require strengthening), then a quadrupling of capacity could be achieved simply by doubling the material inputs.

There is one odd symmetry in this ‘technical’ case of increasing returns. Whereas decreasing returns can derive only from substitution and not from scale, increasing returns can derive only from scale, not from substitution! Choice of optimal proportions of inputs (with free disposal and no indivisibilities) will always ensure at least constant returns.

Such technical examples are not, however, the examples which typically come to mind in the discussion of increasing returns to scale. More typical are examples of mass production, of production lines, or, today, of production integrated by means of sophisticated information systems. Yet these examples, which are akin to Adam Smith's analysis of increasing returns, are associated more with technological change, and with the possibilities for change inherent in a larger, or more rapidly growing, market, than with a simple increase in the scale of identical inputs. Generalization of the concept to ‘dynamic increasing returns’ (Young, 1928; Kaldor, 1966) increasing returns associated with growth of output further distances the idea of increasing returns from the formal characteristics of scale.

These arguments suggest that the concept of ‘returns to scale’ is not merely a very limited means of
characterizing technology, but it is also a very \textit{limiting} concept. None of the interesting characteristics of
the relationship between scale of production and method of production are captured by the idea of
returns to scale. Indeed, the only really satisfactory formal characterization of returns to scale is that of
constant returns – and this only because replication is formally a precise notion, however empty
empirically.

returns to schooling

David Card
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The returns to schooling represent the incremental increase in earnings associated with an increase in schooling. Under assumptions first spelled out by Jacob Mincer in 1958, each additional year of schooling will lead to a percentage gain in earnings that is equal to the interest rate. More recent research has treated the return to schooling as a causal parameter that can vary across people, and by the level of education.

ability bias; control functions; degree effects; equalizing differences; human capital earnings function; instrumental variables; Mincer, J.; publication bias; returns to schooling; self-selection bias; treatment effect; wage differentials

Article

1 Introduction

The return to schooling is the internal rate of return on an additional year of schooling: the discount rate at which the present value of the gains associated with the investment equals the costs. The notion of treating education as a capital investment – and calculating the return accordingly – was proposed by Walsh (1935) in an aptly titled article, ‘Capital Concept Applied to Man’. Subsequent contributions (Mincer, 1958; 1974; Becker, 1962; 1964; 1967) have elaborated the theoretical underpinnings of this exercise, while advances in data availability and econometric methods have led to refinements in the empirical procedures used to calculate the return to schooling (see Griliches, 1977; Card, 2001; Harmon, Oosterbeek and Walker, 2003, for surveys).

Following Mincer (1974), the term return to schooling also refers to the coefficient of years of schooling in a linear regression of log earnings on years of schooling and controls for labour market experience.
Under certain simplifying assumptions this coefficient is approximately equal to the internal rate of return to an additional year of schooling (see Section 2.1 below). More generally, however, applied economists use the term return to schooling to denote the causal effect of additional schooling on log earnings, holding constant experience (or in some cases age). In this sense, which I will adopt below, the return to schooling is a structural parameter that may vary with the level of schooling, personal characteristics, and the economic environment. Moreover, the observed ex post returns to schooling can differ from the ex ante returns that were anticipated when the schooling decision was made (Cunha and Heckman, 2006).

2 Theoretical framework

2.1 The internal rate of return and equalizing differences

The internal rate of return is an accounting concept that can be implemented without reference to a particular theory of wages and schooling. As was recognized by Walsh (1935), however, if there is free entry into different schooling options, and if increases in the supply of workers with a given schooling level reduce relative wages for the group, internal rates of return to different choices will be driven down to a common level.

(Walsh, 1935, p. 284, wrote: 'Investment in training … tends to be made as long as the returns promise to cover the cost of that training with an ordinary commercial profit. And this of course is the fundamental characteristic of the competitive, equalizing market …')

Using this ‘equalizing differences’ framework, Mincer (1958) showed that the equilibrium wage differential between two occupations requiring differing amounts of schooling will equal the difference in years of schooling multiplied by the discount rate.

Willis (1986) considers the choice of an optimal schooling level $S$ (measured in units of time) under four assumptions: (1) individuals maximize the discounted present value of earnings using a common interest rate $r$; (2) earnings are zero while in school, and equal to $f(S)g(t - S)$ at age $t$ (where age is measured in units of time since the completion of compulsory schooling); (3) the duration of work life is independent of $S$; (4) the only cost of schooling is the opportunity cost of forgone earnings. Under these assumptions, the internal rate of return for a marginal increase in schooling from an initial level $S_0$ is:

$$r = \frac{f'(S_0)}{f(S_0)}$$

that is, the proportional earnings differential per year of education between people with schooling $S_0$ and those with a little more (or less), holding constant work experience. (Under the assumptions specified, the internal rate of return $r$ equates $V(S_0, r)$ and $V(S_0 + \varepsilon, r)$, where

$$V(S, r) = \int_{S}^{S+n} f(S)g(t - S) e^{-rt} dt = f(S)e^{-rS} \int_{0}^{n} g(x) e^{-rx} dx.$$ 

Equality implies that

$$e^{r\varepsilon} = f(S_0 + \varepsilon) / f(S_0) \approx 1 + \varepsilon f'(S_0) / f(S_0)$$

and taking the limit as $\varepsilon \to 0$ gives

$$r = f'(S_0) / f(S_0).$$

If people can choose freely between schooling opportunities, in equilibrium log earnings will be a linear function of years of schooling (with slope $r$), and the internal rate of return for any schooling choice will equal $r$. Consistent with this insight, one of the most important regularities in labour economics is that a regression of log earnings on years of schooling and controls for experience yields a coefficient that is...
comparable to a discount rate for a risky investment – of the order of 5–15 per cent per year. Though the precise magnitude of such a coefficient varies over time and across labour markets, the predictability of the magnitude of the estimated return to schooling is unmatched in any other area of empirical microeconomics.

2.2 An extended model

While a simple equalizing differences framework provides a useful starting point for understanding the relationship between earnings and schooling, it does not explain why different people choose different levels of schooling. In fact, children's education choices are strongly correlated with their parent's schooling and socio-economic status, and with their own test scores in early grades. (See Card, 1999, and Solon, 1999.)

These correlations raise a fundamental question: to what extent do people with more education have other attributes – like ability or privileged family background – that would cause them to earn more even in the absence of extra schooling? In the literature this possibility is known as ability bias. A closely related question is whether people who acquire additional schooling have higher returns than those who do not – a sorting or self-selection bias of the type identified by Roy (1951).

Becker (1967) presented a simple model of earnings and schooling determination that can be used to address these issues. In this model, an individual faces a market opportunity locus \( y(S) \) that gives the level of earnings \( y \) associated with different schooling choices \( S \), and chooses a level of schooling by equating the marginal benefit of schooling with the marginal cost. Following Card (1995a), it is convenient to assume the individual chooses \( S \) to maximize a utility function \( U(S, y) = \log y - h(s) \), where \( h \) is an increasing convex function. An optimal schooling choice satisfies the first-order condition

\[
h'(S) = \frac{y'(S)}{y(S)}.\]

Note that, because the objective function is linear in \( \log y \), the optimal choice of schooling is independent of factors that generate a parallel shift in the \( \log y(S) \) function. Griliches (1977) presented a more general model of preferences with the feature that a uniform upward shift in \( \log \) earnings for all levels of schooling leads to a lower schooling choice.

Individual heterogeneity in the optimal schooling outcome arises from two sources: differences in the costs of (or tastes for) schooling, represented by heterogeneity in \( h(S) \); and differences in the economic benefits of schooling, represented by heterogeneity in the marginal return \( y'(S)/y(S) \). A tractable assumption is that both functions are linear in \( S \), with additive heterogeneity components:

\[
y'(s)/y(S) = b_i - k_1s, h'(S) = r_i + k_2s.\]
Here $b_i$ and $r_i$ are random variables with means $\bar{b}$ and $\bar{r}$ and some joint distribution across individuals (indexed by $i$), and $k_1$ and $k_2$ are non-negative constants. This specification implies that the optimal schooling choice is linear in the individual-specific heterogeneity terms:

$$S_i^* = (b_i - r_i) / k,$$

where $k = k_1 + k_2$. The assumed model for the marginal returns to schooling implies that log earnings are generated by a model of the form

$$\log y_i = \alpha_i + b_i S_i - \frac{1}{2} k_1 S_i^2,$$

where $\alpha_i$ is a person-specific constant of integration. This is a generalization of the semi-logarithmic functional form adopted in Mincer (1974) and hundreds of subsequent studies. In particular, individual heterogeneity potentially affects both the intercept of the earnings equation (via $\alpha_i$) and the slope of the earnings-schooling relation (via $b_i$). In general the optimal schooling choice will be positively correlated with $b_i$, leading to a ‘self-selection bias’ that arises because people with higher returns to schooling acquire more schooling. If $\alpha_i$ is also positively correlated with $S_i$ (via a positive correlation with $b_i$ or a negative correlation with $r_i$) the relationship between earnings and schooling will also include an ‘ability bias’, that is, a bias that arises because people with a higher level of earnings for each level of schooling have characteristics that lead them to acquire more schooling.

A particularly simple version of this model has only two schooling choices (Willis and Rosen, 1979). In this case the model reduces to a discrete choice model for the longer schooling option, and an earnings equation with a random intercept and random coefficient on a dummy representing the longer schooling option. A more general version arises if one relaxes the linearity assumptions for the marginal costs and marginal returns, but maintains additive heterogeneity: that is, $y'(S)/y(S) = b_i + \lambda(S)$, $h'(S) = r_i + \mu(S)$. In this case, Rau-Binder (2006) shows the optimal schooling is $S = \theta^{-1}(b_i - r_i)$, where $\theta(S) = \mu(S) - \lambda(S)$, and log earnings are generated by a model of the form $\log y_i = \alpha_i + \phi(S) + b_i S_i$, where $\phi'(S) = \lambda(S)$.

What does this class of models imply about the return to schooling? For individual $i$, the marginal return to the last unit of schooling is:

$$\beta_i = b_i - k_1 S_i^* = b_i (1 - k_1 / k) + r_i k_1 / k,$$
which varies across people unless one of two conditions is satisfied: either \( b_i = \bar{b} \) for all \( i \) and \( k_1 = 0 \) (so each additional unit of schooling has the same proportional effect on earnings for everyone); or \( r_i = \bar{r} \) for all \( i \) and \( k_2 = 0 \) (so everyone uses the same discount rate and invests in schooling until the return on their last unit of schooling is driven down to \( \bar{r} \)). Even if one of these conditions is satisfied and \( \beta_i \) is constant across the population, it is not necessarily true that one can obtain an unbiased estimate of the average marginal return to schooling \( \bar{\beta} = E[\beta_i] \) from observational data on earnings and schooling. In the first case (homogeneous returns) the implied earnings model is

\[
\log y_i = \alpha_i + \bar{b}S_i.
\]

Only if \( \alpha_i \) and \( S_i \) are uncorrelated will an ordinary least squares (OLS) regression yield a consistent estimate of \( \bar{b} \). In the second case (homogeneous interest rates) the implied earnings model is:

\[
\log y_i = \alpha_i + \bar{r}S_i + \frac{1}{2} k_1 S_i^2.
\]

Since people with higher values of \( b_i \) invest in more schooling, the implied relationship between earnings and schooling is convex, leading to an upward bias in the OLS estimator relative to the true marginal return to schooling, \( \bar{r} \) (Mincer, 1997). Any correlation between \( \alpha_i \) and \( S_i \) will confound the situation even further.

For the general case where marginal returns vary across the population, Card (1999) shows that an OLS regression of earnings on schooling yields a coefficient \( b_{ols} \) that has probability limit

\[
\text{plim } b_{ols} = \bar{\beta} + \lambda + \psi S_i,
\]

where \( \lambda = \text{cov}[\alpha_i, S_i]/\text{var}[S_i] \) represents an ability bias term and \( \psi = \text{cov}[b_i, S_i]/\text{var}[S_i] \) represents a self-selection or sorting bias term. (This expression assumes that the heterogeneity terms have symmetric distributions – see Card, 1999.) Since people with higher returns at each level of schooling will tend to acquire more schooling, the sorting bias term should be positive, although the magnitude may be small. The sign of the ability bias term is less clear: several studies – including the seminal paper by Willis and
Rosen (1979) – have obtained negative estimates of $\lambda$. In any case, observed pay differences between people with different levels of education may imply rates of return that are above or below $\bar{\lambda}$, the average marginal return to education in the population. The Mincer–Willis equalizing differences model is a long-run general equilibrium model in which wage differentials across education groups are determined by a free entry condition on the supply side. Becker's (1967) model, in contrast, is a partial equilibrium model describing the schooling decisions made by different individuals in a given cohort, taking the earnings generating function as given. Once these decisions are made, shifts in the demand and supply for different education groups can lead to realized returns that are higher or lower than were originally anticipated \textit{ex ante}. Moreover, the fraction of a cohort that acquires higher education can affect their \textit{ex post} returns – a general equilibrium effect. In the mid-1970s for example, the college-high school premium in the United States was relatively low, and analysts described an ‘oversupply’ of college-educated labour (Freeman, 1976). Within 15 years, however, the premium bounced back, and it now appears that cohorts born in the 1950s have enjoyed higher returns to education than they expected \textit{ex ante}.

### 2.3 Dynamic models of schooling

A more realistic alternative to the static Becker (1967) model is one in which young people make a series of decisions about whether to enrol in school (for example, Keane and Wolpin, 1997; 2001). If they do, their education increments by an amount which may depend on effort and ability, and they then become eligible to enter a higher level of schooling the next period. Individuals also choose a level of savings or borrowing which can depend on tuition costs, earnings, family transfers, and access to loans and grants. This class of models sheds light on a number of features that are inconsistent with (or simply ignored by) a static framework. For example, a dynamic model can be used to formally address the question of how students learn about their potential returns to different levels of schooling (Arcidiacono, 2004), and how schooling choices are affected by risk aversion and access to credit markets (Keane and Wolpin, 2001).

A dynamic framework is also helpful for understanding the distribution of observed education choices in the presence of ‘sheepskin’ or ‘degree’ effects that create non-concavities in the earnings–schooling relationship. In the United States, for example, people with three years of college education have about the same earnings as those with only two years of college (Park, 1994). (Likewise, people with three years of high school earn about the same as those with only two years of high school; see Hungerford and Solon, 1987.) From a static modelling perspective it is unclear why anyone would ever plan to leave college after three years. From a dynamic perspective, however, the outcome of three years of college can be explained by noting that the true return to the third year of college is the option value of entering the fourth year (Altonji, 1993). Students begin their third year of college knowing it is a necessary step to graduation, but may receive some information – for example, about their ability to complete the programme – that causes them to re-evaluate the costs and benefits of enrolment and drop out without graduating.

A dynamic perspective suggests that one should calculate the distribution of final education outcomes conditional on starting a specific education programme, and use this distribution, in combination with
the estimated costs and earnings for each outcome, to measure the \textit{ex ante} return to programme entry. (In fact, such a calculation is explicitly built into dynamic optimization models like the ones estimated by Keane and Wolpin, 1997 and Eckstein and Wolpin, 1999.) An interesting case in point is entry to a junior college, which has three main outcome possibilities: early dropout, completion of an Associates (AA) degree, or entry (with two years of college credit) to a four-year college programme. The third node creates an option value to entering an academic programme at junior college that is ignored in simple \textit{ex post} comparisons of earnings between those who are observed holding an AA degree and those with only high school education.

3 Evidence on the returns to schooling

3.1 Mincerian studies

Most of the existing evidence on the returns to schooling is based on Mincer's (1974) ‘human capital earnings function’: an OLS regression of log earnings on years of completed schooling and a polynomial of post-schooling experience (that is, current age minus an estimate of age at the completion of schooling). As noted in Section 2.1, under certain simplifying assumptions the coefficient of schooling can be interpreted as an estimate of the internal rate of return to alternative education choices. Though the empirical validity of these assumptions varies from application to application, Mincer's model has fitted in hundreds of studies of earnings determination around the world.

Several issues arise in the specification of the human capital earnings function (HCEF) that affect the magnitude of the estimated returns to schooling. One is the choice of earnings measure. Since better-educated people tend to work more hours per week and weeks per year than those with less education, the estimated returns to schooling are usually larger for annual earnings than for weekly or hourly earnings (Card, 1999).

Arguably, earnings should also include the cash value of work-related benefits like health insurance and pensions, leading to an additional source of ‘returns’ to schooling. A related issue is the treatment of taxes and transfer income during periods of nonwork, for example, from unemployment insurance and welfare programmes. From the perspective of an individual investor, the return to a given schooling choice presumably depends on the expected net incomes associated with the choice (that is, taking into account expected taxes and transfers). Interestingly, the earnings measures available in conventional surveys for many European countries (for example, France and Spain) are net of social security and income taxes, whereas the earnings measures available for other countries (in particular the United States) exclude taxes. Thus, there is some adjustment for taxes built-in to conventional human capital earnings functions estimated for many European countries, but not for the United States. Finally, schooling may affect longevity or health, leading to another indirect effect on earnings.

A second issue is functional form. Mincer's equalizing differences framework implies that log earnings are related to the opportunity cost of a given schooling choice, measured in years of forgone earnings, plus an additive term in years of post-schooling experience. Mincer (1974) assumed a linear path for on-the-job investments in human capital after the completion of schooling and showed that earnings would then depend on a \textit{quadratic} function of years of post-schooling experience. Unless the assumptions underlying this derivation are correct, however, the conditional expectation of earnings, given education
and age, will differ from this highly restrictive functional form. Empirically, the model adopted by Mincer (1974) is probably too restrictive (Lemieux, 2006). For example, Murphy and Welch (1990) conclude that a model with a third- or fourth-order polynomial in experience provides a significant improvement in fit.

Researchers have generalized the HCEF by including dummies for degrees (or a complete set of dummies for all possible schooling choices), by including interactions between schooling and experience (or cohort), and by including interactions between schooling and characteristics like gender, cognitive ability, family background, and school quality. Estimation results from such models can be used to calculate ‘returns’ to schooling that vary by the level or type of schooling and by individual characteristics. Although the resulting estimates cannot be strictly interpreted as internal rates of return, it is conventional to refer to the implied marginal effects as returns to schooling.

Related to the issue of functional form is the question of whether post schooling choices – like occupation or industry – should be added as controls to HCEF. From the perspective of calculating the returns to alternative schooling choices, the answer is ‘no’, since some of the return to additional schooling is the increased chance of working in a more highly paid occupation or industry (Becker, 1964). A more subtle issue is region or urban location, since some part of the wage differential associated with these choices is caused by differences in the cost of living (which presumably should be subtracted from earnings to calculate the return to schooling).

Recent surveys of the returns to schooling based on the Mincerian HCEF (Psacharopoulos, 1994; Psacharopoulos and Patrinos, 2004; Harmon, Walker and Westergaard-Nielsen, 2001; 2003) suggest that returns are in the range of 5–15 per cent for most OECD countries, and somewhat higher in developing countries, on average. In Europe, returns appear to be relatively low in Scandinavia (around 5 per cent) and relatively high in the United Kingdom and Ireland (10 per cent or more). Estimated returns in the United States are comparable to those in the United Kingdom, with evidence of a positive trend in both countries over the 1980–2000 period (Katz and Murphy, 1992; Card and Lemieux, 2001; Gosling and Lemieux, 2003). Using meta-analytic techniques, Harmon, Walker and Westergaard-Nielsen (2001) conclude that estimated returns are on average 1–2 points lower when the sample is limited to the public sector, when the earnings model includes controls for occupation or ‘ability’ measures, and when allowances are made for taxes. They also conclude that returns are slightly higher for women than men. In the United States, estimated returns for the mid-1990s from a conventional HCEF based on hourly earnings were about 10 per cent for men and 11 per cent for women (Card, 1999, Table 1).

3.2 Causal studies

In his pioneering study Walsh noted: ‘No doubt the students who go on from high school to college are, on average, richer in natural endowments than those who are left behind. They are a selected lot …’ (Walsh, 1935, pp. 272–3). Two main methods have been developed to control for the potential selection biases that confound simple earnings comparisons between people with different levels of schooling: (1) comparisons of siblings or twins; (2) comparisons based on interventions or exogenous factors that affected the education choices of one group relative to another. Detailed discussions of these methods are presented in Card (1995a; 1999; 2001), Krueger and Lindahl (2001), Harmon, Oosterbeek
returns to schooling: The New Palgrave Dictionary of Economics

and Walker (2003), and Blundell, Dearden and Sianesi (2004). This section presents a brief overview of some of the main methodological issues – and some of the associated findings – without attempting a comprehensive review.

Gorseline (1932) first proposed the use of sibling comparisons to control for selection biases between different education groups. The basic idea can be illustrated using a variant of the ‘homogeneous returns’ model discussed in Section 2.2. Letting $y_{ij}$ and $S_i$ denote the earnings and schooling of sibling $j$ ($j=1,2$) from family $i$, the homogeneous returns model posits:

$$\log y_{ij} = \alpha_{ij} + \bar{b}S_{ij},$$

where $\alpha_{ij}$ represents the level of earnings that sibling $j$ would receive in the absence of schooling. One possible assumption is that $\alpha_{i1} = \alpha_{i2}$: that is, that the two siblings have equal ‘ability’. In this case, one can obtain an unbiased estimate of the true return to schooling from a within-family regression, since

$$\log y_{i1} - \log y_{i2} = \bar{b}(S_{i1} - S_{i2}).$$

Chamberlain and Griliches (1975) re-analysed Gorseline’s sample of Indiana brothers and obtained a within-family estimate of $\bar{b}$ equal to 0.080 – only slightly below the estimate of 0.082 obtained from a conventional earnings model estimated by OLS on the same data. (Chamberlain and Griliches, 1975, also included the sibling’s differences in age and age-squared as added regressors.) Of course siblings may not have identical abilities, and if they don’t, a within-family estimator $b_w$ can be worse (that is, more biased) than the corresponding OLS estimator $b_{ols}$. Assuming a homogenous returns model is correct, the bias in the OLS estimate is

$$\text{plim } b_{ols} - \bar{b} = \text{cov}[\alpha_{ij}, S_{ij}] / \text{var}[S_{ij}],$$

while the bias in the within-family estimator is

$$\text{plim } b_w - \bar{b} = \text{cov}[\alpha_{ij} - \alpha_{i2}, S_{i1} - S_{i2}] / \text{var}[S_{i1} - S_{i2}].$$
Although differencing eliminates the shared component of $\alpha_{i1}$ and $\alpha_{i2}$, it is possible that the remaining within-family difference in ability is large relative to the within-family variance of schooling, implying a larger bias in $b_w$ than $b_{ols}$. (A similar analysis can be conducted when both the slope and intercept of the earnings function have person-specific components; see Card, 1999.)

One approach to the concern over ability differences between siblings is to focus on identical (monozygotic) twins. Unfortunately, schooling differences are small among identical twins, and even a little measurement error in reported education can lead to large attenuation bias in the within-twin estimate of the return to schooling. Ashenfelter and Krueger (1994) proposed an innovative solution based on asking each twin about its own and its sibling's education. Their method has been widely adapted in the literature (for example, Ashenfelter and Rouse, 1998; Miller, Mulvey and Martin, 1995; Bonjour et al., 2003) and leads to estimated returns within twins that are comparable to the corresponding OLS estimates, or only slightly smaller. (As noted by Bound and Solon, 1999, if the measurement error in schooling is mean-reverting, the Ashenfelter–Krueger approach ‘over-corrects’ and leads to an upward bias in the resulting estimator.)

Despite the intuitive appeal of identical twins to some researchers, others (for example, Bound and Solon, 1999) have questioned whether twins who choose different schooling levels are really ‘identical’ or whether the small differences in upbringing and experience that lead them to choose different schooling also contribute to their different earnings. Fundamentally, the problem is that the source of the differential schooling choices is unobserved, so different observers can argue that the choice was driven by factors that are either correlated or uncorrelated with earnings. A similar problem arises in ‘matching’ estimates of the return to schooling (see Blundell, Dearden and Sianesi, 2004), which attempt to compare earnings between people who are very similar in all dimensions except their choice of schooling. Indeed, a perfect matching algorithm applied to a sample of twins would presumably match twins to each other, leading to a within-family estimate of the return to schooling.

A second approach to the issue of selection bias is the use of instrumental variables (IV) methods. Specifically, the researcher posits the existence of a variable $Z$ that is exogenous to individuals but affects their schooling choices. As shown by Heckman (1978) in a different context, the equation relating $S$ to $Z$ need not represent a well-specified model, only a linear projection. For example, assume:

$$S_i = Z_i \pi + \xi_i.$$

If earnings are generated by the homogeneous returns model:

$$\log y_i = \alpha_i + \bar{b}S_i.$$
and $Z_i$ is orthogonal to $\alpha_i$, then a consistent estimate of $\beta$ can be obtained by IV, using $Z_i$ as an instrument for $S_i$. Individual-level instruments that have been proposed include quarter of birth (Angrist and Krueger, 1991), the sex composition of one's siblings (Butcher and Case, 1994), and distance to the nearest college (Card, 1995b). Other IV studies use school system reforms such as changes in the minimum school-leaving age (Harmon and Walker, 1995; Oreopoulos, 2006; Meghir and Palme, 2005), changes in tuition at local state colleges (Kane and Rouse, 1993; Fortin, 2006), and expansions in local infrastructure (Duflo, 2001).

Many IV studies yield estimated returns to schooling that are as large as or slightly larger than the corresponding IV estimates (see for example, Card, 2001; Harmon, Oosterbeek and Walker, 2003). Since the IV approach was motivated by the concern that OLS leads to an overestimate of the returns to schooling, this is potentially puzzling, and three explanations have been offered. First, OLS estimates are downward-biased by measurement error in education, and the measurement error bias may offset any upward selectivity bias (Griliches, 1977). Second, the search for IV designs that yield statistically significant estimates may create a ‘publication bias’ in favour of samples and specifications with relatively large IV coefficients (Ashenfelter, Harmon and Oosterbeek, 1999). Third, if the returns to education vary across the population, certain instruments may identify returns for subgroups with relatively high marginal returns to schooling (Card, 1995a).

The third explanation can be most easily understood in the context of a social experiment with a randomly assigned intervention (indexed by $Z_i=1$). Let $(S_{i0}, y_{i0})$ represent the schooling and earnings outcomes for person $i$ if he or she were assigned to the control group, and $(S_{i1}, y_{i1})$ denote the outcomes if he or she was assigned to treatment (note that only one of these pairs is observed). The treatment effect on schooling for person $i$ is $\Delta S_i=S_{i1}−S_{i0}$, while the effect on log earnings is $\Delta \log y_i=\log y_{i1}−\log y_{i0}$. Assuming that individual $i$'s marginal return to schooling in the absence of the intervention is $\beta_i$, and that the intervention only affects earnings through its effect on schooling, $\Delta \log y_i=\beta_i \Delta S_i$. An IV estimate of the return to schooling based on assignment status is numerically equal to the difference in mean log earnings between the treatment and control groups, divided by the corresponding difference in their average schooling, and has probability limit

$$\text{plim } b_{IV} = \frac{E[\log y_i|Z_i = 1] − E[\log y_i|Z_i = 0]}{E[S_i|Z_i = 1] − E[S_i|Z_i = 0]} = \frac{E[\beta_i \Delta S_i]}{E[\Delta S_i]}.$$  

If $E[\beta_i \Delta S_i] = E[\beta_i] E[\Delta S_i]$, then the IV estimator gives a consistent estimate of the average marginal return to education $\bar{\beta} = E[\beta_i]$. This will be true if the intervention induces the same change in schooling for everyone, or more generally if $E[\Delta S_i|\beta_i]$ is independent of $\beta_i$. Otherwise, provided that $\Delta S_i \geq 0$ for all $i$ (that is, no one reduces schooling because of the intervention) the IV estimate is a weighted average of the $\beta_i$'s, with the weight for person $i$ equal to $\Delta S_i/E[\Delta S_i]$.

An intervention that induces larger gains in schooling for people with high values of $\beta_i$ can lead to an
IV estimate that overstates $\beta$. Card (1995a) argued that this might be true for interventions – like the increases in the minimum school leaving age studied by Harmon and Walker (1995) and Oreopoulos (2006) – that mainly affect children from disadvantaged family backgrounds who stop school early because of high marginal costs rather than because of low marginal benefits. An alternative explanation for the finding that an IV estimate exceeds the corresponding OLS estimate is that the assumptions underlying the particular instrumental variable are invalid. In particular, in the absence of a true experiment, one can never ‘prove’ that the instrument is as good as randomly assigned. Even in an experimental setting, it is also possible that an intervention has an independent causal effect on earnings, confounding the interpretation of the IV estimate. (For example, Willis and Rosen, 1979, and Heckman and Li, 2004, use parental education as instruments for schooling, though others have argued that parental education has an independent effect on earnings.)

A generalization of IV that is useful when a researcher believes there may be random payoffs to schooling is a control function approach, first used in the schooling context by Garen (1984). (Other recent applications include Conneely and Uusitalo, 1997, Blundell, Dearden and Sianesi, 2004, and Rau-Binder, 2006.) This method relies on assumptions about the relationship between the error component in the equation relating schooling to the instrument(s) $Z$, and the random slope and intercept in the earnings equation. Assuming these are satisfied, a control function approach can recover unbiased estimates of the average marginal return to schooling, as well as useful information on how the returns to education vary with the unobserved factors driving the choice of schooling (Rau-Binder, 2006).

4 Summary

The idea of treating schooling as an investment that yields internal rates of return comparable to other investments in the economy has proven extremely useful, and has led to an unusually coherent body of research that combines theoretical modelling and detailed empirical analysis. Much of the existing empirical work is conducted in the framework of Mincer's (1974) human capital earnings function, which relates the logarithm of earnings to completed schooling – measured in years to reflect the opportunity cost of the investment – and a control for post-schooling experience. In a strict equalizing differences framework the coefficient of schooling is the internal rate of return to schooling. In a more general framework that recognizes the endogenous nature of the schooling decision, and the importance of ability differences that partially determine the choice of schooling, observed differences in earnings across different education groups will not necessarily reveal the rate of return to schooling for any one person, or for the population as a whole. Nevertheless, existing evidence from studies of siblings and twins, and from studies that focus on arguably exogenous sources of variation in education choices, suggest that the return to schooling is in the range of 5–15 per cent, and not too different from the value implied by the simple Mincerian approach.

Economists do not observe preferences. They may, however, observe demand behaviour – the choices made by consumers. Is there a way for economists to tell whether the observed behaviour is generated through the maximization of a preference relation or utility function? Since most economic theories are ultimately based on a consumer who maximizes a preference or utility, the question is clearly important for developing and testing theories. Revealed preference theory answers this question by characterizing choice behaviour that is generated by preference or utility maximization. Relating choice behaviour and preference maximization is also a goal of integrability theory. What distinguishes the theories from each other, and from the other parts of rationality theory, is the special nature of their tools: integrability theory uses mathematical integration in its proofs, and usually states its hypotheses in differential form; revealed preference theory uses a variety of mathematical tools for its proofs, and its hypotheses are usually in a discrete ‘revelation’ form. The distinctions are not always sharp, however, and we shall see areas in which the theories overlap.

Samuelson invented revealed preference theory in 1938. The basic idea, much of the terminology, and some of the axioms are due to him. In the following outline, a useful paradigm is the one that guided the first three decades: a consumer with a finite-dimensional euclidean commodity space, facing ‘competitive’ budgets determined by fixed positive prices, and satisfying a budget equality constraint.

1 The problem of rationality

From the economist’s point of view, unobservable preferences generate observable choices. Since many preference relations may generate the same choice correspondence, the map from preferences to choice correspondences is many-one: We cannot hope to find the preference generating choices, but only some preferences – a set of ‘equivalent’ preferences. For example:

It is well known in preference theory that a lexicographic preference on the plane does not admit a real-valued utility function (Debreu, 1954). A hasty conclusion might be that there is no hope of representing a lexicographic-maximizing consumer as a utility-maximizing consumer. Too hasty! For her behaviour clearly maximizes this function $g$ on the non-negative plane (for positive prices):
revealed preference theory: The New Palgrave Dictionary of Economics

\[ g(x_1, x_2) = x_1 \]

Even if her ‘intention’ is to maximize a lexicographic preference, she acts as if her intention were to maximize \( g \). In fact, even if the choices were made by a committee, a machine, or any other mindless decision maker, we can still say the actions are as if the intent were \( g \)-maximization.

This example shows the distinction between a typical question in utility and preference theory (‘Does this preference have a utility function?’), and the basic question in revealed preference and integrability theories (‘Is this demand generated by some preference?’). It also demonstrates the need for precise definitions. (Our notation will follow the glossaries of Richter, 1966, 1971.)

To describe choices, the theory requires an underlying set \( X \) and a family \( \mathcal{B} \) of subsets \( \mathcal{B} \subset X \). (Often \( X \) is the non-negative orthant of \( n \)-space and each \( B \) is a ‘competitive’ budget determined by positive prices and income.) We call any \( B \in \mathcal{B} \) a budget. A choice or demand correspondence \( h \) is a function assigning to each \( B \in \mathcal{B} \) a subset \( h(B) \subset B \) interpreted as the set of elements chosen from \( B \). And any binary relation on \( X \) is called a preference. Rationality theory relates choices \( h \) on \( (X, \mathcal{B}) \) to preferences \( R \) on \( X \) in two ways.

(i) If we start with a preference relation \( R \) we can ask what kind of choice it generates. There are two obvious senses in which it could generate a choice \( h \). First, we might have, for all \( B \in \mathcal{B} \)

\[
h(B) = \{ x \in B : \forall y \in B \, y R x \},
\]

(2)

i.e., the set of elements chosen from \( B \) is the set of \( R \)-most preferred elements in \( B \). Then we say that \( R \) rationalizes \( h \) (Richter, 1971).

Alternatively, we might have, for all \( B \in \mathcal{B} \)

\[
h(B) = \{ x \in B : \forall y \in B \, y R x \},
\]

(3)

i.e., the set of elements chosen from \( B \) is the set of elements in \( B \) for which nothing in \( B \) is \( R \)-more preferred. Then we say that \( R \) motivates \( h \) (Kim and Richter, 1986).

Definition (2): is appropriate if we think of \( R \) as a ‘weak’ (i.e. reflexive) relation, while (3) is appropriate if we think of \( R \) as a ‘strict’ (asymmetric) relation.

(ii) Conversely, if we start with a choice \( h \) we can ask whether any preference \( R \) generates, or ‘explains’
revealed preference theory: The New Palgrave Dictionary of Economics

If there exists some $R$ generating $h$ in the sense of (2) (Richter, 1966, 1971), then we say that $h$ is rational. Often we are interested in reflexive-rationality (rationalization by a reflexive preference), transitive-rationality (rationalization by a transitive preference), regular-rationality (rationalization by a reflexive, transitive, and total preference), etc. For example, utility-rationality requires the existence of a function $f : \mathcal{X} \to \mathbb{R}^+$ satisfying

$$h(B) = \{x \in B: \forall y \in B \ f(x) \geq f(y)\}$$

(4)

for all $B \subseteq B$ – i.e., the set of elements chosen from $B$ is the set of those elements in $B$ with the highest utility.

If there exists some $R$ generating $h$ in the sense of (3), then we say that $h$ is motivated (Kim and Richter, 1986). Again, we are often interested in asymmetric-motivation (motivation by an asymmetric preference), etc. In fact, $h$ is rational if and only if it is motivated (Clark, 1985; Kim and Richter, 1986).

Of course, the example (1) makes it clear that such a rationalizing or motivating $R$ will not usually be unique: there will be a whole equivalence class of such relations generating the same choice (Kim and Richter, 1986).

It is important to note that rationality and motivation have been defined as properties of demand, not of preference. We do not say, for example, that a particular preference is rational or irrational. Instead, the definitions relate demand and preferences.

An economist who derives comparative statics results from preference maximization is answering qsts of type (i). The issue arises – for both theoretical development and empirical testing – whether any further results can be derived, or whether all the (independent) consequences of preference maximization have been found. This is usually a much more difficult problem. A major task of both revealed preference and integrability theory is to address this issue, by answering qsts of type (ii). The two qsts are parts, then, of the fundamental Problem of Rationality: give necessary (i) and sufficient (ii) conditions for a demand to be rational (of a particular type), or motivated (of a particular type). Revealed preference theory solves the problem through axioms with a unique flavour.

2 Revealed Preference Solutions

It is important to distinguish revealed preference definitions from revealed preference axioms, and these in turn from revealed preference theorems.

2.1 Revelation Definitions

If consumer (i.e. choice) $h$ selects alternative $x \in B$ from $B$ – i.e., if $x \in h(B)$ – when alternative $y$ could have been selected – i.e., if $\forall y \in B$ – then we write $xVy$. And it is natural to say that $x$ is revealed as good as $y$. If also $x \neq y$ then we write $xSy$, and it is natural to say that $x$ is revealed preferred to $y$. This
The terminology of Samuelson’s is very suggestive, because if $\succ$ is any rationalization, then $x \succ y$ implies $x \succ y$ as does $x \succ y$. In fact, if $x \in h(B)$ & $y \in (B)h(B)$ and if $\succ$ is regular, then its asymmetric part $\succ$ also satisfies $x \succ y$. So an observer of $h$ can deduce properties common to all rationalizations. But beware: $x \succ y$ is a statement about choice, not about a particular preference.

Unlike the psychologist, who may be able to present an individual with binary choices, and thereby uncover a total ordering, the economist will typically observe $S$ as only a partial ordering. This is one of the challenging features of revealed preference theory. It is why, mathematically, revealed preference theory is a study of partial orders, in contrast to the classical theory of preference, which is a theory of total orders. It is also why there is generally more than one preference in the equivalence class of preferences that rationalize or motivate a given choice.

### 2.2 Revelation axioms

We describe four revealed preference axioms. Samuelson proposed the asymmetry of $S$ as a basic axiom of consumer theory: for all $x, y \in X$

$$x \succ y \Rightarrow y \succ x. \tag{5}$$

In other words, if $x$ is revealed preferred to $y$ (under some budget), then $y$ is never (under any budget) revealed preferred to $x$. As Samuelson noted, this is a property of any single-valued demand function maximizing a regular preference. This is now called the **Weak Axiom of Revealed Preference**.

Houthakker noted other necessary consequences of regular-rationality, for single-valued demand functions: there can be no cycles of the form

$$x \succ y_1 \succ y_2 \succ \ldots \succ y_k \succ x. \tag{6}$$

In other words, $x$ is never, even indirectly, revealed preferred to itself. Houthakker proposed this as a new axiom, now called the **Strong Axiom of Revealed Preference**. If we define $xHy$ to mean that $x \succ y$ or $x \succ y_1 \succ y_2 \succ \ldots \succ y_k \succ y$, then we can rephrase Houthakker’s axiom as saying that $H$ is asymmetric. In other words, if $x$ is (even indirectly) revealed preferred to $y$, then $y$ is never (even indirectly) revealed preferred to $x$.

Richter noted still another consequence of regular-rationality. For this it is convenient to define $xWy$ to mean either $xV y$ or $xV y_1 V \ldots V y_k V y$. Clearly regular-rationality implies: for all $x, y \in X$ & $B \in B$
revealed preference theory: The New Palgrave Dictionary of Economics

\[ x \in h(B) & \forall y \in B & y \preceq x \Rightarrow y \in h(B). \] (7)

In other words, if \( x \) is chosen from \( B \), and if \( y \) is also available in \( B \) and is revealed (even directly) as good as \( x \), then \( y \) is also chosen from \( B \). This is the Congruence Axiom of Revealed Preference. He also noted a behavioural consequence of any rationality: for all \( x, y \in X & B \in \)

\[ x \in B \forall y \in g^{x} y \Rightarrow x \in h(B). \] (8)

In other words, if \( x \) is in \( B \) and is revealed as good as everything in \( B \), then \( x \) is chosen from \( B \). This is the V-Axiom.

We will use these axioms to discuss the main solutions to the Problem of Rationality.

2.3 Revelation theorems

(a) Weak Axiom. Samuelson proposed the Weak Axiom in 1938, as a foundation for all consumer theory (1938 a,b). He did not name it, but he suggested that (for single-valued demand functions) it followed from maximizing a utility function (cf. also Samuelson (1955), pp. 110–11). In the opposite direction, his idea of founding consumer theory on it was implicitly a conjecture that it implied utility-rationality, or at least regular-rationality. Indeed, after preliminary work by I.M.D. Little, Samuelson succeeded in showing that, for two commodities and Lipschitz-continuous demand functions, the Weak Axiom implied regular-rationality (Samuelson, 1948).

(b) Strong Axiom. Then in 1950 Houthakker (1950) proposed the Strong Axiom (by a different name) as a basis for consumer theory, and showed that, for any number of commodities, it implied utility-rationality for Lipschitz-continuous demand functions. Samuelson (1950) then gave the Weak and Strong Axioms their modern names.

In 1959, Uzawa (1960, 1971) developed a more precise analogue of Houthakker's result, showing that the Strong Axiom and a Lipschitzian hypothesis on the demand implied irreflexive-transitive-monotone-convex-lower semi continuous-motivation. His proof was along the lines of the Samuelson–Little–Samuelson–Houthakker analytic methods.

Although the Strong Axiom implied the Weak, it was still not clear whether the Weak implied the Strong. Indeed, Rose (1958) showed that the Weak Axiom does imply the Strong Axiom, when there are only two commodities and prices are positive (needed!). Then Gale (1960) constructed an example with three commodities, showing that the Weak Axiom did not imply the Strong. And Kihlstrom, Mas-Colell and Sonnenschein (1976) showed how to obtain very easily many examples, for any number of commodities greater than two. And Shafer (1977b), affirming a conjecture of Samuelson (1953), showed...
that the full strength of the Strong Axiom is needed: even for three goods, there is no upper bound on the length of $S$-cycles that must be ruled out. In the opposite direction, several authors have discussed special conditions under which the Weak Axiom does imply the Strong (Arrow, 1959; Uzawa, 1960, 1971).

Richter (1966) used set-theoretic methods – very different from the analytic methods of Samuelson, Little, Houthakker and Uzawa – to simplify the proofs, eliminate extraneous assumptions, and strengthen the rationality results. In a framework of abstract budget spaces, and without the technical assumptions required by the earlier analytical approaches, he showed that the Strong Axiom is equivalent to regular-rationality for demand functions. Thus the Strong Axiom completely exhausts the theory of demand functions maximizing a regular preference.

Richter (1966) also showed that, if a competitive demand satisfies the Strong Axiom, then it is utility-rational if its range is well behaved, but it may not be utility-rational otherwise (Richter, 1971).

**Extensions**

There have been many extensions. Richter (1966) showed that the V-Axiom characterized rationality, and the Congruence Axiom characterized regular-rationality, for demand correspondences. (Hansson (1968) gave an alternative criterion for regular-rationality.) Other extensions have obtained stronger properties of the rationalization under special hypotheses (Hurwicz and Richter, 1971; Mas-Colell, 1978, Theorem 1; Richter, 1986; Matzkin and Richter, 1986); uniqueness of the rationalization within certain classes (Mas-Colell, 1977); revealed preference axioms characterizing more general rationality types (Richter, 1971; Kim and Richter, 1986; Kim, 1987); dual axioms (Sakai, 1977; Richter, 1979); and axioms for stochastic rationality (McFadden and Richter, 1970).

**Applications**

Several applications have supported Samuelson's original idea that revealed preference could provide an alternative to preference theory as a foundation for consumer theory. Revealed preference techniques have been applied to prove the existence of competitive equilibrium (Wald, 1936, 1951); to prove the stability of competitive equilibrium (Arrow and Hurwicz, 1958, 1960); to prove the Hicks Composite Commodity Theorem (Richter, 1970; Calsamiglia, 1978); to analyse and characterize aggregate excess demand functions (Debreu, 1974; McFadden et al., 1974); to prove aggregation properties for correspondences (Shafer, 1977a); to prove properties of measurable demand correspondences (Yamazaki, 1984); to prove theorems about social choice functions (Plott, 1973); etc.

3 Revealed preference and integrability

With the same rationality goal as revealed preference theory, integrability theory uses axioms on the Slutsky or Antonelli matrices to characterize rational choice (cf. Hurwicz, 1971; see also integrability of demand). Under some smoothness assumptions on the demand function, the basic theorems state that
Samuelson established a link between revealed preference theory and integrability theory by showing that his Weak Axiom implied negative semidefiniteness of the matrices (Samuelson, 1938b, 1955, pp. 111–14). Later Kihlstrom, Mass-Colell, and Sonnenschein (1976) demonstrated that negative semidefiniteness was equivalent to a Weak Weak Axiom. This left open the question of finding a revealed preference axiom equivalent to the symmetry. The Strong Axiom was clearly too strong, since it already implied regular-rationality, and therefore both symmetry and negative-semidefiniteness. Then Hurwicz and Richter (1979a,b) showed that a differential axiom of Ville (1946, 1951) provided the exact strength needed. Although it does not even imply the Weak Axiom, it is similar in spirit to the Strong Axiom and can be given a revealed preference inpt. It thus serves, like Kihlstrom, Mas-Colell and Sonnenschein’s Weak Weak Axiom, as a bridge between the Revealed Preference and Integrability approaches to consumer rationality. Richter (1979) discussed these bridges from the viewpoint of duality.

4 Other notions of rationality

Many economists have used notions of rationality different from Richter’s notion (2). Sometimes the term ‘rational’ has been applied to preference, rather than demand. (In such applications it is often a synonym for ‘transitive’.) In Uzawa (1957) and Arrow (1959), on the other hand, it was applied to demand, but only in terms of axioms on demand behaviour. By contrast, (2) is applied to demand, but in terms that relate both demand and preferences.

Some economists have used weaker notions of rationality than (2), requiring only: for all $x, y \in X$ & $B \in \mathcal{B}$

$$h(B) \subseteq \{x \in B: \forall y \in B, x R y\}.$$  

In other words, every element chosen from $B$ is $R$-most preferred in $B$, but $B$ may contain other $R$-most preferred elements that are not chosen. We will call this subsemi-rationality, although it has often been referred to as rationality.

A drawback of this concept is its loose linkage of preference and demand. Any constant function, for example, satisfies (9). On the other hand, if one interprets $h(B)$ as a set of incomplete observations, then one might wonder whether, with more observations of choices from $B$, the set $h(B)$ of chosen elements might grow. Then one might want to find a preference $R$ satisfying just (9), rather than insisting (as does (2)) that $R$ explain precisely the observed set $h(B)$.

Afriat (1967) gave conditions on a demand function, over a finite set of budgets, that are necessary and sufficient for it to be subsemi-rationalized by a continuous monotone concave function. His work was clarified by Diewert (1973) who gave a criterion for continuous-monotone-concave-subsemirationality
revealed preference theory: The New Palgrave Dictionary of Economics

in terms of a linear programming problem. Varian (1983) restated Afriat's finite-budgets result in terms of a Generalized Axiom of Revealed Preference – weaker than the Strong Axiom. Matzkin and Richter (1986) obtained full rationality by replacing the Generalized Axiom with the Strong Axiom, which they proved was necessary and sufficient for continuous-monotone-strictly concave-utility-rationality in the finite case. No revealed preference criterion for concave-regular-rationality is known for the not-necessarily finite case.

Article

Communication is central to the economic problem (Hayek, 1945). Opportunities for mutually beneficial transactions cannot be found unless individuals share information about their preferences and endowments. Markets and other economic institutions should be understood as mechanisms for facilitating communication. However, people cannot be expected to reveal information when it is against their interests; for example, a seller may conceal his willingness to sell at a lower price. Rational behaviour in any specific communication mechanism can be analysed using game-theoretic equilibrium concepts, but efficient institutions can be identified only by comparison with all possible communication mechanisms. The revelation principle is a technical insight that allows us, in any given economic
situations, to make general statements about all possible communication mechanisms. The problem of making statements about all possible communication systems might seem intractably complex. Reports and messages may be expressed in rich languages with unbounded vocabulary. Communication systems can include both public announcements and private communication among smaller groups. Communication channels can have noise that randomly distorts messages. A communication mechanism may also specify how contractually enforceable transactions will depend on agents' reports and messages. So a general communication mechanism for any given set of agents may specify (a) a set of possible reports that each agent can send, (b) a set of possible messages that each agent can receive from the communication system, and (c) a probabilistic rule for determining the messages received and the enforceable transactions as a function of the reports sent by the agents.

However, the revelation principle tells us that, for many economic purposes, it is sufficient for us to consider only a special class of mechanisms, called 'incentive-compatible direct-revelation mechanisms'. In these mechanisms, every economic agent is assumed to communicate only with a central mediator. This mediator may be thought of as a trustworthy person or as a computer at the centre of a telephone network. In a direct-revelation mechanism, each individual is asked to report all of his private information confidentially to the mediator. After receiving these reports, the mediator then specifies all contractually enforceable transactions, as a function of these reports. If any individual controls private actions that are not contractually enforceable (such as efforts that others cannot observe), then the mediator also confidentially recommends an action to the individual. A direct-revelation mechanism is any rule for specifying how the mediator determines these contractual transactions and privately recommended actions, as a function of the private-information reports that the mediator receives. A direct-revelation mechanism is said to be 'incentive compatible' if, when each individual expects that the others will be honest and obedient to the mediator, then no individual could ever expect to do better (given the information available to him) by reporting dishonestly to the mediator or by disobeying the mediator's recommendations. That is, the mechanism is incentive compatible if honesty and obedience is an equilibrium of the resulting communication game. The set of incentive-compatible direct-revelation mechanisms has good mathematical properties that often make it easy to analyse because it can be defined by a collection of linear inequalities, called 'incentive constraints'. Each of these incentive constraints expresses a requirement that an individual's expected utility from using a dishonest or disobedient strategy should not be greater than the individual's expected utility from being honest and obedient, when it is anticipated that everyone else will be honest and obedient.

The analysis of such incentive-compatible direct-revelation mechanisms might seem to be of limited interest, because real institutions rarely use such fully centralized mediation and often generate incentives for dishonesty or disobedience. For any equilibrium of any general communication mechanism, however, there exists an incentive-compatible direct-revelation mechanism that is essentially equivalent. This proposition is the revelation principle. Thus, the revelation principle tells us that, by analysing the set of incentive-compatible direct-revelation mechanisms, we can derive general properties of all equilibria of all coordination mechanisms.

The terms 'honesty' and 'obedience' here indicate two fundamental aspects of the general economic problem of communication. In a general communication system, an individual may send out messages or reports to share information that he knows privately, and he may also receive messages or recommendations to guide actions that he controls privately. The problem of motivating individuals to report their private information honestly is called 'adverse selection', and the problem of motivating
individuals to implement their recommended actions obediently is called ‘moral hazard’. To describe the
intuition behind the revelation principle, let us consider first the special cases where only one or the
other of these problems exists.

**Pure adverse selection**

First, let us formulate the revelation principle for the case of pure adverse selection, as developed in
Bayesian social choice theory. In this case we are given a set of individuals, each of whom has some
initial private information that may be called the individual’s ‘type’, and there is a planning question of
how a social allocation of resources should depend on the individuals’ types. Each individual's payoff
can depend on the resource allocation and on the types of all individuals according to some given utility
function, and each type of each individual has some given probabilistic beliefs about the types of all
other individuals. A general communication system would allow each individual i to send a message \( m_i \)
in some rich language, and then the chosen resource allocation would depend on all these messages
according to some rule \( \gamma(m_1, \ldots, m_n) \). In any equilibrium of the game defined by this communication
system, each individual \( i \) must have some strategy \( \sigma_i \) for choosing his message as a function of his type
\( t_i \), so that \( m_i = \sigma_i(t_i) \).

For the given equilibrium \( (\sigma_1, \ldots, \sigma_n) \) of the given social-choice rule \( \gamma \), the revelation principle is
satisfied by a mediation plan in which each individual is asked to confidentially report his type \( t_i \) to a
central mediator, who then implements the social choice

\[
\mu(t_1, \ldots, t_n) = \gamma(\sigma_1(t_1), \ldots, \sigma_n(t_n)).
\]

So the mediator computes what message would be sent by the reported type of each individual \( i \) under
his or her strategy \( \sigma_i \), and then the mediator implements the resource allocation that would result from
these messages under the rule \( \gamma \). It is easy to see that honesty is an equilibrium under this mediation
plan \( \mu \). If any individual could gain by lying to this mediator, when all others are expected to be honest,
then this individual could have also gained by lying to himself when implementing his equilibrium
strategy \( \sigma_i \) under the given mechanism \( \gamma \), which would contradict the optimality condition that defines
an equilibrium. So \( \mu \) is an incentive-compatible direct-revelation mechanism that is equivalent to the
given general mechanism \( \gamma \) with the given equilibrium \( (\sigma_1, \ldots, \sigma_n) \).

In this case of pure adverse selection, the revelation principle was introduced by Gibbard (1973), but for
a narrower solution concept (dominant strategies, instead of Bayesian equilibrium). The revelation
principle for the broader solution concept of Bayesian equilibrium was recognized by Dasgupta,
Hammond and Maskin (1979), Harris and Townsend (1981), Holmstrom (1977), Myerson (1979), and

**Pure moral hazard**
Next let us formulate the revelation principle for the case of pure moral hazard, as developed in Aumann's (1974) theory of correlated equilibrium. In this case we are given a set of individuals, each of whom controls some actions, and each individual's payoff can depend on the actions \((c_1, \ldots, c_n)\) that are chosen by all individuals, according to some given utility function \(u_i(c_1, \ldots, c_n)\). That is, we are given a game in strategic form. In this case of pure moral hazard, nobody has any private information initially, but a communication process could give individuals different information before they choose their actions. In a general communication system, each individual \(i\) could get some message \(m_i\) in some rich language, with these messages \((m_1, \ldots, m_n)\) being randomly drawn from some joint probability distribution \(\rho\). In any equilibrium of the game generated by adding this communication system, each individual \(i\) has some strategy \(\sigma_i\) for choosing his action \(c_i\) as a function of his message \(m_i\), so that \(c_i = \sigma_i(m_i)\).

For the given equilibrium \((\sigma_1, \ldots, \sigma_n)\) of the game with the given communication system \(\rho\), the revelation principle is satisfied by a mediation plan in which the mediator randomly generates recommended actions in such a way that the probability of recommending actions \((\hat{c}_1, \ldots, \hat{c}_n)\) is the same as the probability of the given communication system \(\rho\) yielding messages \((m_1, \ldots, m_n)\) that would induce the players to choose \((c_1, \ldots, c_n)\) in the \(\sigma\) equilibrium. That is, the probability \(\mu(\hat{c}_1, \ldots, \hat{c}_n)\) of the mediator recommending \((\hat{c}_1, \ldots, \hat{c}_n)\) is

\[
\mu(\hat{c}_1, \ldots, \hat{c}_n) = \rho(\{(m_1, \ldots, m_n)|\sigma_1(m_1) = c_1, \ldots, \sigma_n(m_n) = c_n\}).
\]

Then the mediator confidentially tells each individual \(i\) only which action \(c_i\) is recommended for him. Obedience is an equilibrium under this mediation plan \(\mu\) because, if any individual could gain by disobeying this mediator when all others are expected to be obedient, then this individual could have also gained by disobeying himself in implementing his equilibrium strategy \(\sigma_i\) in the given game with communication system \(\rho\). So \(\mu\) is an incentive-compatible direct-revelation mechanism that is equivalent to the given mechanism \(\rho\) with the given equilibrium \((\sigma_1, \ldots, \sigma_n)\).

**General formulations**

Problems of adverse selection and moral hazard can be combined in the framework of Harsanyi's (1967) Bayesian games, where players have both types and actions. The revelation principle for general Bayesian games was formulated by Myerson (1982; 1985). A further generalization of the revelation principle to multistage games was formulated by Myerson (1986). In each case, the basic idea is that any equilibrium of any general communication system can be simulated by a maximally centralized communication system in which, at every stage, each individual confidentially reports all his private information to a central mediator, and then the mediator confidentially recommends an action to each individual, and the mediator's rule for generating recommendations from reports is designed so that honesty and obedience form an equilibrium of the mediated communication game.
The basic assumption here is that, although the motivations of all economic agents are problematic, we can find a mediator who is completely trustworthy and has no costs of processing information. Asking agents to reveal all relevant information to the trustworthy mediator maximizes the mediator's ability to implement any coordination plan. But telling any other agent more than is necessary to guide his choice of action would only increase the agent's ability to find ways of profitably deviating from the coordination plan.

For honesty and obedience to be an equilibrium, the mediation plan must satisfy incentive constraints which say that no individual could ever expect to gain by deviating to a strategy that involves lying to the mediator or disobeying a recommendation from the mediator. In a dynamic context, we must consider that an individual's most profitable deviation from honesty and obedience could be followed by further deviations in the future. So, to verify that an individual could never gain by lying, we must consider all possible deviation strategies in which the individual may thereafter choose actions that can depend disobediently on the mediator's recommendations (which may convey information about others' types and actions).

When we use sequential equilibrium as the solution concept for dynamic games with communication, the set of actions that can be recommended in a sequentially incentive-compatible mechanism must be restricted somewhat. In a Bayesian game, if some action \( d_i \) could never be optimal for individual \( i \) to use when his type is \( t_i \), no matter what information he obtained about others' types and actions, then obedience could not be sequentially rational in any mechanism where the mediator might ever recommend this action \( d_i \) to \( i \) after he reports type \( t_i \). Myerson (1986) identified a larger set of co-dominated actions that can never be recommended in any sequentially incentive-compatible mechanism. Suppose that, if any individual observed a zero-probability event, then he could attribute this surprise to a mistake by the trembling hand of the mediator. Under this assumption, Myerson (1986) showed that the effect of requiring sequential rationality in games with communication is completely characterized by the requirement that no individuals should ever be expected to choose any co-dominated actions. (See Gerardi and Myerson, 2007.)

**Limitations**

The revelation principle says that each equilibrium of any communication mechanism is equivalent to the honest-obedient equilibrium of an incentive-compatible direct-revelation mechanism. But this direct-revelation mechanism may have other dishonest equilibria, which might not correspond to equilibria of the original mechanism. So the revelation principle cannot help us when we are concerned about the whole set of equilibria of a communication mechanism. Similarly, a given communication mechanism may have equilibria that change in some desirable way as we change the players' given beliefs about each others' types, but these different equilibria would correspond to different incentive-compatible mechanisms, and so this desirable property of the given mechanism could not be recognized with the revelation principle.

The assumption that perfectly trustworthy mediators are available is essential to the mathematical simplicity of the incentive-compatible set. Otherwise, if individuals can communicate only by making public statements that are immediately heard by everybody, then the set of equilibria may be smaller and harder to compute.
