Simultaneously, each of $n$ players chooses one of two computers, $I$ or $M$. But before choosing, with 0.50–0.50 i.i.d. probabilities, every player is privately informed that she is an $I$-type or an $M$-type. The payoff of every player is 0.1 if she chooses the computer of her type (zero otherwise) plus 0.9 times the proportion of opponents whose choices she matches. (Identical payoffs and prior probabilities are assumed only to ease the presentation. The robustness property holds without these assumptions.) Consider the favourite-computer equilibrium (FC) where every player chooses the computer of her type. Structural robustness implies that the equilibrium must be \textit{invariant to sequential play}: it should survive in alterations in which the (publicly observed) computer choices are made sequentially. Clearly this is not the case for small $n$, where any equilibrium must involve herding. But as $n$ becomes large, the structural robustness theorem below implies that FC becomes an equilibrium in all sequential alterations. More precisely, the Prob[some player, by deviating to her non favorite computer, can achieve an $\epsilon$ -improvement at her turn] decreases to zero at an exponential rate.

The general definition of structural robustness, presented next, accommodates the above examples and much more.

\textbf{Structural robustness}\n
A mixed-strategy (Nash) equilibrium $\sigma = (\sigma_1, \ldots, \sigma_n)$ of a one-simultaneous-move $n$-person strategic game $G$ is structurally robust if it \textit{remains an equilibrium} in every structural alteration of $G$. Such an alteration is described by an extensive game, $A$, and for $\sigma$ to remain an equilibrium in $A$ means that every adaptation of $\sigma$ to $A$, $\sigma^A$, must be an equilibrium in $A$.

Consider any $n$-person one-simultaneous-move Bayesian game $G$, like the Computer Choice game above.

\textbf{Definition 1: A (structural) alteration of $G$ is any finite extensive game $A$ with the following properties:}
1. A includes the (original) G-players: The players of A constitute a superset of the G-players (the players of G).

2. Unaltered type structure: At the first stage of A, the G-players are assigned a profile of types by the same prior probability distribution as in G. Every player is informed of his own type.

3. Playing A means playing G: with every final node of A, z, there is an associated unique profile of G pure-strategies, a(z) = (a_1(z), ..., a_n(z)).

4. Unaltered payoffs: the payoffs of the G-players at every final node are the same as their payoffs in G (at the profile of realized types and final pure-strategies a(z)).

5. Preservation of original strategies: every pure-strategy a_i of a G-player i has at least one A adaptation. That is, an A-strategy \( \tilde{a}_i^A \) that guarantees (w.p. 1) ending at a final node z with \( \tilde{a}_i(z) = a_i \) (no matter what strategies are used by the opponents).

In the computer choice example, every play of an alteration A must produce a profile of computer allocations for the G-players. Their preferences in A are determined by their preferences over profiles of computer allocations in G. Moreover, every G-player i has at least one A-strategy \( \tilde{l}_i \) (which guarantees ending at a final node where she is allocated I), and at least one A-strategy \( \tilde{M}_i \) (which guarantees ending at a final node where she is allocated M).

**Definition 2:** An A (mixed) strategy-profile, \( \sigma^A \), is an adaptation of a G (mixed) strategy-profile \( \sigma \), if for every G-player i, every \( \tilde{\sigma}_i^A \) is an A-adaptation of \( \sigma_i \). That is, for every G pure-strategy \( a_i \),

\[
\tilde{\sigma}_i(a_i) = \sigma_i^A(\tilde{\sigma}_i^A) \text{ for some A-adaptation } \tilde{\sigma}_i^A \text{ of } a_i.
\]

In the computer choice example, for a G-strategy where player i randomizes 0.20 to 0.80 between I and M, an A adaptation must randomize 0.20–0.80 between a strategy of the type \( \tilde{l}_i^A \) and a strategy of the type \( \tilde{M}_i^A \).

**Definition 3:** An equilibrium \( \sigma \) of G is structurally robust if in every alteration of G, A, and in every adaptation of \( \sigma \), \( \sigma^A \), the strategy of every G-player i, \( \sigma_i^A \), is best response to \( \sigma_i^A \).

**Remark 1:** The structural robustness theorem, discussed later, presents an asymptotic result: the equilibria are structurally robust up to two positive numbers (\( \epsilon \), \( \rho \)), which can be made arbitrarily small as n becomes large. The notion of approximate robustness is the following.

An equilibrium is (\( \epsilon \), \( \rho \))-structurally robust if in every alteration and every adaptation as above, Prob [visiting an information set where a G-player can improve his payoff by more than \( \epsilon \)] \( \leq \rho \). (\( \epsilon \) - improvement is computed conditional on being at the information set. To gain such improvement the player may coordinate his deviation: he may make changes at the information set under consideration together with changes at forthcoming ones.)

For the sake of brevity, the next section discusses full structural robustness. But all the observations presented there also hold for the properly defined approximate counterparts. For example, the fact that structural robustness implies ex post Nash also implies that approximate structural robustness implies approximate ex post Nash. The implications of approximate (as opposed to full) structural robustness are important, due to the asymptotic nature of the structural robustness theorem.
Structural robustness of an equilibrium \( \sigma \) in a game \( G \) is a strong property, because the set of \( G \)-alterations that \( \sigma \) must survive is rich. The simple examples below are meant to suggest the richness of its implications, with the first two examples showing how it implies the notions already discussed (see Dubey and Kaneko, 1984 for related issues).

**Remark 2:** Ex post Nash and being information-proof

\( G \) with revisions, \( G \mathcal{R} \), is the following \( n \)-person extensive game. The \( n \) players are assigned types as in \( G \) (using the prior type distribution of \( G \) and informing every player of his own type). In a first round of simultaneous play, every player chooses one of his \( G \) pure strategies; the types realized and pure strategies chosen are all made public knowledge. Then, in a second round of simultaneous play, the players again choose pure strategies of \( G \) (to revise their first round choices). The payoffs are as in \( G \), computed at the profile of realized types with the profile of pure strategies chosen in the second round. Clearly \( G \mathcal{R} \) satisfies the definition of an alteration (with no additional players), and every equilibrium \( \sigma \) of \( G \) has the following \( G \mathcal{R} \) adaptation, \( \sigma^{\text{NoRev}} \): in the first round the players choose their pure strategies according to \( \sigma \), just as they do in \( G \); in the second round nobody revises his first round choice.

Structural robustness of \( \sigma \) implies that \( \sigma^{\text{NoRev}} \) must be an equilibrium of \( G \mathcal{R} \), that is, \( \sigma \) is ex post Nash. Moreover, the above reasoning continues to hold even if the information revealed between the two rounds is partial and different for different players. The fact that \( \sigma^{\text{NoRev}} \) is an equilibrium in all such alterations shows that \( \sigma \) is information-proof: no revelation of information (even if strategically coordinated by \( G \)-players and outsiders) could give any player an incentive to revise. Thus, structural robustness is substantially stronger than all the variants of the ex post Nash condition. (In the non-approximate notions, being ex post Nash is equivalent to being information proof. But in the approximate notions information proofness is substantially stronger.)

**Remark 3:** Invariance to order of play

\( G \) played sequentially, \( G \mathcal{S} \), is the following \( n \)-person extensive game. The \( n \) players are assigned types as in \( G \). The play progresses sequentially, according to a fixed publicly known order. Every player, at his turn, knows all earlier choices. Clearly, \( G \mathcal{S} \) is an alteration of \( G \), and every equilibrium \( \sigma \) of \( G \) has the following \( G \mathcal{S} \) adaptation: At his turn, every player \( i \) chooses a pure-strategy with the same probability distribution \( \sigma_i \) as he does in the simultaneous-move game \( G \). Structural robustness of \( \sigma \) implies that this adaptation of \( \sigma \) must be an equilibrium in every such \( G \mathcal{S} \).

Moreover, the above reasoning continues to hold even if the order of play is determined dynamically, and even if it is strategically controlled by \( G \)-players and outsiders. Thus, a structurally robust equilibrium is invariant to the order of play in a strong sense.

**Remark 4:** Invariance to revelation and delegation

\( G \) with delegation, \( G \mathcal{D} \), is the following \((n+1)\)-players game. The original \( n \) \( G \)-players are assigned types as in \( G \). In a first round of simultaneous play, every \( G \)-player chooses between (1) self-play and (2) delegate-the-play and report a type to an outsider, player \( n+1 \). In a second round of simultaneous play all the self-players choose their own \( G \) pure strategies, and the outsider chooses a profile of \( G \) pure strategies for all the delegators. The payoffs of the \( G \) players are as in \( G \); the outsider may be assigned any payoffs.
Clearly, $G_D$ is an alteration of $G$, and every equilibrium $\sigma$ of $G$ has adaptations that involve no delegation.

In the computer choice game, for example, consider an outsider with incentives to coordinate: his payoff equals one when he chooses the same computer for all delegators, zero otherwise. This alteration has a new (more efficient) equilibrium, not available in $G$: everybody delegates and the outsider chooses the most-reported type.

Nevertheless, as structural robustness implies, FC remains an equilibrium in $G_D$ (nobody delegates in the first round and they choose their favorite computers in the second). Moreover, FC remains an equilibrium under any scheme that involves reporting and voluntary delegation of choices.

**Remark 5: Partially specified games**

Structurally robust equilibria survive under significantly more complex alterations than the ones above. For example, one could have multiple opportunities to revise, to delegate, to affect the order of play, to communicate, and more. Because of these strong invariance properties, such equilibria may be used in games which are only partially specified as illustrated by the following example.

**Example 3: A game played on the Web**

Suppose that instead of being played in one simultaneous move, the Computer Choice game has the following instruction: ‘Go to Web site xyz before the end of the week, and click in your computer choice.’ This instruction involves substantial structural uncertainty: In what order would the players choose? Who can observe whom? Who can talk to whom? Can players sign binding agreements? Can players revise their choices? Can players delegate their choices? And so forth.

Because it is unaffected by the answers to such qsts, a structurally robust equilibrium $\sigma$ of the one-simultaneous-move game can be played on the Web in a variety of ways without losing the equilibrium property. For example, players may make their choices according to their $\sigma$ probabilities prior to the beginning of the click-in period, then go to the Web and click in their realized choices at individually selected times.

**Remark 6: Competitive prices in Shapley–Shubik market games**

For a simple illustration, consider the following $n$-trader market game (see Shapley and Shubik, 1977, and later references in Dubey and Geanakoplos, 2003, and McLean, Peck and Postlewaite, 2005). There are two fruits, apples and bananas, and a finite number of trader types. A type describes the fruit a player owns and the fruit he likes to consume. The players’ types are determined according to individual independent prior probability distributions. Each trader knows his own type, and his payoff depends on his own type and the fruit he ends up with, as well as on the distribution of types and fruit ownership of his opponents (externalities are allowed, for example, a player may wish to own the fruit that most opponents like). In one simultaneous move, every player has to choose between (1) keeping his fruit and (2) trading it for the other kind.

The banana/apple price is determined proportionately (with one apple and banana added in to avoid division by zero). For example, if 199 bananas and 99 apples are traded, the price of bananas to apples would be $(199+1)/(99+1)=2$, that is, every traded apple brings back two bananas and every traded banana brings back 0.5 apples.

With a small number of traders, the price is unlikely to be competitive. If players are allowed to re-trade after the realized price becomes known, they would, and a new price would emerge. However, when $n$ is large, approximate structural robustness implies being approximately information-proof. So even when the realized price becomes known, no player has significant incentive to re-trade,
that is, the price is approximately competitive (\(\text{Prob}[\text{some player can } \varepsilon \text{-improve his expected payoff by re-trading at the observed price}] \leq \rho\)).

This is stronger than classical results relating Nash equilibrium to Walras equilibrium (for example, Dubey, Mas-Colell and Shubik, 1980). First, being conducted under incomplete information, the above relates Bayesian equilibria to rational expectations equilibria (rather than Walras). Also the competitive property described here is substantially stronger, due to the immunity of the equilibria to alterations represented by extensive games. If allowance is made for spot markets, coordinating institutions, trade on the Web, and so on, the Nash-equilibrium prices of the simple simultaneous-move game are sustained through the intermediary steps that may come up under such possibilities.

**Remark 7: Embedding a game in bigger worlds**

Alterations allow the inclusion of outside players who are not from \(G\). Moreover, the restrictions imposed on the strategies and payoffs of the outsiders are quite limited. This means that alterations may describe bigger worlds in which \(G\) is embedded. Structural robustness of an equilibrium means that the small-world (\(G\)) equilibrium remains an equilibrium even when the game is embedded in such bigger worlds.

**Remark 8: Self-purification**

Schmeidler (1973) shows that in a normal-form game with a continuum of anonymous players, every strategy can be purified, that is, for every mixed-strategy equilibrium one can construct a pure-strategy equilibrium (Ali Khan and Sun, 2002 survey some of the large follow-up literature).

The *ex post* Nash property above constitutes a stronger (but asymptotic) result. Since the resulting play of a mixed strategy equilibrium yields pure-strategy profiles that are Nash equilibria (of the perfect information game), one does not need to construct pure-strategy equilibria: simply playing a mixed-strategy equilibrium yields pure-strategy profiles that are equilibria.

The approximate statement is: for every \((\varepsilon, \rho)\) for sufficiently large \(n\), \(\text{Prob}[\text{ending at a pure strategy profile that is not an } \varepsilon \text{ Nash equilibrium of the realized perfect information game}] \leq \rho\). Since both \(\varepsilon\) and \(\rho\) can be made arbitrarily small, this is asymptotic purification. Note that the model of Schmeidler, with a continuum of players, requires non-standard techniques to describe a continuum of independent random variables (the mixed strategies of the players). The asymptotic result stated here, dealing always with finitely many players, does not require any non-standard techniques.

**Remark 9: ‘As if’ learning**

Kalai and Lehrer (1993) show that in playing an equilibrium of a Bayesian repeated game, after a sufficiently long time the players best-respond as if they know their opponents’ realized types and, hence, their mixed strategies.

But being information-proof, at a structurally robust equilibrium (even of a one shot game) players’ best respond (immediately) as if they know their opponents’ realized types, their mixed strategies and even the pure-strategies they end up with.

**Sufficient conditions for structural robustness**

**Theorem 1: Structural Robustness** (rough statement): the equilibria of large one-simultaneous-move Bayesian games are (approximately) structurally robust if
Payoff anonymity means that in addition to his own type and pure-strategy, every player's payoff may depend only on aggregate data of the opponents' types and pure-strategies. For example, in the computer choice game a player's payoff may depend on her own type and choice, and on the proportions of opponents in the four groups: \(I\)-types who chose \(I\), \(I\)-types who chose \(M\), \(M\)-types who chose \(I\), and \(M\)-types who chose \(M\).

The players in the games above are only semi-anonymous, because there are no additional symmetry or anonymity restrictions other than the restriction above. In particular, players may have different individual payoff functions and different prior probabilities (publicly known).

The continuity condition relates games of different sizes and rules out games of the type below.

**Example 4: Match the expert**

Each of \(n\) players has to choose one of two computers, \(I\) or \(M\). Player 1 is equally likely to be one of two types: ‘an expert who is informed that \(I\) is better’ (\(I\)-better) or ‘an expert who is informed that \(M\) is better’ (\(M\)-better). Players 2, \ldots, \(n\) are of one possible ‘non-expert’ type. Every player's payoff is one if he chooses the better computer, zero otherwise. (Stated anonymously: choosing computer \(X\) pays one, if the proportion of the \(X\)-better type is positive, zero otherwise.)

Consider the equilibrium where player 1 chooses the computer he was told was better and every other player chooses \(I\) or \(M\) with equal probabilities. This equilibrium fails to be *ex post* Nash (and hence, fails structural robustness), especially as \(n\) becomes large, because after the play approximately one-half of the players would want to revise their choices to match the observed choice of player 1. (With a small \(n\) there may be ‘accidental *ex post* Nash’, but it becomes extremely unlikely as \(n\) becomes large.)

This failure is due to discontinuity of the payoff functions. The proportions of \(I\)-better types and \(M\)-better types in this game must be either \((1/n, 0)\) or \((0, 1/n)\), because only one of the \(n\) players is to be one of these types. Yet, whatever \(n\) is, every player's payoff is drastically affected (from 0 to 1 or from 1 to 0) when we switch from \((1/n, 0)\) to \((0, 1/n)\) (keeping everything else the same).

As \(n\) becomes large, this change in the type proportions becomes arbitrarily small, yet it continues to have a drastic effect on players' payoffs. This violates a condition of uniform equicontinuity imposed simultaneously on all the payoff functions in the games with \(n=1, 2, \ldots\) players.

Laspeyres, Ernst Louis Etienne (1834–1913)

W.E. Diewert

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Drobisch price index; index numbers; Laspeyres index; Laspeyres, E. L. E.

Article

Laspeyres was born at Halle, Germany, on 28 November 1834 and died on 4 August 1913 at Giessen, Germany.

From 1853 to 1857, he studied at the universities of Tübingen, Berlin, Göttingen and Halle. He received a law degree from the University of Halle in 1857. He studied at the University of Heidelberg from 1857 to 1859, and in 1860 he obtained his Ph.D. from Heidelberg for the thesis, ‘The Correlation between Population Growth and Wages’.

From 1860 until 1864 he worked as a lecturer at Heidelberg, where he wrote a history of the economic views of the Dutch (1863). In the following ten years, he taught at four different universities: 1864 – Basel; 1866 – the Polytechnic at Riga; 1869 – Dorpat; 1873 – Karlsruhe. Finally, from 1874 to 1900, he taught at the Justus-Liebig University at Giessen.

Laspeyres’ main contribution to economics was his development of the index number formula that bears his name. Let the price and quantity of commodity \( n \) in period \( t \) be \( p_n^t \) and \( q_n^t \) respectively for \( n = 1, \ldots, N \) and \( t = 0, 1, \ldots, T \). Then the Laspeyres price index of the \( N \) commodities for period \( t \) (relative to the base period 0) is defined as

\[
P_L = \frac{\sum_{n=1}^{N} p_n^t q_n^0}{\sum_{n=1}^{N} p_n^0 q_n^0}.
\]

Laspeyres wrote his classic paper (1871), which suggested the above formula partly as an outgrowth of
Laspeyres, Ernst Louis Etienne (1834–1913) : The New Palgrave Dictionary of Economics

His empirical work on measuring price movements in Germany and partly to criticize the index number formula of Drobisch (1871). Using the notation defined above, the Drobisch price index for period $t$ is defined as

$$P_D = \frac{\sum_{n=1}^{N} p_n^t q_n^t / \sum_{n=1}^{N} q_n^t}{\sum_{n=1}^{N} p_n^0 q_n^0 / \sum_{n=1}^{N} q_n^0}.$$

Laspeyres criticized this formula by showing that the index generally changed even if all prices remained constant (that is, $P_D$ does not satisfy an identity test, to use modern terminology). An even more effective criticism of $P_D$ is that it is not invariant to changes in the units of measurement (whereas $P_L$ is invariant).

Laspeyres did not write any further papers on index number theory. He wrote papers on economic history, the history of economic thought and on topical economic issues of his time; see Rinne (1981).

Born in Breslau, 13 April 1825; died in Geneva, 31 August 1864. The only son of a prosperous Jewish silk merchant, Lassalle studied philosophy and history at the University of Breslau and subsequently at the University of Berlin, where he encountered the radical ideas of the ‘Young Hegelians’ and of the French socialist thinkers. During the 1848 revolution he was associated with Marx and the *Neue Rheinische Zeitung*, and was arrested for his activities but acquitted by a jury in 1849. In the course of his short and turbulent life (which ended as a result of an absurd duel with the former fiancé of a woman he wished to marry), Lassalle became known primarily as a political and economic theorist, and as a leading figure in the radical and working-class movements, who organized in 1863 the first socialist party in Germany (the General Union of German Workers).

Lassalle's economic ideas were derived to a large extent from Marx, often without acknowledgement, but he diverged from the latter in important respects. As Bernstein (1891) observed: ‘Lassalle was much more indebted to Marx than he admitted in his writings, but he was a disciple of Marx only in a restricted sense.’ The main divergence can be summarized as the substitution of an evolutionary conception of the movement from capitalism to socialism for Marx's idea of a revolutionary transition. In his ‘Workers’ Programme’ (1862) and his ‘Open Letter’ (1863), Lassalle advocated a course of political action for the working-class movement with two principal aims: first, the achievement of universal and equal suffrage; second, the development, with state aid, of workers’ cooperatives that would lead to a gradual socialization of the economy. His reliance upon the action of the state (conceived in the manner of Hegel rather than Marx) was very great, and in the ‘Open Letter’ he adduced an ‘iron law of wages’, derived from classical political economy, to show that neither individually nor collectively could workers improve their conditions of life except by replacing the wage system with self-employment (cooperative production), for which the necessary capital must be...
provided by the state. It was in this context that Lassalle responded to Bismarck's invitation (11 May 1863) to express his views on ‘working class conditions and problems’ and subsequently had several meetings with him; a course of action which Engels (letter to Kautsky, 23 February 1891) later assessed harshly as a step towards allying the workers’ movement with German nationalism and the monarchy. Marx had a low opinion of Lassalle's abilities as an economist and political thinker, and in his *Critique of the Gotha Programme* (1875) on the occasion of the unification of the two existing German workers’ parties (the Social Democratic Workers’ Party and the General Union of German Workers) he strongly criticized the Lassallean ideas which were embodied in the draft programme; in particular, the erroneous restriction of ownership of the instruments of labour to the capitalist class, excluding landowners, and the confused notion of an ‘iron law of wages’, which is simply, Marx argued, ‘the Malthusian theory of population’.

Article
Born into a Scottish aristocratic family, Lauderdale entered the House of Commons at the age of 21 as a supporter of the Liberal Whig leader Charles Fox. Following the death of his father, he entered the House of Lords in 1790, where he became known for his defence of civil liberties. After a visit to France in 1792 he publicly expressed sympathy for the ideals of the French Revolution and supported a motion in Parliament (1795) to make peace with the new government of France. In his middle years he swung over to the Tory side and adamantly opposed most economic and political reform measures, especially bills to protect labour (even one which would restrict the use of young children in cleaning chimney flues). His views covered the political spectrum: in 1792 he flirted with Jacobinism, becoming a founding member of the Friends of the People; 40 years later he worked against the Reform Bill of 1832. He died in 1839 at 80, a ripe age indeed for a man known for his apoplectic temper.

Lauderdale had a sustained interest in trade policy, but here he also shifted ground. In 1804 he argued ‘that all impediments thrown in the way of commercial communication, obstruct the increase of wealth’ (1804, p. 365). Yet in his pamphlet A Letter on the Corn Laws (1814) he claimed Adam Smith was in error, and advocated protection for agriculture, a position which he strongly held in the House of Lords for some 20 years.

Apart from some tracts on currency questions and debt policy, Lauderdale's contributions to economic thought are found in one major work, An Inquiry into the Nature and Origin of Public Wealth (1804). A second edition (1819) contained only minor revisions. This suggests that Lauderdale's involvement with economic theory was a one-time affair. The intellectual ferment generated by Ricardo's Principles (1st and 2nd editions), and the earlier tracts by Malthus, Edward West, and Ricardo on rent and profits seems
to have passed him by: no mention of his contemporaries or the theoretical issues which they raised appeared in his new introduction or in the footnotes to the 1819 edition. The focus of both editions is the Wealth of Nations, and a large part of the Inquiry is given over to a negation of Smith's conclusions. Specifically, Lauderdale asserts that: (1) the maximization of private riches does not lead to maximum public wealth and welfare; (2) labour is not the cause of value or an adequate measure of value; (3) division of labour is not a major factor in economic growth; (4) parsimony and saving are frequently a public detriment as they may lead to over-investment and a capital glut; and (5) government tax revenues applied to rapid debt reduction (‘a forced conversion of revenue into capital’) will reduce aggregate consumption, deflate profits and capital values, and result in economic distress.

In developing these ideas Lauderdale exposes his deficiencies as a thinker. His analysis is sketchy, his style prolix and repetitious, and his conclusions based on weak or incomplete reasoning occasionally seem pretentious. Not surprisingly, his contemporaries focused on these flaws. Henry Brougham wrote a long very critical commentary on Lauderdale's Inquiry in the Edinburgh Review (July 1804), to which Lauderdale responded with an acerbic but not too effective pamphlet. Ricardo exposed several of his logical errors (Ricardo, 1823, pp. 267–77, 371n., 384–5), and Malthus, who on a number of issues (capital glut, value theory and agricultural protectionism) was his intellectual heir, failed to acknowledge his intellectual debt; instead, he accused Lauderdale of ‘going too far’ in his condemnation of parsimony and savings (Malthus, 1836, p. 314), even though, as we shall see, their arguments were quite similar.

Despite the negative opinions of his contemporaries, and his modest theoretical ability, Lauderdale now occupies a firm, albeit secondary, place in the history of economic doctrine. We may ask why. The answer I believe lies in the fact that Lauderdale had a number of valuable insights into the workings of the economy which later economists thought important. Böhm-Bawerk considered Lauderdale's theory of profit a limited but significant step towards the true and complete explanation of interest and profit (that is, his own theory). Following the appearance of Keynes's General Theory there was a re-examination of earlier writers who might have anticipated Keynesian ideas on saving, investment and employment. Malthus obviously was placed in the centre of this pantheon of economists, and Lauderdale as an earlier thinker espousing similar ideas was accorded lesser status. This is not a wholly satisfactory way of evaluating past intellectual contributions, but there is no doubt that each age searches for harmonious resonances in the historical literature. Here I shall try to broaden the perspective.

In the Inquiry Lauderdale challenged the natural harmony of interests propounded by Smith; namely, that individuals seeking private riches would lead a nation to maximize public wealth. To destroy this identity, Lauderdale tried to prove that the sum of private riches could increase while public wealth and welfare declined. Unfortunately, Lauderdale obfuscated the problem by treating the individual riches occasionally produced by monopoly or a sudden scarcity of supply as a net addition to aggregate riches when it was clear that Adam Smith meant aggregate riches in real terms, so the scarcity-induced gains of some are more than offset by real losses of others. Furthermore, Lauderdale overlooked Smith's postulate of free competition as a necessary condition for the coincidence of private and public interest. Ricardo came to Smith's defence and cleared up Lauderdale's ten pages of confusion in a couple of succinct paragraphs (Ricardo, 1823, p. 276).

But something positive came out of Lauderdale's discussion of value and riches. His examination of the effect of monopoly on total revenue led to an early and fairly sophisticated discussion of demand curves. Lauderdale reviews empirical estimates of the relationship between a percentage change in the price of a good and the percentage change in the quantity demanded, and notes that for various kinds of consumer
goods elasticities may differ. In addition to the concept of price elasticity, Lauderdale gave us the beginnings of a theory of consumer choice, noting the utility sacrifices involved in giving up alternative bundles of goods when consumers make new choices in response to price changes (1804, pp. 59–86). Not surprisingly, Lauderdale rejected the labour theory of value, both as a cause of value and a measure of value (1804, p. 12). Although he related consumer preferences to demand, and was aware of demand in the schedule sense, he failed to relate costs to supply, and hence his theory of value suffered the inadequacies of all the early supply and demand theories, a weakness which Ricardo pointed out (1823, pp. 384–5).

We now come to the section of the Inquiry which has been of most interest in the post-Keynesian period: that dealing with saving, investment and fiscal policy. Lauderdale argues that the social benefits from savings have distinct limits: ‘In every state of society, a certain quantity of capital, proportioned to the existing state of knowledge of mankind, may be usefully and profitably employed.’ Invention may enlarge the scope for the application of capital, but outlets for profitable investment are still limited by the demand for consumer goods (Lauderdale, 1804, p. 227). Individual parsimony may be misguided, but the harm it does tends to be offset by the prodigality of others. However, when a belief in parsimony leads to bad legislation such as a mandated sinking fund, which forces an increase in public parsimony through taxation and debt reduction, then the results may be ‘fatal to the progress of wealth’ (Lauderdale, 1804, pp. 228–30, 271). But there remains the question of what is the mechanism by which high savings rates or forced parsimony become ‘fatal to the progress of wealth’. Superficially this discussion of the evils of parsimony has a Keynesian air to it, but actually Lauderdale (and Malthus) go on to describe a situation in which savings are invested, and it is over-investment relative to restricted consumption (made lower by taxation) which finally produces a collapse in profitability.

It is noteworthy that both writers developed a model in which productive applications of net additions to the capital stock are dependent on increases in consumption. They both also failed to recognize that for long periods a nation can use part of its investment for further investment – a deepening of the capital structure or, in Böhm-Bawerk's terms, a lengthening of the period of production, certainly an attribute of 19th-century capitalism. Whatever their limitations, it seems clear that the macroeconomic contributions of Lauderdale and Malthus are more closely related to the growth models of the Harrod–Domar type than to a short-run Keynesian analysis in which output drops because savings are not invested.

Nevertheless, there is a tenuous connection with Keynes when we look at their descriptions of the late phase of the over-investment cycle. For Lauderdale over-investment reduces profits and the value of capital, and the resulting low prices ‘discourage reproduction’. When we observe such deflation we ‘must be cautious not to mistake for the effects of abundance that which in reality may be only the effect of failure of demand’ (Lauderdale, 1804, pp. 263–4). Malthus wrote in a similar vein when he pointed to owners of floating capital vainly seeking investment outlets in the glutted capital markets of Europe (Malthus, 1836, p. 420).

We may conclude that the Lauderdale–Malthus theory of total output was not for the most part in the Keynesian mould, but surely that is no reason to downgrade it. Both men saw defects in the Smith–Say–Ricardo theory of total output and employment, and they recognized that restricted consumption and high rates of saving and investment could lead to a sectoral imbalance – a glut of capital, falling profits and, finally, a drop in the inducement to invest. In the policy arena, Lauderdale used these insights to oppose tax surpluses and debt reduction in a period of recession (Paglin, 1961, pp. 98–107; Lauderdale,

cost-push inflation; free silver; Laughlin, J. L.; quantity theory of money; Veblen, T.

Article

Scholar, teacher, monetary reformer and university administrator, Laughlin was born in Deerfield, Ohio of middle-class parents of modest means. A scholarship plus outside work, largely tutoring, enabled him to attend Harvard. After completing his undergraduate study in history, he did graduate work under Henry Adams, receiving a Ph.D. for a thesis on ‘The Anglo-Saxon Legal Procedure’. His subsequent academic career, however, was entirely in economics.
From 1878 to 1888 he taught at Harvard, from 1888 to 1890 he was successively Secretary and President of the Philadelphia Manufacturers’ Mutual Fire Insurance Company, from 1890 to 1892 Professor of Political Economy and Finance at Cornell, and in 1892 was persuaded by President Harper to become Head Professor of Political Economy at the new University of Chicago, the position he held until he retired in 1916. From 1916 until his death in 1933 he continued his scientific writing and public activities.
Laughlin's scholarly work was almost entirely in the field of money and banking. Much of it, notably his History of Bimetallism in the United States (1885), consisted of a thorough and extremely careful presentation of historical evidence on the development of money and monetary institutions. But Laughlin also wrote extensively on monetary and banking theory, and on proposals for monetary reform. His work on these topics was marred by a dogmatic and rigid opposition to the quantity theory of money, an opposition that developed out of his public activities opposing the free silver movement. The proponents of free silver used a crude form of the quantity theory to support their position, which sufficed to render the theory anathema to Laughlin.
Laughlin's attack on the quantity theory had much in common with recent cost-push or structural or supply shock theories of inflation, in emphasizing the role of factors affecting specific goods and services rather than general monetary influences. Then, as now, such theories ran against the major stream of monetary analysis as exemplified in Laughlin's time by the work of Irving Fisher. As a result,
Laughlin, James Laurence (1850–1933) : The New Palgrave Dictionary of Economics

his writings on theory have had no lasting influence on economic thought. According to Wesley C. Mitchell, one of his students,

Professor Laughlin's indubitable success as a teacher puzzled many who did not pass through his classroom. He was not an original thinker of great power. He did not enrich economics … . He did not even keep abreast of current developments in economic theory … . He had a prim and tidy mind, which he kept in perfect order by admitting nothing that did not harmonize with the furnishings installed in the 1880's … . Yet he held that a teacher's aim should be 'the acquisition of independent power and methods of work, rather than specific beliefs'.

The very limitations I have listed helped Professor Laughlin to accomplish this aim. … [His] honesty of purpose impelled others to be honest, which meant that doubting students had to work out the reasons for their dissent … . Laughlin forced one to face intellectual conflicts in his own mind and find out where he stood in the world of ideas. That, I have long believed, was the secret of his success in helping so many students of such diverse capacities to make the most of their several gifts. (1941, pp. 879–80)

As monetary reformer, Laughlin was a leading opponent of the advocates of free silver. He wrote, lectured, and campaigned extensively in favour of 'hard money'. In his widely circulated free-silver pamphlet, Coin's Financial School, William Hope Harvey used Laughlin as a hard-money foil for the fictional Coin's free-silver argument. That episode terminated in a widely reported public debate in Chicago in 1885 between Laughlin and Harvey.

After the defeat of William Jennings Bryan and the free-silver forces in the presidential election of 1896, financial and commercial interests in the country organized the Indianapolis Monetary Commission to develop proposals for reform of the monetary and banking system. One of the 11 members of the commission, Laughlin was also the author of its extensive final report, which served as an important stepping-stone en route to the Aldrich–Vreeland Act of 1908 and the Federal Reserve Act of 1913. In addition, Laughlin served for nearly two years from 1911 to 1913, on leave from the University of Chicago, as full-time chairman of the executive committee of the National Citizens League, an organization formed to mobilize public opinion in favour of banking reform.

Laughlin's close links with the Republican Party prevented him from playing any public role in the final preparation of the Federal Reserve Act under a Democratic administration. However, he exerted considerable influence behind the scenes through extensive private correspondence with his former student and assistant, H. Parker Willis, who, as banking expert for the House Banking and Currency Committee, has been regarded as primarily responsible for drafting the Act.

Laughlin's most important and lasting contribution was as head of the Department of Political Economy of the new University of Chicago. Though himself a hard-money man of rigidly conservative views, he demonstrated an extraordinary degree of tolerance for divergent views in staffing and guiding the department. At the very outset, he brought with him from Cornell Thorstein Veblen, who remained in the department for 14 years, the longest period Veblen spent at any single university during his stormy career. Veblen served as managing editor of the Journal of Political Economy, which Laughlin founded as one of his first acts at Chicago. Laughlin himself was the editor. As John U. Nef wrote in his obituary
notice of Laughlin, ‘his wide cultural interests combined with his other qualities to enable him to gather about him a more remarkable group of younger men than was to be found in any other economics department in the country and to help these men in making the most of their own gifts.’ Nef notes that a very considerable portion of all the men who have made an important mark in economic thought between 1895 and 1930, beginning with Thorstein Veblen and coming down to Jacob Viner (Laughlin’s last appointment) were connected at one time or another, as members or students, with the department of political economy. … Laughlin frequently chose the best men when they were of very different persuasions from his own. … And so it came about that one of the most conservative heads of an economics department in the country had politically the most liberal and economically the least orthodox department. (1934, p. 2)

Laughlin's emphasis on quality rather than ideology was combined with an emphasis on research by his faculty, as well as by graduate students as part of their training. A corollary was his belief in personal teaching as opposed to formal lecturing. These have remained key characteristics of the Chicago Department of Economics from that day to this. In more recent years, as in his day, the department has been widely regarded as a stronghold of proponents of a free-market economy. That reputation was justified in the sense that throughout the period the department had prominent members who held these views and presented them effectively. But they were always a minority. The department has been characterized by heterogeneity of policy views, not homogeneity. The economists at Chicago who held the generally fashionable views – who were ‘liberal’ in the 20th-century sense – could be matched at other institutions; the ones who were ‘liberal’ in the 19th-century sense could not be. That, plus the emphasis on economics as a serious scientific subject, capable of being tested by empirical and historical evidence, and of being used to illuminate important practical issues of conduct and policy, made Chicago economics unique. These were Laughlin's bequest to the department he built.

discrimination; quantity theory of money; rate of interest; rent; transportation economics; wage
differentials; Walras, L.

Article
Launhardt was born on 4 April 1832 in Hannover, where he died on 14 May 1918. His work is
Germany's most important and in fact only significant contribution to the ‘marginal revolution’ in the
last three decades of the 19th century. In the economic analysis of transportation and location, this
contribution was not surpassed until the 1930s. Available only in German, some of it in publications that
are hard to find, it still has not found the recognition it deserves, and Schumpeter's references in the
History of Economic Analysis are inadequate.
Like Dupuit, Launhardt began his professional life as a civil engineer, working for the public road
administration. In 1869 he joined the faculty of the Hannover Polytechnic Institute as a professor for
roads, railways and bridges. This was the beginning of a distinguished academic career, in the course of
which he served as the director of the institute and, when it became the Technische Hochschule
Hannover, its first rector. He was made a member of the Königliche Akademie des Bauwesens and of
the Preussische Herrenhaus. Dresden gave him an honorary degree for his contributions to the
technology and economics of transportation.
Practical problems of highway planning led Launhardt to the gradually more general analysis of efficient
transportation networks. This work was later systematized in Theorie des Trassirens (Theory of
Network Planning). Part I, entitled ‘Commercial Network Planning’, contains the derivation of
efficiency criteria without regard to topography. This part is the second edition, much revised and
enlarged, of the 1872 publication, and also incorporates sections from the 1885 book. Part II, entitled
‘Technical Network Planning for Railroads’, applies economic efficiency criteria to curves and gradients
imposed by topography; an earlier version was published in 1877.
The contributions to economics are found in Part I. This begins with a discussion of investment criteria. From a social point of view, networks should be planned in such a way that the sum of operating and capital costs is a minimum. Private capitalists, however, try to maximize the internal rate of return on their capital. Under perfect competition the two criteria would coincide, since the internal rate of return, if duly maximized, would equal the market rate of interest. In reality, however, since the railroad industry is inherently non-competitive, rates of return can be pushed above market rates of interest by keeping railroad investment below the social optimum. This was one of Launhardt's basic arguments for government ownership of railroads. For his own analysis he uses, of course, the social criterion. Using geometry and calculus, Launhardt derives rules, depending on freight costs and volumes, for the optimal direction and density of highways connecting given market centres. He shows that highways of different quality (and thus with different freight costs) should meet at angles analogous to those of refracted light, a rule later popularized by Stackelberg as the ‘law of refraction’. According to the ‘law of nodes’, transport costs on a star-shaped transportation network connecting three cities are minimized if the sines of the angles between its rays bear the same proportions as the total transportation costs per mile along the rays. The efficient combination of different modes, like highways, waterways and railways, is also considered.

Applying his analysis of network nodes to the location of plants, Launhardt produced the first substantial theory of industrial location (1882). In this basic contribution he determines the efficient location of a plant with given sources of supplies and given sales outlets by minimizing transportation costs. The optimum is found by an ingenious geometrical construction which became known as the ‘pole principle’, later amplified by Palander. It is given a mechanical interpretation as the centre of gravity of forces, representing freight rates, acting at the different input and output locations. After first assuming that the network of routes is being planned from scratch, Launhardt also derives rules for optimal additions to existing networks. The analysis is far superior to that in Alfred Weber's later book on the location of industries, in which Launhardt is not mentioned, and whose only claim to attention is the appendix by Georg Pick.

Launhardt's main contribution to the theory of railway rates is found in chapter 32 of (1885). It was elaborated in (1887) and further detail was added in (1890a) and (1890b), but these extensions add nothing for more general economic interest. The paper on ‘Economic Problems of the Railway Industry’ provides an extensive analysis, based on consumer surplus, of the social rate of return of railroads, both theoretical and numerical, including a cost–benefit analysis of future railway development.

For railway rates, Launhardt establishes the principle that the maximization of social welfare requires – in modern terminology – marginal cost pricing. But this, in turn, requires competition, while profit maximization by monopolistic railway firms implies that rates exceed marginal cost. In particular, if a railway transports homogeneous goods from a uniform plain to a market centre, the monopoly price is calculated to exceed marginal cost by 50 per cent (because, in modern terminology, freight volume reacts to the freight rate with an elasticity of – 2 and ton-miles thus with an elasticity of – 3). As a consequence, the freight volume is suboptimal. By perfect discrimination according to ‘what the traffic will bear’ over each distance, both railway profits and general welfare can be increased compared with simple monopoly. This, however, is only a second-best solution. For Launhardt, the efficiency of marginal cost pricing is another basic argument for government ownership.

Launhardt's main claim to a prominent place in the history of economic analysis is his slender treatise *Mathematische Begründung der Volkswirtschaftslehre* (Mathematical Foundations of Economics) of
1885. It was written in the light of Walras's *Mathematische Theorie der Preisbestimmung wirtschaftlicher Güter* (1881) and the second edition of Jevons's *Theory of Political Economy* (1879). At the same time, it is clearly pre-Marshall and pre-Edgeworth (though *Mathematical Psychics* had appeared in 1881). Two other books by Walras, sent by the author, arrived too late to be of use, nor was Launhardt acquainted with Cournot at that time. He reports that the copy he finally obtained from a library had apparently never been read, and Gossen could nowhere be found (because virtually no copies had been sold). Launhardt shows what a competent engineer with an economic turn of mind and a little calculus could do (and also what he could not do) in economics a hundred years ago. Launhardt's addiction to special functional forms, particularly quadratic utility functions, often results in spurious precision, limited generality and reduced lucidity, but the basic contributions are sound, important and original.

In his theory of exchange (Part I), Launhardt rightly criticizes Walras for believing (if taken literally) that there is no way for a trader to improve his position relative to free competition at uniform prices. His counter-examples relate to monopoly and price discrimination, leading him to the idea of an optimal tariff. While valid in principle, this analysis falls short of Edgeworth's. The discussion of the total gain from trade and its distribution, whose shortcomings were pointed out by Wicksell, was soon obsolete because of its dependence on the interpersonal additivity of utility.

In his discussion of distributive shares, Launhardt recognizes the backward-bending supply curve of labour and the effect of property incomes on labour supply and thus on wages. He also recognizes that the inter-occupational mobility of labour tends to equalize relative wage rates with both the ratios of the marginal products of labour and (to the extent an individual can choose between occupations) the ratio of its marginal disutilities. For profits, Launhardt's 'basic equation' expresses, substantially, the familiar optimality condition that the profit margin, as a percentage of price, is the inverse of the elasticity of demand (though this concept is not used, of course). It is clearly explained that the entrepreneur, in setting his price, considers only marginal costs, while prices are equalized to the average costs of the marginal firm by exit and entry. The profits of intra-marginal firms are correctly interpreted as rents, and the same principle is used to explain wage differentials.

Launhardt's theory of interest is Jevonian in spirit. Though brief and somewhat sketchy, it anticipates all the basic elements of Fisher's theory. In many respects Launhardt achieves more in 20 pages than Böhm-Bawerk in about 500. Using modern terminology, the rate of interest is explained by the interplay between a psychological preference for present consumption, modified by variations in expected income, and the marginal productivity of capital (ch. 24). Saving is interpreted as a sacrifice of current consumption for the sake of an infinite stream of additions to future consumption. It is shown mathematically that, with a rising rate of interest, given the rate of time preference, saving first rises to a maximum and then declines, because at high interest rates small savings are enough to buy a lot of future income. According to the 'basic principle of accumulation’, the present value of the future marginal utility of income is made equal to the current marginal utility of income. In the course of time, optimal saving, if initially positive, will decline until a steady state is reached (ch. 15). Investments will be made up to the point where the marginal saving in operating costs is equal to the rate of interest.

The subject of Part III is the effect of transportation on production and consumption. Launhardt starts out by determining production and prices of a single seller supplying an unlimited market of uniform density. Delivered prices are seen to rise towards the periphery in the shape of a hollow cone, known as the ‘Launhardt Funnel’ (ch. 27). If sellers of differentiated products compete in a uniformly populated...
plain, their market areas are shown to be polygons, whose sides, depending on circumstances, are pieces of ellipses, hyperbolas or straight lines. In this context there emerges what Palander later called the Launhardt–Hotelling solution for heterogeneous duopoly. Forty-four years before Hotelling, Launhardt already used the paradigm of two competing suppliers, located at different points along a street, each maximizing his profits on the assumption that the price of his competitor is given. His solution, forgotten for half a century, is substantially identical to Hotelling's. An analogous analysis is provided for suppliers of differentiated products at the same location, showing how their ring-shaped market areas depend on transportation costs (ch. 29).

From the market areas of given suppliers, Launhardt shifts his attention to the supplying areas of given markets, which brings rent to the foreground. His description of the product ‘rings’ surrounding a single market city in an unlimited plain adds nothing to Von Thünen (ch. 30). The analysis is then extended to a number of markets, each with its limited supplying area. If identical cities are located in a pattern of regular triangles, the supplying areas are, of course, hexagonal. While this foreshadows Lösch's later work, Launhardt's triangular pattern is based on intuition and not on explicit optimality conditions. It is shown, however, how the mutual limitation of adjoining supplying areas raises rent and product prices (ch. 31). Much of this material was later incorporated in the second edition of Commercial Network Planning (1887).

Launhardt's monetary theory is far inferior to his microeconomics. Its centrepiece is the rejection of the quantity theory of money. In part, this is based, in the tradition of Senior and the Banking School, on the argument that under a gold standard an increase in the quantity of paper money just leads to an external (and/or internal) gold drain, while commodity prices remain tied to international prices or, in a closed economy, the gold price. To this extent, Launhardt is on firm ground. He went much further, however. In the theory of relative prices he had assumed that the marginal utility of money is constant. When first introduced, this was an innocuous simplification, but in the theory of money it became the source of fatal confusion, for it induced Launhardt to treat money incomes, which he chose as the proximate determinant of absolute prices, as if they were ‘real’ variables, independent of the money supply. After that, one is hardly surprised to read that higher interest rates result in higher prices and that gold discoveries have no influence on prices. The basic argument is found in Mathematische Begründung (1885); later elaborations (1889; 1894) and historical illustrations and applications.

The most familiar version of the law of demand says that as the price of a good increases the quantity demanded of the good falls. The principal use of the law of demand in economic theory is to provide sufficient and, in some contexts, necessary conditions for the uniqueness and stability of equilibrium, and for intuitive comparative statics. To guarantee such properties in equilibrium models with more than one good, the familiar one-good law of demand just stated is not sufficient – some multi-good version of the law is needed. In its multi-good form, the law of demand is said to hold for a particular change in prices if the prices and the quantities demanded move in opposite directions; in formal terms, the vector of price changes and the vector of resulting demand changes have a negative inner product.

In this article, we examine different formulations of the law of demand. They differ principally in the
The law of demand: The New Palgrave Dictionary of Economics

Domain of price changes over which the law applies. It is not always the case that the law of demand is required to hold for all price changes: the version of the law which is required for stability analysis and comparative statics varies from one context to another. For each formulation of the law of demand, we discuss the conditions which are sufficient to guarantee that it is satisfied.

To point out the obvious, the law of demand, in whatever form, is not a universal law at all but a condition which may hold in some situations and not others. It is well known that, in transactions where asymmetric information is an important consideration, violations of the law can occur. For example, lowering the price of a set of used cars does not necessarily lead to higher demand if potential buyers think that the lower price reflects the quality of the cars being offered. (For a discussion of violations of the law of demand and other issues which arise when price has an impact on the perceived quality of the good being exchanged, see Stiglitz, 1987.) In this article we make the classical assumption that the features of the good being transacted are commonly known and independent of the price. As we shall see, even in this classical setting various forms of the law of demand will hold only under conditions which are often neither obviously onerous nor obviously innocuous; in these cases, one must necessarily turn to empirical work to ascertain whether or not the law holds.

We use the notation and terminology of Mas-Colell, Whinston and Green (1995, chs. 2, 3, 5) and assume that the reader is familiar with the basic consumer and producer theory described there. We assume that there are \( L \) commodities and that consumers are price-takers. The demand of a consumer of type \( \alpha \) with income \( w \) at price vector \( p = (p_1, \ldots, p_L) \in \mathbb{R}_+^L \), satisfying the budget identity \( p \cdot x(p, w, \alpha) = w \) for all \( p \) and \( w \). Unless stated otherwise, we assume the demand function \( x(\cdot, \cdot, \alpha) \) to be \( C^1 \). Then it has a Slutsky matrix of substitution effects \( S(p, w, \alpha) \) with \( j \)-element \( S_{j} (p, w, \alpha) = \partial x_{j}(p, w, \alpha) / \partial p_{j} + [ \partial x_{j}(p, w, \alpha) / \partial w ] x_{j}(p, w, \alpha) \). The Slutsky matrix \( S(p, w, \alpha) \) is the Jacobian matrix of the Slutsky-compensated demand function \( x^* \), defined by \( x^*(q) = x(q, q \cdot x(p, w, \alpha), \alpha) \), evaluated at \( q = p \). The term \( [ \partial x_{j}(p, w, \alpha) / \partial w ] x_{j}(p, w, \alpha) \) is called an income effect since it approximates the effect on the demand for good \( j \) when income rises enough to compensate for a unit increase in the price of good \( j \). If the consumer chooses demand bundles by maximizing a well-behaved utility function, then the Slutsky matrix is symmetric and negative semidefinite. The latter means that \( \nabla \cdot S(p, w, \alpha) \nabla \leq 0 \) for all \( \nabla \in \mathbb{R}_+^L \); in particular, the diagonal terms of the Slutsky matrix are non-positive.

One-good and multi-good laws of demand

The term ‘law of demand’ most often refers to the effect of price changes on consumers with fixed incomes. The law for a single good \( \bullet \) and a single consumer of type \( \alpha \) is

\[
(p_q - \bar{p}_q)(x_q(p, w, \alpha) - x_q(\bar{p}, w, \alpha)) \leq 0,
\]

(1)
for \( p \) and \( \vec{p} \), with \( \rho_i \rho_i = \vec{\rho}_i \) for all \( i \neq \ell \) and income \( w \) fixed. (In the strict version of the law, the weak inequality in (1) is replaced by strict inequality when \( \rho \neq \vec{\rho} \); all the laws of demand discussed in this article can be stated in their corresponding strict forms, though we generally do not do so.) The inequality (1) is equivalent to

\[
0 \geq \frac{\partial x_\ell}{\partial \rho_\ell} (p, w, \alpha) = S_\ell \ell (p, w, \alpha) - x_\ell (p, w, \alpha) \frac{\partial x_\ell}{\partial w} (p, w, \alpha), \quad \forall (p, w).
\]

It holds if the substitution effect \( S_\ell \ell \) is negative and larger in magnitude than the income effect \( x_\ell (p, w, \alpha) \frac{\partial x_\ell}{\partial w} (p, w, \alpha) \). If the consumer is utility-maximizing, then \( S_\ell \ell \leq 0 \), so a sufficient condition for good \( \bullet \) to obey the law of demand is that the demand for this good is normal \((\partial x_\ell (p, w, \alpha) / \partial w \geq 0)\). If the demand for good \( \bullet \) is not normal, the price effect \( \partial x_\ell / \partial \rho_\ell \) may be positive. This is called a Giffen effect and good \( \bullet \) is called a Giffen good. All goods are normal and Giffen effects are ruled out if the demand function is generated by homothetic preferences or by a concave additive utility function \( u(x) = \sum_{\ell}^L u_\ell (x_\ell) \), or, more generally, by a supermodular concave function \( u \), that is, one in which all commodity pairs are Auspitz–Lieben–Edgeworth–Pareto complements: \( \partial^2 u(x) / \partial x_j \partial x_\ell \geq 0 \) for all \( j \neq \ell \) (Chipman, 1977).

Giffen goods are rarely observed. Sometimes demand for a durable good like oil may increase with its current price if traders expect an even higher price in the future. However, if commodities are distinguished by date, this is not a Giffen effect since a future price changes along with the current price. A possible example of a Giffen good is proposed by Baruch and Kannai (2002). They give evidence suggesting that, in Japan of the 1970s, shochu, a cheap (and, by some accounts, nasty) alcoholic drink, fits the definition. One may explain the demand for shochu in the following way. A consumer chooses between sake (good 1) and shochu (good 2). He always prefers sake to shochu, but he also must have a minimum alcohol intake (which we fix at 1). Formally, his utility is \( u(x_1, x_2) = x_1 \), subject to the ‘survival’ constraint \( x_1 + x_2 \geq 1 \). If the consumer is sufficiently poor, both the budget and survival constraints bind, with the consumer consuming as much sake – and as little shochu – as possible. A fall in the price of shochu allows him to buy less shochu and more sake and still meet his alcohol requirement; this he chooses to do since he always prefers sake to shochu.

Turning now to multi-good laws of demand, let \( P \subseteq \mathbb{R}^L_+ \) be a set of prices and let \( \chi: P \rightarrow \mathbb{R}^L \) be a function representing individual or aggregate demand of firms or of consumers. The natural multi-good generalization of the one-good law in (1) is

\[
(p - p') \cdot (\chi(p) - \chi(p')) \leq 0
\]
for all \((p, p')\) in some subset of \(P \times P\). If \(P\) is convex and open and \(X\) is \(C^1\), (2) holds on \(P \times P\) if and only if the Jacobian matrix \(\partial X(p)\) is negative semidefinite at each \(p\) (Hildenbrand and Kirman, 1988). Suppose that the supply vector of the \(L\) goods changes from \(\omega\) to \(\omega'\). Let \(p\) and \(p'\) be corresponding equilibrium prices so \(X(p) = \omega\) and \(X(p') = \omega'\). Then, if \(X\) obeys (2) for all prices, we obtain \((p - p') \cdot (\omega - \omega') \leq 0\). It is clear that this comparative statics property and the law of demand on \(X\) are essentially two sides of the same coin. Note also that, according to this property, an increase in the supply of good \(k\), with the supply of all other goods held fixed, will lead to a fall in the price of \(k\).

Suppose that \(P\) is open and \(X\) obeys the strict law of demand, that is, \(X\) satisfies (2) with strict inequality for all distinct \(p\) and \(p'\) in \(P\). This implies in particular that \(X\) is \(1-1\) and that, for each \(\overline{\omega}\) in \(X(P)\), there is a unique equilibrium price vector \(\overline{p} = X^{-1}(\overline{\omega})\). A tâtonnement path for the function \(X - \overline{\omega}\) is the solution to \(dp / dt = X(p(t)) - \overline{\omega}\) for some initial condition \(p(0) = p'\) in \(P\). We say that \(X - \overline{\omega}\) is monotonically stable for \(\overline{\omega}\) if each of its tâtonnement paths satisfies \(d|p(t) - \overline{p}|^2 / dt < 0\) whenever \(p(t) \neq \overline{p}\). It is easy to check that \(X - \overline{\omega}\) is monotonically stable for all \(\overline{\omega}\) in \(X(P)\) if and only if \(X\) obeys the strict law of demand. Furthermore, because \(P\) is open, a tâtonnement path for \(X - \overline{\omega}\) which begins at a price sufficiently close to \(\overline{p} = X^{-1}(\overline{\omega})\) stays in \(P\) for all \(t > 0\). Lyapunov's second theorem then guarantees that the tâtonnement path converges to \(\overline{p}\).

Laws of demand are thus useful as intuitive sufficient conditions for the uniqueness and stability of equilibrium and for comparative statics. We will examine, in different contexts, circumstances under which they hold.

**Law of demand for competitive firms and consumers with quasilinear utility**

For a firm with production set \(Y\), profit maximizing net output vector \(y\) at price vector \(p\) and \(\overline{y}\) at \(\overline{p}\) satisfy \(\overline{p} \cdot \overline{y} \geq p \cdot \overline{y}\) and \(\overline{p} \cdot \overline{y} \geq p \cdot y\). The net demand vectors \(x = -y\) and \(\overline{x} = -\overline{y}\) satisfy \(p(x - \overline{x}) \leq 0\) and \(\overline{p}(x - \overline{x}) \geq 0\), hence satisfy the law of demand: \((p - \overline{p}) \cdot (x - \overline{x}) \leq 0\). Similarly, a consumer with utility function \(u(x_0, x) = x_0 + \varphi(x_1, \ldots, x_L)\) (quasilinear with respect to good 0) and with sufficiently high income \(w\) satisfies the law of demand on a restricted domain, where the price of good 0 is fixed (say at 1). This is a special case of the law for firms. The consumer's optimal demand for goods 1 through \(L\) at \(p\) (the price vector for goods 1 to \(L\)) and income \(w\) maximizes \(w - p \cdot x + \varphi(x)\). This is equivalent to profit maximization with \(x\) an input vector and \(\varphi(x)\) the value of output.

Bewley (1977) shows that a long-lived consumer with a random income stream and a random but stationary time-separable utility function, who is constrained from borrowing, will accumulate savings so that the marginal utility of income is nearly constant. In the short run, this consumer acts (nearly) as if its utility is quasilinear with respect to money, and its short run demands for other goods satisfy the law of demand. Vives (1987) formalizes Marshall's idea (in his *Principles*) that consumer demands for goods with small expenditure shares are close to demands generated by quasilinear utility.
Multi-good laws of demand for a consumer

Suppose the demand of a consumer of type $\alpha$ is determined by maximizing a utility function $u^\alpha$. The Hicksian compensated demand $h(p, \bar{u}, \alpha)$ is a bundle that minimizes $p \cdot x$ subject to $u^\alpha(x) \geq \bar{u}$. Keeping the utility level fixed at $\bar{u}$, this Hicksian demand function satisfies the multi-good law of demand: (2) holds for $X(p) = h(p, \bar{u}, \alpha)$. Utility maximization also guarantees that $x(\cdot, \alpha)$ satisfies the weak weak axiom of revealed preference: $p \cdot x(p', w', \alpha) \leq w = p \cdot x(p, w, \alpha) \geq w'$. Equivalently, for any fixed $w$, $x(p) = x(p, w, \alpha)$ satisfies (2) on the restricted domain with $p \cdot x(p') = w$. This is also called the compensated law of demand since the demand vector $X(p')$ remains barely affordable when the price vector changes from $p'$ to $p$. The weak weak axiom is satisfied so long as the consumer maximizes a complete preference relation; the preferences need not be transitive. When $x(\cdot, \alpha)$ is $C^1$, the following are equivalent: (i) $x(\cdot, \alpha)$ obeys the weak weak axiom; (ii) its Slutsky matrix $S(p, w, \alpha)$ is negative semidefinite (but not necessarily symmetric); (iii) its Jacobian matrix $\partial_p x(p, w, \alpha)$ is negative semidefinite on the hyperplane orthogonal to $x(p, w, \alpha)$ (Kihlstrom, Mas-Colell and Sonnenschein, 1976; Brighi, 2004).

When we say that $x(\cdot, \alpha)$ obeys the unrestricted law of demand (or law of demand, for short) we mean that for each $w$, $X(p) = x(p, w, \alpha)$ satisfies (2) for all price changes. Since this is equivalent to negative semidefiniteness of the Jacobian $\partial_p x(p, w, \alpha)$ for all $p$, it is stronger than simply saying that the diagonal terms of the matrix are non-positive. Thus it is not equivalent to the one-good law of demand for every good and does not follow from the assumption that the demand for every good is normal.

Let $M(p, w, \alpha)$ be the income effects matrix, with $j$ component $[\partial w x_j(p, w, \alpha)] x_j(p, w, \alpha)$. From the Slutsky decomposition, $\partial_p x(p, w, \alpha) = S(p, w, \alpha) - M(p, w, \alpha)$, we see that type $\alpha$ satisfies the law of demand if it satisfies the weak weak axiom and $M(p, w, \alpha)$ is positive semidefinite at each $p$. However, the latter condition is strong; it occurs if and only if demand is linear in income for all goods, which excludes the possibility of luxuries or necessities.

A more promising approach is to find conditions under which the Slutsky matrix always 'dominates' the income effects matrix even when the latter 'misbehaves'. On the assumption that type $\alpha$ has a concave utility function $u^\alpha$, a sufficient and (in a sense) necessary condition for the law of demand is

$$- [x^T \partial^2 u^\alpha(x) x] / (\partial u^\alpha(x) x) \leq 4, \forall x.$$ 

This result was obtained independently by Milleron (1974) and Mitjuschin and Polterovich (1978) (see also Mas-Colell, Whinston and Green, 1995, p. 145, and an alternative formulation in Kannai, 1989).

An important application of this result is in the theory of portfolio choice. In that case, the demand bundle is the consumer's contingent consumption over $L$ states of the world; it is standard to assume that the consumer has a von Neumann–Morgenstern utility function $u^\alpha(x) = \sum_i \pi_i v^\alpha(x_i)$, where $\pi_i$ is the subjective probability of state $i$ and $v^\alpha : R_{++} \to R$ is the Bernoulli utility function. Suppose the coefficient of relative risk aversion, $- v^{\alpha''} / v^{\alpha'}$, does not vary by more than four on the domain of $v^\alpha$. Then the consumer's demand for contingent consumption at different state prices will obey the law of demand; this in turn implies that the law of demand holds for the consumer's demand for
securities, whether or not the market is complete (Quah, 2003).

Laws of market demand when the income distribution is independent of price

Consider a large economy with consumers drawn at random from a probability space $\mathcal{A} \times \mathbb{R}^+$ of consumer types and their incomes, with distribution $\mu$. The expected aggregate (market) demand vector at prices $p$ is $X(p) = \int_{\mathcal{A} \times \mathbb{R}^+} x(p, w, \alpha) \, d\mu$. We are interested in conditions under which $X$ obeys the unrestricted law of demand, that is, (2) holds for all price changes; equivalently, $\partial X(p)$ is negative semidefinite for all $p$. If $x(\cdot, \cdot, \alpha)$ obeys the law of demand for all $\alpha$, then, clearly, so will $X$. One justification for studying the law of demand at the individual level is that it is preserved by aggregation. Aggregating the Slutsky decomposition across all agents, the law of demand requires

$$v \cdot \partial X(p) v = v \cdot \left( \int_{\alpha \in \mathcal{A}} x(p, w, \alpha) \, d\mu \right) v = v \cdot \bar{S}(p) v - v \cdot \bar{M}(p) v \leq 0, \quad \forall v \quad (3)$$

where $\bar{S}(p) = \int \partial x_j(p, w, \alpha) / \partial w \, x_j(p, w, \alpha) \, d\mu$ is the mean Slutsky matrix, and $\bar{M}(p)$ is the mean income effects matrix, with $j$ element $\int \partial x_j(p, w, \alpha) / \partial w \, x_j(p, w, \alpha) \, d\mu$. (We assume here and below that these integrals exist.) If all consumers obey the weak weak axiom, which they do if they are utility maximizers, then $S(p, w, \alpha)$ and hence $\bar{S}(p)$ are negative semidefinite; so $\partial X(p)$ is negative semidefinite if $\bar{M}(p)$ is positive semidefinite.

The matrix $\bar{M}(p)$ is determined by the consumers' Engel curves $x(p, \cdot, \alpha)$ at $p$. Positive semidefiniteness of this matrix is known as increasing spread (Hildenbrand, 1994). To see why, note that

$$2v \cdot \bar{M}(p) v = \partial_t \int \left[ v \cdot x(p, w + t, \alpha) \right]^2 d\mu(\alpha, w)_{t=0} \quad (4)$$

We can interpret $v \cdot x(p, w, \alpha)$ as $\alpha$'s demand for a commodity (call it $T_v$), which is consumed when the other goods are consumed; specifically, the consumption of one unit of good $j$ requires $v_j$ units of $T_v$. Then $\int \left[ v \cdot x(p, w, \alpha) \right]^2 d\mu$ measures the spread of the consumers' demands for $T_v$ around the origin. By (4), $\bar{M}(p)$ is positive semidefinite if and only if for every $v$ the consumers' demands for $T_v$ spread out from 0 as their incomes rise. This is the multi-good generalization of normality, where the consumers' demands for a single good increase (spread from 0) as their incomes rise.

We now consider various interpretable conditions on the distribution of consumer characteristics which
guarantee increasing spread (and thus the law of demand). This property holds if consumers have the same demand function and income is distributed with a non-increasing density function $\rho$ on $[0, \bar{w}]$ (Hildenbrand, 1983). In that case, integrating by parts, (4) becomes

$$2v \cdot \overline{M}(p)v = [v \cdot x(p, \bar{w}, \alpha)]^2 \rho(\bar{w}) - \int [v \cdot x(p, w, \alpha)]^2 \rho'(w) \, dw \geq 0.$$  

While the non-increasing density condition is strong, imposing some weak restrictions on the Engel curves will guarantee increasing spread for a significantly larger class of income density functions (Chiappori, 1985).

However, to guarantee increasing spread for every non-trivial income distribution requires stringent conditions on the consumers’ Engel curves: $x(p, \cdot, \alpha)$ must lie in a single plane (depending on $p$) and the demand for each good is either a concave or convex function of income (Freixas and Mas-Colell, 1987; Jerison, 1999).

Increasing spread is also implied by certain kinds of behavioural heterogeneity across consumers. We consider consumers with the same income $w$ and demands of the form

$$x(\alpha) = e^{\alpha} \xi_\alpha(e^{\alpha} \rho_1, \ldots, e^{\alpha} \rho_L, w),$$

where $\xi$ is an arbitrary demand function and $\alpha = (\alpha_1, \ldots, \alpha_L) \in R^L$. If $\xi$ is generated by some utility function $\hat{u}$, then $x(\cdot, \alpha)$ is generated by the utility function $u^\alpha(x) = \hat{u}(e^{-\alpha_1} x_1, \ldots, e^{-\alpha_L} x_L)$. Increasing spread is guaranteed if $\alpha$ has a sufficiently flat density over $R^L$. This condition also ensures that the mean Slutsky matrix $\overline{S}(p)$ is negative semidefinite even if $\xi$, hence each $x(\cdot, \alpha)$, violates the weak axiom (and so is not generated by a utility function). Thus when $\alpha$ has a sufficiently flat density, $X$ satisfies the law of demand; in fact it can be shown that $X$ is nearly generated by Cobb–Douglas preferences (Grandmont, 1992). Whether flatness of the $\alpha$ density implies heterogeneity (in some meaningful sense) of the consumers’ demands depends on the behaviour of $\hat{\xi}$ (Giraud and Quah, 2003).

Even when $\overline{M}(p)$ is not positive semidefinite, that is, $v \cdot \overline{M}(p)v < 0$ for some $v$, it is clear from (3) that $v \cdot \partial x(p)v < 0$ can hold provided the substitution effects are large enough, that is, $v \cdot \overline{S}(p)v$ is sufficiently negative. This feature can be exploited; for example, one can substantially weaken the non-increasing density condition in Hildenbrand (1983; described above) and still obtain the law of demand if substitution effects are accounted for through restrictions on the utility function (Quah, 2000).

Similarly, a large enough positive income effect can compensate for consumers’ violations of the weak axiom, that is, situations where, for some $v$, $v \cdot \overline{S}(p)v > 0$.

Whether the substitution effect $v \cdot \overline{S}(p)v$ dominates the income effect $v \cdot \overline{M}(p)v$ is an empirical question. The sizes of the effects must be estimated. Härdle, Hildenbrand and Jerison (1991) show how this can be done with cross-section data under standard econometric assumptions, without restrictions on the functional forms of the consumer demands. In most empirical demand analyses, consumers are grouped according to observable attributes other than income, and within a group, $a$, the consumers’ budget share vectors are assumed to have the form $b^a(p, w) + \epsilon$, where $\epsilon$ is a mean 0 random variable with distribution independent of income $w$. Under this assumption, a consumer’s type is its attribute group and a realized value of $\epsilon$. Within group $a$, the distribution of types with income $w$, denoted $\mu^a(\alpha|w)$, does not vary with $w$. Thus, if the income distribution in the group has a density $\rho^a$, then
The left side of (5) equals \( 2v \cdot M^a(p)v \), where \( M^a(p) \) is the mean income effect matrix of the consumers in group \( a \). The right side of (5) is the mean of the derivative of \( \int [v \cdot x(p, w, \alpha)]^2 d\mu^a(\alpha|w) \) with respect to \( w \). It can be efficiently estimated by the nonparametric method of average derivatives (Härdle and Stoker, 1989). The mean income effect matrix \( \overline{M}(p) \) is a weighted average of the matrices \( M^a(p) \), weighted by the shares of the population in the groups \( a \). Condition (5), called metonymy, is weaker than the assumption that the budget shares have the form \( b^a(p, w) + \xi \), so weak, in fact, that it is not potentially refutable with infinite cross-section data (Evstigneev, Hildenbrand and Jerison, 1997; Jerison, 2001). Income effect matrices estimated in this way using cross-section expenditure data from several countries are all positive semidefinite (Härdle, Hildenbrand and Jerison, 1991; Hildenbrand and Kneip, 1993).

### Laws of demand in private ownership economies

In the previous section, we assumed consumer incomes to be exogenously given independently of prices. This is plainly not true in general equilibrium. For example, consider a private ownership economy with consumers drawn randomly from a distribution \( \mu \) over types, where type \( \alpha \) has the demand function \( x(\cdot, \cdot, \alpha) \) and an endowment vector \( \omega^\alpha \). If the consumers receive no profits, the income of type \( \alpha \) at price vector \( p \) is \( p \cdot \omega^\alpha \). We are interested in laws of demand that can be satisfied by the consumer sector's aggregate demand \( \hat{X}(p) = \int x(p, \cdot, \omega^\alpha, \alpha) d\mu \) or aggregate excess demand \( \zeta(p) = \hat{X}(p) - \overline{\omega} \), where \( \overline{\omega} = \int \omega^\alpha d\mu \) is the aggregate endowment.

The first thing to note is that under standard assumptions, both \( \hat{X} \) and \( \zeta \) are zero-homogeneous and, essentially for this reason, satisfy the unrestricted law of demand only in exceptional cases (Hildenbrand and Kirman, 1988). However, if the consumers’ endowments are collinear (that is, if for each \( \alpha \) there is some \( k \geq 0 \) with \( \omega^\alpha = k\overline{\omega} \)) then the sufficient conditions for the law of market demand given in the previous section are also sufficient for \( \hat{X} \) (and hence \( \zeta \)) to satisfy (2) for \( p \) and \( p' \) in \( P = \{ p \in \mathbb{R}^L_+: p \cdot \overline{\omega} = 1 \} \); in other words, the law of demand holds for mean income preserving price changes. This is so because, when endowments are collinear, a price change which preserves mean income also preserves the income of every agent.

When we drop the strong assumption of collinear endowments, this restricted form of the law of demand is not guaranteed even if all consumers have homothetic preferences (Mas-Colell, Whinston and Green, 1995, p. 598). However, it does hold when the consumer sector has two properties: \( a \) all agents have homothetic preferences and \( b \) the preferences and endowments are independently distributed. Quah (1997) shows that this scenario can be understood as the idealization of a more general situation. The
crucial feature of homothetic preferences here is that they generate demand functions which are linear in income. Retaining the independence assumption (\(b\)), one can show that, when substitution effects are non-trivial (in some specific sense), \(\bar{X}\) obeys the restricted law of demand provided the mean demand of agents with identical endowments is not ‘too non-linear’ in income. This last property can arise from an appropriate form of heterogeneity in demand behaviour, which can be modelled using the parametric framework employed by Grandmont (1987; 1992).

It is interesting to ask when aggregate consumer excess demand \(\zeta\) satisfies the weak weak axiom: \(p \cdot \zeta(p) \leq 0 \Rightarrow p' \cdot \zeta(p) \geq 0\). This condition ensures that the set of equilibrium prices is convex in all competitive production economies with convex technology and constant returns to scale; furthermore, it is the weakest restriction on \(\zeta\) guaranteeing this conclusion (Mas-Colell, Whinston and Green, 1995, p. 609). The sufficiency of this condition hinges on the fact that the production side of the economy satisfies the law of demand. Since the equilibrium set is generically discrete, its convexity implies generic uniqueness of equilibrium (up to scalar multiple). When \(\zeta\) satisfies the weak weak axiom it also satisfies the law of demand (2) on the restricted set with \(p \cdot \zeta(p) = 0\). If (2) holds strictly on this set when \(p\) and \(p'\) are not collinear, then the unique equilibrium is globally stable under tâtonnement, and there are natural comparative statics.

With the use of a Slutsky decomposition, it can be shown that \(\zeta\) satisfies the weak weak axiom if the mean Slutsky matrix \(S(p)\) is negative semidefinite (as it is if the consumers are utility maximizing) and the consumers’ excess demand vectors spread apart on average when their incomes rise. The latter condition is called non-decreasing dispersion of excess demand (NDED). To formalize it, define \(z(p, t, \alpha) \equiv x(p, t + p \cdot \omega^\alpha) - \omega^\alpha\), the excess demand of type \(\alpha\) with income transfer \(t\). The corresponding aggregate excess demand is \(Z(p, t) \equiv \int z(p, t, \alpha) \, d\mu\). NDED holds if

\[
\partial_t \{v \cdot [z(p, t, \alpha) - Z(p, t)]\} \geq 0 \quad \text{for every } p \in \mathbb{R}_+^L \text{ and every } v \text{ with } v \cdot p = 0 \text{ and } v \cdot \zeta(p) = 0;
\]

in other words, the income transfers raise the variance of the composite excess demands \(v \cdot z(p, t, \alpha)\) (Jerison, 1999). Quah’s 1997 model (described above) is an example of an economy where NDED is satisfied approximately.

law of indifference

F.Y. Edgeworth
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

law of indifference

Article

A designation applied by Jevons to the following fundamental proposition: ‘In the same open market, at any one moment, there cannot be two prices for the same kind of article.’ This proposition, which is at the foundation of a large part of economic science, itself rests on certain ulterior grounds: namely, certain conditions of a perfect market. One is that monopolies should not exist, or at least should not exert that power in virtue of which a proprietor of a theatre, in Germany for instance, can make a different charge for the admission of soldiers and civilians, of men and women. The indivisibility of the articles dealt in appears to be another circumstance which may counteract the law of indifference in some kinds of market, where price is not regulated by cost of production. [Jevons (1875), Theory of Exchange, 2nd edn, p. 99 (statement of the law). Walker (1886), Political Economy, art. 132 (a restatement). Mill (1848), Political Economy, bk. ii. ch. iv. § 3 (imperfections of actual markets). Edgeworth (1881), Mathematical Psychics, pp. 19, 46 (possible exceptions to the law of indifference).]

law(s) of large numbers

Werner Ploberger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

It is a well-known fact that averages of most random variables converge. The laws of large numbers are mathematical theorems which explain this phenomenon. We discuss the various forms of this theorem. Generalizations to dependent variables (ergodic ths) are introduced. We also mention uniform laws of large numbers, which are quite indispensable tools to prove consistency of estimators.

Keywords

Bernoulli experiments; Bernoulli, J.; ergodic theorems; law of large numbers; maximum likelihood; Poisson, S. D.; probability; strong law of large numbers; variance; weak law of large numbers

Article

When we have a large number of independent replications of a random experiment, we observe that the frequency of the outcomes can be very well approximated by the probabilities of the corresponding events. The profits of many commercially successful enterprises – like casinos or insurance companies – are based on random events obeying some laws.

Mathematically, this idea was first formulated by Jacob Bernoulli, for experiments with only two outcomes (‘Bernoulli experiments’). The terminology ‘law of large numbers’ was introduced by S.D. Poisson in 1835.

In the most basic version, LLN (the standard abbreviation for ‘law(s) of large numbers’) describes results of the following type. We assume that we have given a sequence of random variables $X_1, X_2, \ldots$.

We say we have a LLN if

$$\frac{1}{N} \left( X_1 + \ldots + X_N \right)$$

(1)
converges for $N \to \infty$, preferably to a constant. For stating our results, we have to state the nature of the convergence in our LLN and impose some restrictions on the $X_i$. The more we restrict our $X_i$, the stronger our convergence results will be.

**The weak law of large numbers**

The ‘weak law of large numbers’ states that averages like (1) converge in a ‘weak’ sense (like for example convergence in probability) to a limit. In most cases, the requirements for the random variables involved are not very restrictive. A typical weak LLN is the following theorem.

*Theorem 1: Assume that the random variables $X_i$ satisfy*

\[
EX_i = 0, \quad (2)
\]

\[
\sup E X_i^2 < \infty \quad (3)
\]

and

\[
\lim_{M \to \infty} \sup_{|j-j'| > M} |EX_iX_j| < \infty \quad (4)
\]

*Then for $N \to \infty$*

\[
\frac{1}{N} (X_1 + \ldots + X_N) \to P, \quad 0,
\]
where \( \to^p \) denotes convergence in probability. Our random variables have to be centred, of bounded variance, and condition (4) requires that the correlation of random variables ‘far apart’ converges to zero uniformly. This is a very general and important result. Another advantage is the simplicity of its proof: it is an elementary task to show that the variance of the average converges to zero. Then the theorem is an immediate consequence of Chebyshev's inequality. Moreover, the assumptions of the theorem can easily be checked, and only depend on the second moments of the \( X_i \).

**The strong law of large numbers**

In some cases, we want to have more than convergence in probability of the averages. For this purpose, we have strong laws of large numbers. We do need, however, stricter requirements. The following theorem is a typical strong LLN. A more stringent discussion of this type of theorems

**Theorem 2:** Assume that the random variables \( X_i \) satisfy (2),(3). Let \( \mathcal{F}_i \) be an increasing sequence of \( \sigma \)-algebras (for example \( \mathcal{F}_i = \mathcal{F}_i - 1 \subseteq \mathcal{F}_i \)) so that \( X_i \) is \( \mathcal{F}_i \)-measurable. Then let us assume that

\[
E(X_i / \mathcal{F}_{i-1}) = 0.
\]

(5)

Then

\[
\frac{1}{N} (X_1 + \ldots + X_N) \to 0 \quad P \text{ – almost surely.}
\]

Heuristically, we can interpret \( \mathcal{F}_i \) as information available at time \( i \). Then (5) postulates that we cannot predict \( X_i \) given the information at time \( i - 1 \). One important special case where (5) is fulfilled is the case of independent. In this case, we can choose \( \mathcal{F}_i \) to be the \( \sigma \)-algebra generated by \( X_1, \ldots, X_i \). Then, assuming the \( X_i \) to be independent, we have \( E(X_i / \mathcal{F}_{i-1}) = E(X_i) \).

Hence (5) is more general than the requirement of independence, but still far more restrictive than (4).

**Ergodic theorems**

We can easily see that (5) implies that our \( X_i \) are uncorrelated. In many applications, this requirement is unrealistic. Fortunately, there is a theory guaranteeing convergence of sums like (1) at least for
stationary processes $X_i$. A process $X_i, i \in \mathbb{Z}$ is called (strictly) stationary if for all $n \in \mathbb{Z}$ the distributions of $(X_1, X_2, \ldots X_m)$ and $(X_{n+1}, X_2, \ldots X_{n+m})$ are the same. To describe the limits of our process, we need to introduce the transition operator $T$: This operator is a mapping defined on the space of random variables measurable with respect to the $\sigma$ -algebra generated by the $X_i, i \in \mathbb{Z}$. For random variables

$$
Y = f(X_{t_1}, X_{t_2}, \ldots X_{t_n})
$$

(6)

we define the random variable $TY$ by

$$
TY = f(X_{t_1+1}, X_{t_2+1}, \ldots X_{t_n+1}).
$$

(7)

So the transition operator $T$ shifts every random variable ‘one step in the future’. ($T$ can be considered as the inverse of the usual lag operator). One can show that the definition based on (6), (7) can be uniquely extended to the space of all $X_i, i \in \mathbb{Z}$ measurable random variables. Then an event $A$ is called invariant if

$$
T I_A = I_A \text{ almost surely},
$$

where $I_A$ is the indicator of the event $A$. It can be easily seen that the invariant events form a $\sigma$ -algebra, which we denote by $\mathfrak{F}$. Then the ergodic theorem states that

$$
\lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} X_i = E(X_i / \mathfrak{F}).
$$

(8)

(Since we are taking the conditional expectation with respect to $\mathfrak{F}$, it can easily be seen that $E(X_1 / \mathfrak{F}) = E(X_2 / \mathfrak{F}) = \ldots$).

The ergodic theorem is included in most of advanced textbooks on probability theory (see, for example, Billingsley, 1995). A more detailed exposition can be found in Gray (2007).
We now can take various conclusions from our theorem. First of all, we can regardless of the nature of the $\sigma$-algebra conclude that the limit of $\frac{1}{n} \sum_{i=1}^{n} X_i$ exists. In econometric theory, one often postulates the existence of limits of certain averages (that is, in regression theory we often assume that $\lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} x_i \bar{x}$ exists). In case of stationary processes, the theorem here makes assumptions of this type very plausible.

If the $\sigma$-algebra is trivial (that is, consists only of events of probability 0 and 1), then the right-hand side of (8) is constant. One sufficient criterion for this property is that the process is a causal function of i.i.d. random variables. So if

$$X_i = f(e_i, e_{i-1}, \ldots)$$

where $e_i$ are i.i.d., $\mathcal{F}$ is trivial.

Applications and uniform laws of large numbers

For many statistical applications, we need stronger results. As a first example, consider the asymptotic of the maximum likelihood estimator. As a simplest case, let us discuss the case of i.i.d. random variables $X_i$, distributed according to densities $f_{\theta}$ for parameters $\theta \in \Theta$, and let $\theta_0$ be the true parameter. Then the LLN guarantees that for every fixed $\theta$

$$\frac{1}{n} \sum \ln f_{\theta}(X_i) \to \int \ln f_{\theta} f_{\theta_0}.$$

and the function on the right-hand side is maximized if $\theta = \theta_0$. Since the maximum likelihood estimator maximizes the right-hand side, it seems reasonable to exploit this relation for a proof of consistency of the maximum likelihood estimator. The LLN guarantees only convergence for fixed $\theta$, from our LLN we cannot say anything about the limiting behaviour of

$$\sup_{\theta \in \Theta} \ln \left(\frac{1}{n} \sum \ln f_{\theta}(X_i)\right).$$

This problem would go away if one could establish that the convergence in (9) is uniform in $\Theta$. This
strategy was first realized in a path breaking paper by A. Wald (Wald, 1949), where he first established the consistency of the maximum likelihood estimator. Today the techniques are a little more sophisticated. Nevertheless, consistency proofs for M-estimators still rely to good extend on Wald’s idea. Another application of uniform LLN is the consistency of ‘plug-in’ estimators. In many cases, the asymptotic variance of certain estimators can be expressed as a function of the expectations of certain random functions, possibly depending on the parameter to be estimated (for example, the well-known ‘sandwich formula’ derived by H. White; see for example Hayashi, 2000). A standard strategy is to estimate the parameter, then replace the expectation by an average (and hope that – due to the LLN – average and expectation are close together) and use the estimated parameter as an argument. One can easily see that only a uniform law of large numbers can justify procedures of this type.

Fortunately, there exist a lot of criteria to establish uniform laws of large numbers. For most cases of interest to econometricians, the papers by Andrews (1992) and P•tscher and Prucha (1989) will be sufficient.

A more general and abstract theory can be found in van der Vaart and Wellner (1996). These theories allow us also to estimate the cumulative distribution function of random variables directly. Suppose we have given random variables $X_1, \ldots, X_n$. Then the empirical distribution function $F_n$ is defined as

$$F_n(x) = \frac{1}{n} \sum_{i=1}^{n} I(X_i \leq x)$$

(that is $F_n$ jumps $1/n$ in $X_i$ and is constant in between the jumps). Then the theorem of Glivenko-Cantelli (see van der Vaart and Wellner, 1996) states that if the $X_i$ are i.i.d. with cumulative distribution function $F$, then

$$\sup |F_n(x) - F(x)| \to 0.$$  

It should be noted that there are generalizations to multivariate or even more general $X_i$. In these cases, however, one has to use slightly more sophisticated techniques. Instead of the ‘empirical distribution function’, one has to use the ‘empirical measure’ (a random measure, which puts mass $1/n$ in the points $X_i$, and instead of the maximum difference of the distribution functions one has to consider the maximal difference of the measures over certain classes (‘VC-classes’).

law, economic analysis of

A. Mitchell Polinsky and Steven Shavell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article surveys the economic analysis of five primary fields of law: property law; liability for accidents; contract law; litigation; and public enforcement and criminal law. It also briefly considers some criticisms of the economic analysis of law.

Keywords

adverse possession; asymmetric information; Becker, G.; Bentham, J.; bona fide purchase rule; Coase, R.; collective action; compensated takings; contract formation; contractual interpretation; copyright; corrective tax; criminal law; damage measures; Demsetz, H.; deterrence; direct regulation; disclosure of information; due care; eminent domain; expectation measure of damages; fairness; fault-based liability; finders-keepers rule; fines; first-party insurance; good title; hold-out problem; imprisonment; incapacitation; incomplete contracts; injunction; justice; labels; land registries; law and economics; liability; liability insurance; litigation; moral hazard; negligence rule; original ownership rule; patents; Posner, R.; possessory rights; product liability; property rights; public enforcement of law; public property; punishment; risk; risk aversion; risk-bearing; settlement vs trial; social norms; social welfare; specific performance; strict liability; suit; takings; tort law; trade secret law; trademarks; unilateral accident model; utilitarianism

Article

Economic analysis of law seeks to identify the effects of legal rules on the behaviour of relevant actors and to determine whether these effects are socially desirable. The approach employed is that of economic analysis generally: the behaviour of individuals and firms is described on the assumption that they are forward looking and rational, and the framework of welfare economics is adopted to assess the social desirability of outcomes. The field may be said to have begun with Bentham (1789), who
systematically examined how actors would behave in the face of legal incentives (especially criminal sanctions) and who evaluated outcomes with respect to a clearly stated measure of social welfare (utilitarianism). His work was left essentially undeveloped until four important contributions were made: Coase (1960) on externalities and liability, Becker (1968) on crime and law enforcement, Calabresi (1970) on accident law, and Posner (1972) on economic analysis of law in general. (Calabresi's book was the culmination of a series of articles, the first of which was published in 1961; see Calabresi, 1961.)

Our focus here is on the analytical foundations of five basic legal subjects: property, torts, contracts, civil litigation, and crime and law enforcement (on these, see generally Cooter and Ulen, 2003; Posner, 2003; Miceli, 1997; and Shavell, 2004). We do not treat more particular areas of law, such as antitrust, corporate and tax law, nor do we cite empirical work; for surveys of these and other areas of law and economics, including empirical studies, see Polinsky and Shavell (2007).

1. Property law

Justification and emergence of property rights

A beginning question is why there should be property rights in things. A number of arguments have been stressed, especially by early writers, including that property rights furnish incentives to work and to maintain durable things; that the rights make trade possible; and that, if such rights were absent, individuals would spend effort trying to take things from each other and protecting their things. Property rights would be expected to emerge when their advantages become sufficiently great. For example, Demsetz (1967) explains the development of property rights in land among Indians as a way of preventing overly intensive hunting of valuable animals. Umbeck (1981) shows that when gold was discovered in California in 1848 property rights in gold-bearing land and river beds developed, as this encouraged individuals to pan for gold and to build sluices; it also curbed wasteful efforts to grab land from others. For a survey, see Libecap (1986).

Division of property rights

Property rights can be viewed as composed of possessory rights – rights of use – and rights to transfer possessory rights. Thus, what we commonly conceive of as ownership (say, of land) entails both a large swath of possessory rights (rights to build on land, plant on it, under most contingencies, and into the infinite future) and associated rights to transfer them. Property rights in things are generally held in substantially agglomerated bundles, but there is also significant partitioning of rights contemporaneously, over time and contingencies, and according to whether the rights are possessory or are for transfer. For example, an owner of land may not hold complete possessory rights, in that others may possess an easement giving them the right of passage upon his land, or the right to take timber, or the right to extract oil if found (thus a contingent right). A rental agreement constitutes a division of property rights over time. Trust arrangements, such as those under which an adult manages property for a child, divide possessory rights and rights to transfer.

The division of property rights may be valuable when different parties derive different benefits from them, because gains can then be achieved if rights are allocated to those who obtain the most from them.
There may, however, be disadvantages to the division of rights, including that externalities may arise (a person with a right of passage might trample crops).

Public property and its acquisition; takings and compensation

An important class of property is that owned by the public. As is well known, the main justification for public property concerns the difficulty that private providers would experience in charging for certain goods and services.

When it is desirable for the state to acquire property for public use, the state can either purchase it or take it through the exercise of the power of *eminence domain*. In the latter case, the law typically provides that the state must compensate property owners for the value of what has been taken from them.

A difference between purchase and compensated takings is that the amounts owners receive are determined by negotiation in the former case but unilaterally by the state in the latter. Because of errors in state determination of value, as well as concern about the behaviour of government officials, purchase would ordinarily be superior to compensated takings. When, however, the state needs to assemble many contiguous parcels, such as for a road, acquisition by purchase might be stymied by hold-out problems, making the power to take socially advantageous.

On the assumption that there is a reason for the state to take property, a requirement to pay compensation may curb problems of overzealousness or abuse of authority by public officials, yet it may also exacerbate potential problems of insufficient public activity, because public authorities do not directly receive the benefits of takings (Kaplow, 1986). Payment of compensation also may lead property owners to invest excessively in property (see Blume, Rubinfeld and Shapiro, 1984).

Acquisition of property in unowned things

The law must determine the conditions under which a person will become a legal owner of previously unowned things, such as wild animals, fish, and mineral and oil deposits. Under the *finders-keepers rule*, incentives to invest in capture (such as to hunt for animals or explore for oil) are optimal if only one person is making the effort. However, if many individuals seek unowned things, they will invest a socially excessive amount of resources in search: one person's investment usually will come, at least partly, at the expense of other person's likelihood of finding unowned things. Various aspects of the law ameliorate this problem of excessive search effort. For example, regulations may limit the quantities of fish and wild animals that can be taken; the right to search for minerals on the ocean floor may be auctioned; and oil extraction rights may be assigned to a single party.

Acquisition of good title when property is sold

A basic difficulty associated with sale of property that a legal system must solve is establishing validity of ownership or *title*. Good title is important for trade, since buyers want to be assured that they have property rights in what they purchase. But, if any sale gives a buyer good title, theft is encouraged, since thieves could then easily sell stolen goods. Under a *registration system*, good title means that one's name is listed in the registry as the owner, and title passes at the time of sale by an authorized change in the
registry. Hence, buyers can clearly determine whether they are obtaining good title by checking the registry, and a thief could not easily sell stolen property by claiming that he has good title. Registries, however, are expensive to establish and maintain.

In the absence of registries, the law may employ the original ownership rule, under which the buyer does not obtain good title if the seller did not have good title. Alternatively, under the bona fide purchase rule, a buyer acquires good title as long as he had reason to think that the sale was legitimate, even if the item sold was in fact wrongfully obtained. This rule makes theft more attractive because thieves will often be able to sell their property to buyers who will be motivated to ‘believe’ that sales are bona fide.

Adverse possession

The legal doctrine of adverse possession allows involuntary transfer of land: a person is deemed to become the legal owner of land if he takes possession of it and uses it openly for at least a prescribed period, such as ten years. It may appear that this rule could be desirable because it encourages productive use of idle land. But this overlooks the possibility that a prospective adverse possessor could always bargain with the owner to rent or buy the land, and that there may be good reasons for allowing the land to remain idle. Additionally, the rule induces owners to expend resources policing incursions, and potential adverse possessors to attempt possession. A historical justification for the rule is that, before reliable land registries existed, it allowed a seller of land to establish good title to a buyer relatively easily: the seller need only show that he was on the land for the prescribed period.

Constraints on sale of property

Legal restrictions are often imposed on the sale of goods and services. One standard justification is exter-

nality. For example, the sale of fireworks might be banned because of the externality that their ownership creates, namely, putting others at risk of injury. The other standard justification for legal restrictions on sale is lack of consumer information. For instance, a drug may not be sold without a prescription because of fear that otherwise buyers would not use it properly. Rather than restrict sales, however, the government could supply relevant information to consumers, such as by indicating that the drug has dangerous side effects, or that it should be taken only on the advice of a medical expert.

Externalities

When individuals use property, they may cause externalities, namely, harm or benefit to others. Generally, it is socially desirable for individuals to do more than is in their self-interest to reduce detrimental externalities and to act so as to increase beneficial externalities. The socially optimal resolution of harmful externalities often involves the behaviour of victims as well as that of injurers. If victims can do things to reduce the amount of harm more cheaply than injurers (say, install air filters to avoid pollution), it is optimal for victims to do so. Moreover, victims can sometimes alter their locations to reduce their exposure to harm.

Legal intervention can ameliorate problems of externalities. A major form of intervention that has been studied is direct regulation, under which the state restricts permissible behaviour, such as requiring
Factories to use smoke arrestors. Closely related is the *injunction*, whereby a potential victim can enlist the power of the state to force a potential injurer to take steps to prevent harm or to cease his activity. Society can also make use of financial incentives to induce injurers to reduce harmful externalities. Under the *corrective tax*, a party pays the state an amount equal to the expected harm he causes – for example, the expected harm due to a discharge of a pollutant into a lake. There is also *liability*, a privately initiated means of providing financial incentives, under which injurers pay for harm done if sued by victims. These methods differ in the information that the state needs to apply them, in whether they require or harness information that victims have about harm, and in other respects, such that each may be superior to the other in different circumstances (Shavell, 1993).

Parties affected by externalities will sometimes have the opportunity to make mutually beneficial agreements with those who generate the externalities, as Coase (1960) stressed. But bargaining may not occur, for many reasons: cost; collective action problems (such as when many victims each face small harms); and lack of knowledge of harm (such as from an invisible carcinogen). If bargaining does occur, it may not be successful, owing to asymmetric information. These difficulties often make bargaining a problematic solution to externality problems and imply that liability rules are needed, as discussed by Calabresi and Melamed (1972).

**Property rights in information**

The granting of property rights in information, notably the award of *patents* for inventions and *copyrights* for written works and certain other compositions, involves a major social benefit – the provision of incentives to create intellectual works – but also a social disadvantage – the creation of power to price above marginal cost. Patent and copyright law have been examined to ascertain how they reflect the trade-off between this benefit and disadvantage. A distinct form of legal protection is *trade secret law*, comprising various doctrines of contract and tort law that serve to protect a range of commercially valuable information that is not (or cannot be) protected by patent or copyright, such as customer lists. On property rights in information, see generally Landes and Posner (2003).

An alternative to property rights in information is for the state to offer *rewards* to creators of information, and for information that is developed to be made available to all who want it. Thus, an author of a book would receive a reward from the state for writing the book, possibly based on sales, but anyone who wanted to print it and sell it could do so. This system would create incentives for the creation of information without distorting prices, but requires the state to choose the magnitude of rewards.

**Property rights in labels**

Many goods and services are identified by labels, which have substantial social value because the quality of goods and services may be hard for consumers to determine directly. Labels enable consumers to purchase goods and services on the basis of product quality without requiring consumers to independently determine quality; a person who wants to stay at a high-quality hotel in another city can choose such a hotel merely by its label, such as ‘Ritz Hotel’. In addition, sellers who label their output will have an incentive to produce goods and services of quality because consumers will recognize
law, economic analysis of: The New Palgrave Dictionary of Economics

quality through sellers’ labels. This basic reasoning is used to justify property rights in *trademarks*, as discussed by Landes and Posner (1987b).

2. Liability for accidents

Legal liability for accidents, which is governed by tort law, is a means by which society can reduce the risk of harm by threatening potential injurers with having to pay for the harms they cause. Liability is also frequently viewed as a device for compensating victims of harm, though we emphasize that insurance can provide compensation more cheaply than the liability system. There are two basic rules of liability. Under *strict liability*, an injurer must always pay for harm due to an accident that he causes. Under the *negligence rule*, an injurer must pay for harm caused only when he is found negligent, that is, only when his level of care was less than a standard of care chosen by the courts, often referred to as *due care*. (There are various versions of these rules that depend on whether victims’ care was insufficient.)

In practice, the negligence rule is the dominant form of liability; strict liability is reserved mainly for certain especially dangerous activities. On economic analysis of liability for accidents, see generally Calabresi (1970), Landes and Posner (1987a), and Shavell (1987a).

Incentives to take care

In order to focus on how liability affects the incentive to prevent harm, assume first that parties are risk neutral and that accidents are *unilateral* – only injurers (not victims) influence risk by their choice of care $x$. Let $p(x)$ be the probability of an accident that causes harm $h$, where $p$ is declining in $x$. Assume that the social objective is to minimize total expected costs, $x + p(x)h$, and let $x^*$ denote the optimal $x$. Under strict liability, injurers pay damages equal to $h$ whenever an accident occurs, and they naturally bear the cost of care $x$. Thus, they minimize $x + p(x)h$; accordingly, they choose $x^*$.

Under the negligence rule, suppose that the due care level is set equal to $x^*$, meaning that an injurer who causes harm will have to pay $h$ if $x < x^*$, but will not have to pay anything if $x \geq x^*$. Then it can be shown that the injurer will choose $x^*$: clearly, the injurer will not choose $x$ greater than $x^*$; and he will not choose $x < x^*$, for then he will be liable (in which case the analysis of strict liability shows that he would not choose $x < x^*$). Thus, under both forms of liability, injurers are led to take optimal care. Note that to apply the negligence rule courts need sufficient information to calculate $x^*$ and to observe $x$, whereas under strict liability they only have to observe $x$.

The analysis of incentives and liability has been undertaken as well for *bilateral* accidents, in which victims also take care, and when there is uncertainty in the determination of negligence (such as due to imperfect observation of $x$). On incentives and liability for unilateral and bilateral accidents, see originally Brown (1973) and also Diamond (1974).

Level of activity

An important extension allows for injurers to choose their *level of activity* $z$, which is interpreted as the (continuously variable) number of times they engage in their activity (or, if injurers are firms, their
output). Let $b(z)$ be the benefit (or profit) from the activity, and assume the social objective is to maximize $b(z) - z(x + p(x)h)$; here $x + p(x)h$ is assumed to be the cost of care and expected harm each time an injurer engages in his activity. Let $x^*$ and $z^*$ be optimal values. Note that $x^*$ minimizes $x + p(x)h$, so $x^*$ is as described above, and that $z^*$ is determined by $b'(z) = x^* + p(x^*)h$, which is to say, the marginal benefit from the activity equals the marginal social cost.

Under strict liability, an injurer will choose both the level of care and the level of activity optimally, as his objective will be the same as the social objective, to maximize $b(z) - z(x + p(x)h)$, because damage payments equal $h$ whenever harm occurs. Under the negligence rule, an injurer will choose optimal care $x^*$ as before, but his level of activity $z$ will be socially excessive. In particular, because an injurer will escape liability by taking care $x^*$, he will choose $z$ to maximize $b(z) - zx^*$, so that $z$ will satisfy $b'(z) = x^*$. The injurer's cost of raising his level of activity is only his cost of care $x^*$, which is less than the social cost, which also includes $p(x^*)h$. On liability and the level of activity, see Shavell (1980b).

The failure of the negligence rule to control the level of activity arises because negligence is defined here (and also generally in practice) in terms of care alone. A justification for this restriction is the difficulty courts would face in determining the optimal activity level $z^*$ and the actual $z$. The failure of the negligence rule to control the injurer's level of activity is applicable to any aspect of injurer behaviour that would be difficult to regulate directly (including, for example, research and development activity). If, however, courts were able to incorporate all aspects of injurer behaviour into the definition of due care, the negligence rule would result in optimal behaviour in all respects. (Note that the variable $x$ in the original problem could be interpreted as a vector, with each element corresponding to a dimension of behaviour.)

Product liability

Another extension of the model of liability and incentives concerns product liability, the liability of firms for harms suffered by their customers. Here the degree to which liability creates incentives to reduce risk depends on customer knowledge of risk. If their knowledge is perfect, liability does not affect incentives since customers will recognize risky products and pay appropriately less for them. If their knowledge is imperfect, there is a role for liability, in many respects similar to what has been discussed above.

Risk-bearing and insurance

In addition to affecting incentives to reduce harm, the socially optimal resolution of the accident problem involves the spreading of risk to lessen risk-bearing by risk-averse parties. Risk-bearing is relevant not only because potential victims may face the risk of accident losses, but also because potential injurers may face the risk of liability. The former risk can be mitigated through so-called first-party insurance that covers losses suffered in accidents, and the latter through liability insurance. Because risk-averse individuals tend to purchase insurance, the incentives associated with liability do not function in the direct way discussed above, but instead are mediated by the terms of insurance.
policies. To illustrate, consider strict liability in the unilateral accident model with care alone allowed to vary, and assume that insurance is sold at actuarially fair rates. If injurers are risk averse and liability insurers can observe their levels of care, injurers will purchase full liability insurance coverage and their premiums will depend on their level of care; their premiums will equal $p(x)h$. Thus, injurers will want to minimize their costs of care plus premiums, or $x + p(x)h$, so they will choose the optimal level of care $x^*$. In this instance, liability insurance eliminates risk for injurers, and the situation reduces to the previously analysed risk-neutral case. (Victims do not bear risk either because, in the present case, they are fully compensated for their losses.)

If, however, liability insurers cannot observe levels of care, insurance policies with full coverage could create severe moral hazard, and so might not be purchased. Instead, as we know from the theory of insurance, the typical amount of coverage purchased will be partial, for that leaves injurers with an incentive to reduce risk. In this case, therefore, the liability rule results in some direct incentive to take care because injurers are left bearing some risk after their purchase of liability insurance. But levels of care will still tend to be less than first-best.

This last observation raises the question of whether the sale of liability insurance is socially desirable. (We note that because of concern about diluted incentives, liability insurance was delayed for decades in many countries and is sometimes forbidden today, such as for punitive damages.) Notwithstanding the moral hazard problem, the sale of liability insurance is socially desirable, at least in basic models of accidents and some variations of them. This is because, if the liability insurer and the injurer together have to pay for the harm caused, the insurance policy will appropriately balance the social desire to reduce harm and the social desire to reduce risk-bearing.

Parallel observations apply under the negligence rule, where the focus of concern is on the bearing of risk by victims since injurers generally will take due care and not be liable. Risk-averse potential victims will tend to purchase first-party accident insurance.

The presence of insurance implies that the liability system cannot be justified primarily as a means of compensating risk-averse victims against loss. Rather, the justification for the liability system must lie in significant part in the incentives that it creates to reduce risk. To amplify, although both strict liability and the insurance system can compensate victims, the liability system is much more expensive than the insurance system (see below). Accordingly, if there were not a social need to create incentives to reduce risk, it would be best to dispense with the liability system and to rely on insurance to accomplish compensation. On liability and insurance, see Shavell (1982a).

**Administrative costs**

The administrative costs of the liability system – the legal costs and effort of litigants involved in suit, settlement and trial – are substantial, generally exceeding the amounts received by victims. Consideration of administrative costs affects the comparison of liability rules, but it is not clear which rule involves greater expense: more cases are brought under strict liability than under the negligence rule (victims will not sue under the negligence rule if they believe the injurer was not negligent), but the cost of resolving a case should be greater under the negligence rule (because due care and the injurer's care level need to be ascertained). The presence of administrative costs raises the questions of whether the incentive benefits of the liability system justify incurring these costs, and whether the private incentive to sue is socially optimal. These questions are discussed in section 4.
3 Contracts

A contract is a specification of the actions that named parties are supposed to take at various times, as a function of the conditions that then obtain. A contract is said to be completely detailed, or simply complete, if the contract provides explicitly for all possible conditions. An incomplete contract may well cover all conditions by implication. A contract stating merely that a specified price will be paid for a bushel of wheat is incomplete because it does not mention many contingencies that might affect the parties. Note that such an incomplete contract has no gaps, as it stipulates what the parties are to do in all circumstances. Typically, incomplete contracts do not include conditions which, were they easy to include, would allow both parties to be made better off in an expected sense.

Contracts are here assumed to be enforced by a tribunal, which will usually be interpreted to be a state-authorized court, but it could also be another entity, such as an arbitrator or the decision-making body of a trade association or a religious group. (Reputation and other non-legal factors may also serve to enforce contracts, but we do not discuss these.) Enforcement refers to actions taken by the tribunal when one or more of the parties to the contract decide to come before it.

General reasons for contracts

Broadly speaking, parties make contracts when they have a need to make plans. They also want contracts enforced to prevent opportunistic behaviour that otherwise might occur during the course of the contractual relationship and stymie fulfilment of their plans.

There are two basic contexts in which parties make enforceable contracts. The first concerns virtually any kind of financial arrangement. The necessity of contract enforcement here is transparent. In financial arrangements, there is often a party who extends credit to another for some time period, and contract enforcement prevents his credit from being appropriated, which otherwise would render the arrangements impossible. For example, if borrowers were not forced to repay loans, loans would be unworkable. In addition, financial contracts that allocate risk would generally be useless without enforcement because, once the risky outcome became known, one of the parties would not wish to honour the contract.

The second context in which parties make enforceable contracts involves the supply of customized or specialized goods and services which cannot be purchased on a spot market with a simultaneous exchange for money. The need for enforcement of agreements for supply of customized goods and services inheres in several advantages: averting problems of hold-up, which might distort incentives to invest in the contractual enterprise; allocation of risk; and prevention of inappropriate breach or performance, which can result from imperfect bargaining due to sheer cost or asymmetric information.

Contract formation

The formation of contracts is of interest, in several respects. One issue concerns search effort (Diamond and Maskin, 1979). Parties expend effort in finding contractual partners, and it is apparent that their search effort will not generally be socially optimal. On the one hand, they might not search enough:
because the joint gain from contracting will generally be divided between the parties through the bargaining process, the private return to search may be less than the social return. On the other hand, parties might search more than is socially desirable because of a negative externality associated with discovery of a contract partner: when one party finds and contracts with a second, other parties are thereby prevented from contracting with that party.

A basic question that a tribunal must answer is: at what stage of interactions between parties does a contract become legally recognized? The general legal rule is that contracts are recognized if and only if both parties give a clear indication of assent, such as signing their names on a document. This rule allows parties to make enforceable contracts when they so desire, and it also protects parties from becoming legally obliged against their wishes, such as from one party’s reliance on the other’s statements (Bebchuk and Ben-Shahar, 2001; Wils, 1993). Mutual assent sometimes is not simultaneous; one party will make an offer and time will pass before the other agrees. An issue that this raises is how long, and under what circumstances, the offeror will want to be held to his offer, and whether he should be held to it. If an offeror is held to his terms, offerees will often be led to invest effort in investigating contractual opportunities. Otherwise, offerees might be taken advantage of by offerors if the offerees expressed serious interest after costly investigation (the offeror could change to less favourable terms). The anticipation of such offeror advantage-taking would reduce offerees’ incentive to engage in investigation and thus diminish mutually beneficial contract formation (see, for example, Craswell, 1996; Katz, 1990; 1996).

Another issue of note is disclosure of information at the time of contract formation. Disclosure may be socially beneficial because the disclosed information may be desirably employed by one of the parties; for example, a buyer of a house may learn from the seller that the basement leaks and thus decide not to store valuables there. However, a disclosure obligation discourages parties from investing in acquisition of information (Kronman, 1978). For instance, an oil company contemplating buying land might decide against conducting a geological analysis of it to determine its oil-bearing potential if the company would be required to disclose its findings to the seller of the land, as the seller would then demand a price reflecting the value of the land. The social welfare consequences of the effect of a disclosure obligation on the motive to acquire information depend on whether the information is socially valuable or mere foreknowledge, on whether the party acquiring information is the buyer or the seller, and on inferences that would be drawn from silence (Shavell, 1994).

Even if both parties have given their assent, a contract will not be recognized if it was made when one of the parties was put under undue pressure – for example, if a party was physically or otherwise threatened by another. This legal rule has virtues similar to those of laws against theft; it reduces individuals’ incentives to expend effort making threats and defending themselves against threats.

In addition, contracts may not be legally recognized if they are made in emergency situations, such as when the owner of a ship in distress promises to pay an exorbitant amount for rescue. Non-enforcement in such situations beneficially provides potential victims with implicit insurance against having to pay high prices, but it also reduces incentives for rescue.

Incomplete nature of contracts and their less-than-rigorous enforcement

Contracts are commonly observed to be significantly incomplete, leaving out all manner of variables and
contingencies that are of potential relevance to contracting parties. Moreover, contracts are not enforced with high sanctions, and breach is not an uncommon event. There are three reasons for the incompleteness of contracts. The first is the cost of writing more complete contracts. The second is that some variables (effort levels, technical production difficulties) cannot be verified by tribunals. The third is that the expected consequences of incompleteness may not be very harmful to contracting parties. Incompleteness may not be harmful because a tribunal might interpret an imperfect contract in a desirable manner. Also, as will be seen, the prospect of having to pay damages for breach of contract may serve as an implicit substitute for more detailed terms. Furthermore, the opportunity to renegotiate a contract often furnishes a way for parties to alter terms in the light of circumstances for which contractual provisions had not been made.

**Interpretation of contracts**

Contractual interpretation, which includes a tribunal's filling gaps, resolving ambiguities, and overriding literal language, can benefit parties by easing their drafting burdens or reducing their need to understand contractual detail. For example, if it is efficient to excuse a seller from having to perform if his factory burns down, the parties need not incur the cost of specifying this exception in their contract if they can trust the tribunal to interpret their contract as if the exception were specified. A method of interpretation can be viewed formally as a function that transforms the contract individuals write into the effective contract that the tribunal will enforce. Given a method of interpretation, parties will choose contracts in a constrained-efficient way. Notably, if the parties are concerned that an aspect of their contract would not be interpreted as they want, they could either bear the cost of writing a more explicit term that would be respected by the tribunal, or they could simply accept the expected loss from having a less-than-efficient term. The socially optimal method of interpretation will take this reaction of contracting parties into account and can be regarded as minimizing the sum of the costs the parties bear in writing contracts and the losses resulting from inefficient enforcement. (See Ayres and Gertner, 1989; Hadfield, 1994; Schwartz, 1992; Shavell, 2006.)

**Damage measures for breach of contract**

When parties breach a contract, they often have to pay damages in consequence. The damage measure, the formula governing what they should pay, can be determined by the tribunal or it can be stipulated in advance by the parties to the contract. One would expect parties to specify their own damage measure when it would better serve their purposes than the measure the tribunal would employ, and otherwise to allow the tribunal to select the damage measure. In either case, we now examine the utility of different damage measures to contracting parties, assuming initially that there is no renegotiation of contracts. Clearly, the prospect of having to pay damages provides an incentive to perform contractual obligations, and thus generally promotes enforcement of contracts and the goals of the parties. Under the commonly employed expectation measure, damages equal the amount that compensates the victim of breach for his losses. Under this measure, a seller contemplating breach will be induced to perform if the cost of performance to the seller is less than the value of performance to the buyer, and to breach otherwise. Because the expectation measure leads to maximization of joint value, it would be chosen by the parties...
Another commonly employed measure of damages is the reliance measure: damages equal to the amount spent by the victim relying on contract performance, such as expenditures on advertising an entertainer who has contracted to appear at one's nightclub. The point that the expectation measure of damages induces efficient performance of parties sheds light on the view of many legal commentators that breach is immoral. This view fails to account for the fact that contracts that are breached are generally incomplete, and that breach constitutes behaviour that the parties truly want and would have provided for in a complete contract.

Damage measures not only affect performance, they also influence the ex ante motive to make investments in reliance on contract performance. Under the expectation measure, reliance investments tend to exceed efficient levels: the buyer will treat an investment (like advertising an entertainer) as one with a sure payoff, since he will receive either performance or expectation damages, whereas the actual return to the investment is uncertain, due to the possibility of breach (advertising will be a waste if the entertainer does not appear); see Shavell (1980a). This tendency toward over-reliance stands in contrast to the problem of inadequate reliance investment associated with lack of contract enforcement.

Damage measures affect risk-bearing as well as incentives. Notably, because the expectation measure compensates the victim of a breach, the measure might be mutually desirable as a form of insurance if the victim is risk averse (Polinsky, 1983). However, the prospect of having to pay damages also constitutes a risk for a party who might commit breach (such as a seller whose costs suddenly rise), and he might be risk averse as well. The latter consideration may lead parties to want to lower damages or to employ damages less frequently by writing more detailed contracts (for instance, the parties could go to the expense of specifying in the contract that a seller can be excused from performance if his costs are unusually high).

Specific performance as a remedy for breach

An alternative to use of a damage measure for breach of contract is specific performance: requiring a party to satisfy his contractual obligation. Specific performance can be accomplished with a sufficiently high threat or by exercise of the state's police powers, such as by a sheriff removing a person from the land that he promised to convey. (Note that, if a monetary penalty can be employed to induce performance, then specific performance is equivalent to a damage measure with a high level of damages.)

It is apparent from what has been said about incomplete contracts and damage measures that parties should not want specific performance of many contracts that they write, for they do not wish their incomplete contracts always to be performed. It is therefore not surprising that, in fact, specific performance is not used as the remedy for breach for most contracts for production of goods or for provision of services. Additionally, specific performance might be peculiarly difficult to enforce in these contexts because of problems in monitoring and controlling parties’ effort levels and the quality of production.

However, specific performance does have advantages for parties in certain contexts, such as in contracts for the transfer of things that already exist, like land, and specific performance is the usual legal remedy for sellers’ breaches of contracts for the sale of land.
Renegotiation of contracts

Parties often have the opportunity to renegotiate their contracts when problems arise. Indeed, the assumption that they will do this has appeal because, having made an initial contract, the parties know of each other's existence and of many particulars of the contractual situation. For this reason, much of the economics literature (as opposed to law and economics literature) on contracts assumes that renegotiation always occurs and that, due to symmetric information between the parties, it always results in efficient performance. Hence, damage measures for breach of contract, or more generally, the mechanisms that the parties stipulate in their contracts, establish the threat points for renegotiation. If properly designed, the mechanisms can foster beneficial incentives to invest \textit{ex ante} for both parties. On this extensive literature, see, for example, Rogerson (1984), Hart (1987), Hart and Moore (1988), and Bolton and Dewatripont (2005).

Legal overriding of contracts

A basic rationale for legislative or judicial overriding of contracts is the presence of externalities. Contracts that are likely to harm third parties are often not enforced, including, for example, agreements to commit crimes, price-fixing compacts, liability insurance policies against fines, and certain sales contracts (such as for machine guns).

Another general rationale for non-enforcement of contracts is to prevent a loss in welfare to one or both of the parties to a contract. This concern may justify non-enforcement when a party is incompetent, lacks relevant information, or is in an emergency situation. The rationale also applies in the context of contract interpretation by tribunals. As noted, contract interpretation may amount to the overriding of a written contractual term, and this practice may promote the welfare of contracting parties by allowing them to save writing costs, given that courts will step in and correct inefficient terms.

Additionally, contracts sometimes are not enforced because they involve the sale of things said to be inalienable, such as human organs, babies, and voting rights. In many of these cases, the inalienability justification for lack of enforcement can be recognized as involving externalities or the welfare of the contracting parties.

4. Litigation

We here consider the bringing and adjudication of lawsuits: the decision of a party who has suffered a loss whether to sue; the choice of the litigants whether to settle with each other or instead go to trial; and the choice of litigants, before or during trial, of how much to spend on litigation.

Suit

As a general rule, a party who has suffered loss, the plaintiff, will sue when the cost of suit $c_P$ is less than the expected benefits from suit. The expected benefits from suit incorporate potential settlements or trial outcomes, but assume for simplicity that, if suit is brought, the plaintiff obtains for sure a judgment equal to harm suffered, $h$. Thus the plaintiff will sue when his litigation cost, $c_P$, is less than $h$. 
The private incentive to sue is fundamentally misaligned with the socially optimal incentive to sue, as emphasized by Shavell (1982b; 1997). The deviation could be in either direction. On the one hand, there is a divergence between private and social costs that can lead to socially excessive suit: when a plaintiff contemplates bringing suit, he bears only his own costs; he does not take into account the defendant's costs or the state's costs that his suit will engender. On the other hand, there is a difference between the private and social benefits of suit that can either lead to a socially inadequate level of suit or reinforce the cost-related tendency towards excessive suit. Specifically, the plaintiff considers his private benefit from suit (the gain he would obtain from prevailing) but not the social benefit (the deterrent effect on the behaviour of injurers generally). The private gain could be larger or smaller than the social benefit.

To illustrate, suppose that liability is strict. As stated, victims will sue if and only if $c_P < ph$. Let $x$ be the precaution expenditures that injurers will be induced to make if there is suit, $q$ the probability of harm if suit is not brought, and $q'$ the probability of harm if suit is brought. (Thus, $q'$ will be less than $q$ if $x$ is spent on precautions.) Suit will be socially worthwhile if and only if $q' (c_P + c_D + c_S) < (q - q') h - x$, where $c_D$ is the defendant's litigation cost and $c_S$ is the state's cost. In other words, suit is socially worthwhile if the expected litigation costs are less than the deterrence benefits of suit net of the cost of precautions. The condition for victims to sue and the condition for suit to be socially optimal are very different. Whether victims will sue does not depend on the costs $c_D$ and $c_S$. Moreover, the private benefit of suit is what the victim will receive as a damages award, $h$; in contrast, the social benefit is the harm weighted by the reduction in the accident probability, $q - q'$, net of the cost of precautions, $x$. It is evident, therefore, that victims might sue when suit is not socially desirable, or that victims might not sue even when suit would be socially beneficial.

The main implication of the private-social divergence is that state intervention may be desirable, either to correct a problem of excessive suit (notably by taxing suit or barring it in some domain) or a problem of inadequate suit (by subsidizing suit in some way). For the state to determine optimal policy, however, requires it to estimate the effects of suit on injurer behaviour and weigh them against the social costs of suit.

The importance of the private-social divergence in incentives to sue may be substantial. This is suggested by the high costs of using the legal system; indeed, legal costs may on average actually equal the amounts received by those who sue. Hence, the incentives created by the legal system must be significant to justify its use. Regardless of whether the legal system creates valuable incentives, however, the private motive to bring suit may be great, giving rise to a reason for social intervention. Conversely, in some domains the incentive to sue may be low (say, damages per plaintiff are not great) even though the value of deterrence is significant. This might justify the state's encouraging litigation.

**Settlement versus trial**

Assuming that a suit has been brought, we now consider whether parties will reach a settlement or go to trial. A settlement is a legally enforceable contract, usually involving a payment from the defendant to the plaintiff, in return for which the plaintiff agrees not to pursue his claim further. If the parties do not
reach a settlement, we assume that they go to trial, that is, that some tribunal determines the outcome of their case. In fact, the vast majority of cases settle.

One model of the settlement-versus-trial decision presumes that the parties have somehow each come to a belief about the probability of the trial outcome (Posner, 2003, ch. 21; Shavell, 2004, ch. 17). Let \( p_P \) represent the plaintiff's opinion about his probability of prevailing, and let \( p_D \) be the defendant's opinion about that same probability. Let \( w \) be the amount that would be won (for simplicity assume that they agree about \( w \)). Assume also that the parties are risk neutral. The plaintiff's expected gain from trial, net of his litigation costs, is \( p_Pw - c_P \). The defendant's expected loss from trial, including his litigation costs, is \( p_Dw + c_D \). Hence, a settlement is possible if and only if \( p_Pw - c_P > p_Dw + c_D \), in which case the settlement amount will be in the settlement range \( [p_Pw - c_P, p_Dw + c_D] \). Note that, if the parties agree on the plaintiff's probability of prevailing, a settlement is feasible. A settlement range does not exist, and therefore trial will occur, if \( p_Pw - p_Dw > c_P + c_D \). Risk aversion of the parties increases the size of the settlement range and thus, one presumes, makes settlement more likely: if the plaintiff is risk averse, he will be willing to settle for less than \( p_Pw - c_P \); and if the defendant is risk averse, she will be willing to pay more than \( p_Dw + c_D \).

The model just discussed does not explain the origin of the parties' beliefs and does not include a description of rational bargaining between them. Subsequently, standard asymmetric information models of settlement versus litigation were examined (Bebchuk, 1984; Reinganum and Wilde, 1986; Schweizer, 1989; Spier, 1992; Hay and Spier, 1998; Daughety, 2000). In a simple model of this type, there is one-sided asymmetry of information and the party without private information makes a take-it-or-leave-it settlement proposal. For example, the plaintiff makes a demand \( x \) to the defendant, who has private information about the probability \( p \) that he will lose at trial. If \( p_Dw + c_D < x \), the defendant will reject the demand and the plaintiff will therefore obtain only \( p_Pw - c_P \), but if \( p_Dw + c_D > x \), the defendant will accept and pay \( x \). The plaintiff chooses \( x \) to maximize his expected payoff from settlement or trial. The higher his demand \( x \), the more he will obtain if it is accepted, but the greater the likelihood of rejection and thus of his bearing trial costs. At the optimal demand for the plaintiff, there will generally be a positive probability of trial and also of settlement.

The virtues of such asymmetric information models are twofold. First, they include an explicit account of bargaining and thus of the probability of settlement and the magnitude of the settlement offer or demand. (The outcomes of these models depend, however, on essentially arbitrary modelling choices, such as whether the informed or the uninformed party makes the settlement proposal.) Second, the models explain differences of opinion that give rise to trial in terms of differences in possession of information. (However, the models do not account for why there should be differences in information, given that the parties have incentives to share information and may be forced to do so through legal discovery.)

The private and social incentives to settle generally diverge for several reasons. First, because the litigants do not bear all of the costs of a trial (such as the salaries of judges and the forgone value of juror time), they save less by settling than society does, which tends to make the private incentive to settle socially inadequate. Second, when there is asymmetric information, parties will fail to settle when the plaintiff's demand turns out to have been too high or the defendant's offer too low. But their desire to obtain from each other a greater share of the benefit from settling does not itself translate into any social benefit. Third, the prospect of settlement may reduce deterrence because defendants gain from
Litigation expenditures

A plaintiff will continue spending on litigation as long as this raises his expected return from settlement or trial (net of litigation costs), and a defendant will make such expenditures as long as this lowers his expected total outlays. The effects of each litigant's expenditures will generally depend on what the other does, and the two will often be spending to rebut one another.

There are several reasons why the private and social incentives to spend on litigation diverge. First, to the extent that their expenditures simply offset each other, without altering trial or settlement outcomes, the expenditures constitute a social waste. Second, the litigants’ trial expenditures may mislead the tribunal rather than enhance the accuracy of the outcome, which has negative social value. Third, even if trial expenditures do improve the accuracy of outcomes, they may not be socially optimal in magnitude, for the parties consider only how their expenditures influence the litigation outcome, without regard to their influence (if any) on deterrence.

Because private and social incentives to spend on litigation may diverge, it may be beneficial for expenditures to be either curtailed or encouraged. In practice, courts often restrict the legal effort that parties can undertake, for example by limiting the extent of discovery and the number of testifying experts.

Other topics

A number of other topics that relate to litigation and the legal process have been studied, including the selection of suits for litigation (Priest and Klein, 1984); the accuracy of adjudication (Kaplow, 1994; Png, 1986); ‘discovery’, that is, mandated disclosure of information during litigation (Shavell, 1989); and the appeals process (Daughety and Reinganum, 2000; Shavell, 1995; Spitzer and Talley, 2000).

5. Public law enforcement and criminal law

Law enforcement often is the result of the efforts of public agents, such as inspectors, tax auditors, and police. We here discuss certain characteristics of optimal public law enforcement. As noted, this subject was first analysed by Bentham (1789) and Becker (1968) (for a survey, see Polinsky and Shavell, 2000).

Rationale of public enforcement

A basic question is why there is a need for public enforcement of law in the light of the availability of private suits brought by victims (Becker and Stigler, 1974; Landes and Posner, 1975; Polinsky, 1980). The answer depends importantly on the locus of information about the identity of injurers. When victims of harm naturally possess knowledge of the identity of injurers, allowing private suits for damages will motivate victims to sue and thus harness the information they have for purposes of law enforcement. This may help to explain why the enforcement of contractual obligations and of accident law is primarily private. When victims do not know who caused harm, however, or when finding injurers is
difficult, society tends to rely instead on public investigation and prosecution; this is broadly true of crimes and of many violations of environmental and safety regulations.

**Basic framework for analysing public enforcement**

Suppose that, if an individual commits a harmful act, he obtains a gain and also faces the risk of being caught and sanctioned. The sanction could be a fine or a prison term. Fines will be treated as socially costless because they are mere transfers of money, whereas imprisonment is socially costly because of the expense of operating prisons and the disutility suffered by those imprisoned (which is not offset by gains to others). The higher the probability is of detecting and sanctioning violators, the more resources the state must devote to enforcement.

We assume that social welfare equals the sum of individuals’ expected utilities. If individuals are risk neutral, social welfare can be expressed as the gains individuals obtain from committing their harmful acts, minus the harms caused and the costs of law enforcement. The enforcement authority's problem is to maximize social welfare by choosing enforcement expenditures, or, equivalently, a probability of detection, the form of sanctions, and their level.

**Fines**

Suppose that the sanction is a fine and that individuals are risk neutral. Then the optimal level of the fine is maximal, $f_M$, as emphasized in Becker (1968). If the fine were not maximal, society could save enforcement costs by simultaneously raising the fine and lowering the probability without affecting the level of deterrence. Formally, if $f < f_M$, then raise the fine to $f_M$ and lower the probability from $p$ to $(ff_M/p)$; the expected fine is still $pf$, so that deterrence is maintained, but expenditures on enforcement are reduced, implying that social welfare rises. Moreover, the optimal probability is such that there is some under-deterrence; in other words, at the optimal $p$ the expected fine $pf_M$ is less than the harm $h$. The reason for this result is that, if $pf_M$ equals $h$, behaviour will be ideal, in which case decreasing $p$ must be socially beneficial because the individuals thereby induced to commit the harmful act cause no net social losses (because their gains essentially equal the harm), but reducing $p$ saves enforcement costs.

If individuals are risk averse, the optimal fine may well be below the maximal fine, as stressed in Polinsky and Shavell (1979). This is because the use of a very high fine would impose a substantial risk-bearing cost on individuals who commit harmful acts.

**Imprisonment**

Now suppose that the sanction is imprisonment and that individuals are risk neutral in imprisonment. Then the optimal imprisonment term is maximal. The reasoning is similar to that employed above with respect to fines: if the imprisonment term were not maximal, it could be raised and the probability of detection lowered so as to keep the expected prison term constant; neither individual behaviour nor the costs of imposing imprisonment are affected (because the expected prison term is the same), but enforcement expenditures fall.

If, instead, individuals are risk averse in imprisonment (the disutility of each additional year of
imprisonment grows with the number of years in prison), there is a stronger argument for setting the imprisonment sanction maximally than when individuals are risk neutral. Now, when the imprisonment term is raised, the probability of detection can be lowered even more than in the risk-neutral case without reducing deterrence. Thus, not only are there greater savings in enforcement expenditures, but the social costs of imposing imprisonment sanctions decline because the expected prison term falls. Last, suppose that individuals are risk preferring in imprisonment (the disutility of each additional year of imprisonment declines with the number of years in prison). This possibility seems particularly important: the first years of imprisonment may create unusually high disutility, due to brutalization of the prisoner or due to the stigma of having been imprisoned at all. In addition, individuals generally have positive time discount rates, which are thought to be especially significant for criminals. In the case of risk-prefering individuals, the optimal prison term may well be less than maximal: if the sentence were raised, the probability that maintains deterrence could not be lowered proportionally, implying that the expected prison term would rise. Thus, although there would be enforcement-cost savings, they might not be great enough to offset the increased sanctioning costs.

Fines versus imprisonment

Fines generally are preferable to prison terms as a means of deterrence, since fines are socially cheaper sanctions to impose (Becker, 1968). Hence, fines should be employed to the greatest extent possible – until a party's wealth is exhausted – before imprisonment is imposed. Further, imprisonment should be used as a sanction only if the harm prevented by the added deterrence is sufficiently great.

Fault-based liability

Our discussion so far has presumed that liability is strict, but liability may also be based on fault, an assessment of whether the act that caused harm was socially undesirable (analogous to the negligence rule and due-care standard discussed above in the accident context). Fault-based liability, like strict liability, can induce individuals to behave properly, but fault-based liability possesses an advantage when individuals are risk averse: if they act responsibly, they will not be found at fault, so will not bear the risk of being sanctioned. Similarly, fault-based liability is advantageous when the form of the sanction is imprisonment, for then, again, individuals may be led to behave optimally without the actual imposition of sanctions, and thus without social costs being incurred (Shavell, 1987b). To the extent that mistakes are made in determining fault, however, these two advantages are reduced because risk is imposed and sanctioning costs are incurred. Note, too, that fault-based liability is more difficult to implement, because it requires the state to determine optimal behaviour.

Incapacitation

Society may reduce harm not only through deterrence but also by imposing sanctions that remove parties from positions in which they are able to cause harm, that is, by incapacitating them. Imprisonment is the primary incapacitative sanction, although there are other examples: individuals can lose their drivers' licences, businesses can lose their right to operate in certain domains, and the like.
Suppose that the sole function of imprisonment is to incapacitate. Then it will be desirable to keep someone in jail as long as the reduction in crime from incapacitating him exceeds the costs of imprisonment (Shavell, 1987c). Although this condition could hold for a long period, it is unlikely to unless the harm prevented is very high, because the proclivity to commit crimes apparently declines sharply with age.

Note that, as a matter of economic logic, the incapacitation rationale might imply that a person should be imprisoned even if he has not committed a crime – because the danger he poses to society makes incapacitating him worthwhile. In practice, however, the fact that a person has committed a harmful act may be the best basis for predicting his future behaviour, in which case the incapacitation rationale would suggest imprisoning an individual only if he has committed such an act.

Two observations are worth noting about optimal enforcement when incapacitation is the goal as opposed to when deterrence is the goal. First, when enforcement is based on incapacitation, the optimal magnitude of the sanction is independent of the probability of apprehension, which contrasts with the case when enforcement is based on deterrence. Second, when enforcement is deterrence-oriented, the probability and magnitude of sanctions depend on the ability to deter, and, if this ability is limited (as, for instance, with the insane), a low expected sanction may be optimal, whereas a high sanction still might be called for to incapacitate.

Other issues

A number of other topics have been studied in the economic analysis of public law enforcement, including mistake, marginal deterrence (the effect of sanctions in reducing the severity of harm a party causes), self-reporting of violations (Kaplow and Shavell, 1994a; Innes, 1999), repeat offences, plea bargaining (Reinganum, 1988), general enforcement (when detection resources simultaneously influence the deterrence of a range of harmful acts) (Mookherjee and Png, 1992; and Shavell, 1991), and corruption of law-enforcement agents (Shleifer and Vishny, 1993; Rose-Ackerman, 1999; and Polinsky and Shavell, 2001).

Criminal law

The subject of criminal law may be viewed in the light of the theory of public law enforcement (Posner, 1985; Shavell, 1985). First, the fact that the acts in the core area of crime (robbery, murder, rape, and so forth) are punished by the sanction of imprisonment makes basic sense. Were society to rely on fines alone, deterrence of the acts in question would be grossly inadequate. Notably, the probability of detecting many of these acts is low, making the money sanction necessary for deterrence high, but the assets of individuals who commit these acts often are insubstantial. Hence, the threat of prison is needed for deterrence. Moreover, the incapacitative aspect of imprisonment is valuable because of the difficulty of deterring individuals who are prone to commit criminal acts.

Second, many of the doctrines of criminal law appear to enhance social welfare. This seems true of the basic feature of criminal law that punishment is not imposed on all harmful acts, but instead is usually confined to those that are undesirable. (For example, murder is subject to criminal sanctions, but not all accidental killing is.) As we have stressed, when the socially costly sanction of imprisonment is
employed, the fault system is desirable because it results in less frequent imposition of punishment than strict liability. Also, the focus on intent in criminal law as a precondition for imposing sanctions may be sensible with regard to deterrence because those who intend to do harm are more likely to conceal their acts, and may be harder to discourage because of the benefits they anticipate. That unsuccessful attempts to do harm are punished in criminal law is an implicit way of raising the likelihood of sanctions for undesirable acts. Study of specific doctrines of criminal law seems to afford a rich opportunity for economic analysis.

6. Criticism of economic analysis of law

Many observers, and particularly non-economists, view economic analysis of law with scepticism. We consider several such criticisms here.

Description of behaviour

It is sometimes claimed that individuals and firms do not respond to legal rules as rational maximizers of their well-being. For example, it is often asserted that decisions to commit crimes are not governed by economists’ usual assumptions. Some sceptics also suggest that, in predicting individuals’ behaviour, certain standard assumptions are inapplicable. For example, in predicting compliance with a law, the assumption that preferences be taken as given would be inappropriate if a legal rule would change people’s preferences, as some say was the case with civil rights laws and environmental laws. In addition, laws may frame individuals’ understanding of problems, which could affect their probability assessments or willingness to pay. The emerging field of behavioural economics, as well as work in various disciplines that address social norms, is beginning to examine these sorts of issues (Jolls, Sunstein and Thaler, 1998).

Distribution of income

A frequent criticism of economic analysis of law concerns its focus on efficiency to the exclusion of the distribution of income. The claim of critics is that legal rules should be selected in a manner that takes into account their effects on the rich and the poor. But achieving sought-after redistribution through income tax and transfer programmes tends to be superior to redistribution through the choice of legal rules. This is because redistribution through legal rules and the tax-transfer system both will distort individuals’ labour-leisure decisions in the same manner, but redistribution through legal rules often will require choosing an inefficient rule, which imposes an additional cost (Shavell, 1981; Kaplow and Shavell, 1994b).

Moreover, it is difficult to redistribute income systematically through the choice of legal rules. Many individuals are never involved in litigation; and for those who are there is substantial income heterogeneity among plaintiffs as well as among defendants. Additionally, in contractual contexts the choice of a legal rule often will not have any distributional effect because contract terms, notably the price, will adjust, so that any agreement into which parties enter will continue to reflect the initial distribution of bargaining power between them.
Concerns for fairness

An additional criticism is that the conventional economic approach slights important concerns about fairness, justice and rights. Some of these notions refer implicitly to the appropriateness of the distribution of income and, accordingly, are encompassed by our preceding remarks. Also, to some degree, the notions are motivated by instrumental concerns. For example, the attraction of paying fair compensation to victims must derive in part from the beneficial risk reduction effected by such payments, and the appeal of obeying contractual promises must rest in part on the desirable consequences contract performance has on production and exchange. To some extent, therefore, critics’ concerns are already taken into account in standard economic analysis.

However, many who promote fairness, justice and rights do not regard these notions merely as some sort of proxy for attaining instrumental objectives. Instead, they believe that satisfying these notions is intrinsically valuable. This view also can be partially reconciled with the economic conception of social welfare: if individuals have a preference for a legal rule or institution because they regard it as fair, that should be credited in the determination of social welfare, just as any other preference should.

But many commentators take the position that conceptions of fairness are important as ethical principles in themselves, without regard to any possible relationship the principles may have to individuals’ welfare. This opinion is the subject of long-standing debate among moral philosophers. Some readers may be sceptical of normative views that are not grounded in individuals’ well-being because embracing such views entails a willingness to sacrifice individuals’ well-being. Indeed, consistently pursuing any non-welfarist principle must sometimes result in everyone being made worse off (see Kaplow and Shavell, 2001; 2002).

Efficiency of judge-made law

Also criticized is the contention of some economically oriented legal academics, notably Posner (1972), that judge-made law tends to be efficient (in contrast to legislation, which is said to reflect the influence of special interest groups). Some critics believe that judge-made law is guided by notions of fairness, or is influenced by legal culture or judges’ biases, and thus will not necessarily be efficient. Whatever is the merit of the critics’ claims, they are descriptive assertions about the law, and their validity does not bear on the power of economics to predict behaviour in response to legal rules or on the value of normative economic analysis of law.

Bibliography

How to cite this article

John Law of Lauriston has been regarded by some observers as a monetary crank, by others as a precursor of modern schemes of managed money and Keynesian full-employment policies. He was the originator of the Mississippi Bubble, perhaps the greatest speculative bubble of all time.

Born in Edinburgh, the son of prosperous parents, Law was well educated in political economy. A fugitive from justice in 1694 for killing a man in a duel in England, Law travelled extensively throughout Europe, observing and gaining experience in banking, insurance and finance. He proposed a number of unsuccessful schemes to set up a national bank of issue – in Paris in 1702, Edinburgh in 1705 and Savoy in 1712 – finally attaining success in France with the establishment in 1718 of the Banque Royale.

Law's theories on money and banking are contained in *Money and Trade Considered: With a Proposal for Supplying the Nation With Money* (1705) and other works (Hamilton, 1968; Harsin, 1934). Like other 18th-century writers Law adopted a disequilibrium theory of money, viewing it as a stimulant to trade. In a state of unemployment, Law maintained that an increase in the nation's money supply would stimulate employment and output without raising prices since the demand for money would rise with the increase in output. Moreover, once full employment was attained the monetary expansion would attract factors of production from abroad, so output would continue to increase.

According to Law, a paper-money standard was preferable to one based on precious metals. Suitable candidates for the money supply included government fiat, banknotes, stocks and bonds. Since the primary function of money was as a medium of exchange, it could best be served by a commodity (paper) not subject to considerable fluctuation in value and high resource costs. Thus Law advocated the establishment of note-issuing national banks that would extend productive loans (real bills), providing...
sufficient currency to guarantee prosperity. Two proposals for such banks, in Paris 1702 and Edinburgh 1705, would have had the note issues based on land initially valued in terms of silver. From 1716 to 1720 John Law had the unique opportunity to apply his theories to the French economy. In 1715, the heritage of two exhausting wars was depression and deflation. Law succeeded in convincing the Regent (the Duke of Orleans) that a bank of issue would alleviate the problem of financing the national debt. Accordingly, he established in Paris on 2 May 1716 a private bank, the Banque Générale. In its 31 months of operation, the bank was remarkably successful; its notes (convertible into specie and payable as taxes) were issued in moderation and gained national circulation. On 4 December 1718, the Banque Générale was nationalized and renamed the Banque Royale, with Law in control, and in January 1719 it began to issue notes denominated in livres tournois, the unit of account, replacing the previously issued écus de banque representing fixed amounts of specie.

Alongside the bank, in August 1717, Law established the Compagnie d'Occident after obtaining the franchise on Louisiana and the monopoly of the Canadian fur trade. This company in the succeeding 22 months acquired the tobacco monopoly, the East India Company and the trading monopolies to Africa and China. Law changed its name in June 1719 to the Compagnie des Indes, and the following winter obtained the farm of the royal mints and of the indirect taxes. In October 1719 he refunded the national debt of 1.5 million livres tournois, and in January 1720 became Finance Minister.

The stock of the Compagnie des Indes, initially selling at a par value of £500, within half a year in an unprecedented speculative mania was bid up to many times its original price. The bubble burst in January 1720 after the price of the stock reached a peak of £18,000. To support the price Law made the mistake of pegging it at £9,000, thereby monetizing it and engendering a rapid expansion of notes (125 per cent in two months). In May 1720, in a desperate attempt to salvage his system Law issued a deflationary decree depreciating the stock and reducing the denomination of notes by stages. This decree led to a panic as the public, fearful of further capital losses, sold off both notes and stock. Law's dismissal by the Regent worsened the panic. He was quickly reinstated but his final attempt to restore confidence by reducing the outstanding note issue proved unsuccessful. By December 1720 the ‘system’ collapsed. Law fled to Belgium and payments quickly reverted to a specie basis. The collapse of the system ruined many in all walks of life and made the word ‘bank’ anathema in France for well over a century.

Though Law's system reduced unemployment and stimulated output, it was at the expense of doubling the price level. His system was undermined by his actions breaking the link between the note issue and specie convertibility; by retiring the national debt with bank notes convertible into stock; and by encouraging speculation in stock by declaring dividends unrelated to the company's true prospects. Monetizing the stock by pegging its price in the end destroyed the public's confidence in his system. Law was aware of many of the principles of sound money and banking, but by equating money with stock and relying on the real bills doctrine he sowed the seeds of disaster.

Abstract

This article surveys the economic analysis of public enforcement of law – the use of public agents (inspectors, tax auditors, police, prosecutors) to detect and to sanction violators of legal rules. We first discuss the basic elements of the theory: the probability of imposition of sanctions, the magnitude and form of sanctions (fines, imprisonment), and the rule of liability. We then examine a variety of extensions, including the costs of imposing fines, mistakes, marginal deterrence, settlement, self-reporting, repeat offences, and incapacitation.

Article

In this article we consider the theory of public enforcement of law – the use of public agents (inspectors, tax auditors, police, prosecutors) to detect and to sanction violators of legal rules. After briefly discussing the rationale for public (as opposed to private) enforcement, we present the basic elements of the theory: the probability of imposition of sanctions, the magnitude and form of sanctions (fines, imprisonment), and the rule of liability. We then examine a variety of extensions of the central theory, including the costs of imposing fines, mistakes, marginal deterrence, settlement, self-reporting, repeat offences, and incapacitation. (For a fuller treatment of the material in this entry, see Polinsky and Shavell, 2007.)

Before proceeding, we note that economically oriented analysis of public law enforcement dates primarily from the 18th century contribution of Jeremy Bentham (1789), whose analysis of deterrence
law, public enforcement of : The New Palgrave Dictionary of Economics

was sophisticated and expansive. After Bentham, the subject of enforcement lay essentially dormant in economic scholarship until Gary Becker (1968) published a highly influential article, which has led to a voluminous literature.

Rationale of public enforcement

A basic question is why there is a need for public enforcement of law (see generally Becker and Stigler, 1974; Landes and Posner, 1975; Polinsky, 1980a). In particular, why not rely solely on private suits brought by victims? The answer depends importantly on the locus of information about the identity of injurers. When victims of harm naturally possess knowledge of the identity of injurers, allowing private suits for damages will motivate victims to sue and thus harness the information they have for purposes of law enforcement. This may explain why the enforcement of contractual obligations and of accident law is primarily private. When victims do not know who caused harm, however, or when finding injurers is difficult, society may need to rely instead on public investigation and prosecution; this is broadly true of crimes and of many violations of environmental and safety regulations.

Basic framework for analysing public enforcement

An individual who commits a harmful act obtains a gain and also faces the risk of being caught and sanctioned. The form of sanction could be a fine or a prison term. Fines generally will be treated as socially costless because they are mere transfers of money, whereas imprisonment will be considered as socially costly because of the expense of operating prisons and the disutility suffered by those imprisoned. The higher the probability of detecting violators, the more resources the state must devote to enforcement.

We assume that social welfare equals the sum of individuals’ expected utilities. If individuals are risk neutral, social welfare can be expressed as the gains individuals obtain from committing their harmful acts, minus the harms caused and the costs of law enforcement. The enforcement authority's problem is to maximize social welfare by choosing enforcement expenditures (or, equivalently, a probability of detection), the form of sanctions, and their level.

Fines

Suppose that the sanction is a fine and that individuals are risk neutral. If the probability of detection $p$ is taken as fixed, then the optimal fine is the harm $h$ divided by the probability, that is, $h/p$; for then the expected fine $p(h/p)$ equals $h$. This fine is optimal because, facing it, an individual will commit a harmful act if, and only if, the gain he would derive exceeds the harm he would cause. Such behaviour is first-best. The fundamental formula $h/p$ essentially was noted by Bentham (1789) and it has been observed by many others since.

If the probability of detection can be varied, the optimal fine is maximal, $f_M$, as emphasized by Becker (1968). If the fine were not maximal, society could save enforcement costs by simultaneously raising the fine and lowering the probability without affecting the level of deterrence. If $f < f_M$, then raise the fine...
to \(f_M\) and lower the probability from \(p\) to \((f / f_M) p\); the expected fine is still \(pf\), so that deterrence is maintained but expenditures on enforcement are reduced, implying that social welfare rises.

The optimal probability \(p\) of imposing a fine is low in the sense that it results in some under-deterrence; that is, the optimal \(p\) is such that the expected fine \(pf_M\) is less than the harm \(h\) (Polinsky and Shavell, 1984). The reason is to economize on enforcement resources. In particular, if \(pf_M\) equals \(h\), behaviour will be ideal, meaning that the individuals who are just deterred obtain gains essentially equal to the harm. These are the individuals who would be led to commit the harmful act if \(p\) were lowered slightly.

That in turn must be socially beneficial because these individuals cause no net social losses (their gains essentially equal the harm), but reducing \(p\) saves enforcement costs. How much \(pf_M\) should be lowered below \(h\) depends on the saving in enforcement costs from reducing \(p\) compared with the net social costs of under-deterrence that will result if \(p\) is lowered non-trivially.

If individuals are risk averse, the optimal fine may be well less than the maximal fine, as first shown in Polinsky and Shavell (1979); see also Kaplow (1992). This is because a high fine would impose substantial risk-bearing costs on individuals who commit harmful acts. If \(f < f_M\), it is still true that \(f\) can be raised and \(p\) lowered so as to maintain deterrence, but because of risk aversion this now implies that \(pf\) falls, meaning that fine revenue falls. The reduction in fine revenue reflects the disutility caused by imposing greater risk on risk-averse individuals. The decline in fine revenue could more than offset the savings in enforcement expenditures, causing social welfare to be lower.

**Imprisonment**

Now suppose that the sanction is imprisonment. If the probability of detection is fixed, there is no simple formula for the optimal imprisonment term (see Polinsky and Shavell, 1984). The optimal term could be such that there is either under-deterrence or over-deterrence. On the one hand, a relatively low imprisonment term, implying under-deterrence, might be socially desirable because imprisonment costs are reduced for those individuals who commit harmful acts. On the other hand, a relatively high term, implying over-deterrence, might be socially desirable because imprisonment costs are reduced due to fewer individuals committing harmful acts, even if some of these deterred individuals would have obtained gains exceeding the harm.

If the probability of detection can be varied and individuals are risk neutral in imprisonment, then the optimal imprisonment term is maximal. The reasoning is similar to that employed above: if the imprisonment term were not maximal, it could be raised and the probability of detection lowered so as to keep the expected prison term constant; neither individual behaviour nor the costs of imprisonment are affected, but enforcement expenditures fall.

If, instead, individuals are risk averse in imprisonment (the disutility of each additional year of imprisonment grows with the number of years in prison), there is a stronger argument for setting the imprisonment sanction maximally (Polinsky and Shavell, 1999). Now when the imprisonment term is raised, the probability of detection can be lowered more than in the risk-neutral case without reducing deterrence. Thus, not only are there greater savings in enforcement expenditures, but also the costs of imposing imprisonment sanctions decline because the expected prison term falls.

Last, suppose that individuals are risk preferring in imprisonment (the disutility of each additional year of imprisonment declines with the number of years in prison). This possibility seems particularly
important: the first years of imprisonment may create unusually high disutility, due to brutalization of the prisoner or to the stigma of having been imprisoned at all. Individuals’ positive time discount rates, which are thought to be especially significant for criminals, also make the disutility of later years less significant. In the case of risk-preferring individuals, the optimal prison term may well be less than maximal: if the sentence were raised, the probability that maintains deterrence could not be lowered proportionally, implying that the expected prison term would rise. Thus, although there would be enforcement-cost savings, they might not be great enough to offset the increased sanctioning costs.

When the sanction is imprisonment, the optimal probability of detection may be such that there is either under-deterrence or over-deterrence. On the one hand, the motive to lower the probability is reinforced relative to the case of fines because imprisonment costs, as well as detection costs, decline if fewer offenders are caught. On the other hand, raising the probability of detection results in fewer offenders, which, everything else equal, decreases imprisonment costs because fewer are imprisoned. Either effect may dominate.

**Fines versus imprisonment**

Fines generally are preferable to prison terms as a means of deterrence, since fines are socially cheaper sanctions to impose (Becker, 1968; Polinsky and Shavell, 1984). Hence, fines should be employed to the greatest extent possible – until a party's wealth is exhausted – before imprisonment is imposed. Further, imprisonment should be used as a sanction only if the harm prevented by the added deterrence is sufficiently great.

**Fault-based liability**

Our discussion thus far has presumed that liability is strict (imposed whenever harm occurs), but liability may instead be based on fault (imposed only when behaviour was found to be socially undesirable). Fault-based liability, like strict liability, can induce individuals to behave properly, but fault-based liability possesses an advantage when individuals are risk averse: if they act responsibly, they will not be found at fault, so will not bear the risk of being sanctioned. Similarly, fault-based liability is advantageous when the sanction is imprisonment, for then again individuals may be led to behave optimally without the actual imposition of sanctions, and thus without social costs being incurred (Shavell, 1987b). To the extent that mistakes are made in determining fault, however, these two advantages are reduced.

Fault-based liability is more difficult to implement because it requires more information than strict liability. To apply fault-based liability, the enforcement authority must be able to determine the proper fault standard – that is, socially desirable behaviour – and it must ascertain whether the defendant’s conduct was in compliance with the fault standard. Under strict liability, the authority need only measure harm. (Moreover, for reasons we discuss below, strict liability encourages better decisions by injurers regarding their level of participation in harm-creating activities.)

This concludes the presentation of the basic theory of public enforcement of law. We now turn to various extensions and refinements of the analysis.
Accidental harms

We have been implicitly assuming that individuals decide whether or not to commit acts that cause harm with certainty, that is, they decide whether or not to cause intentional harms. In many circumstances, however, harms are accidental— they occur only with a probability. Essentially all that we have said above applies in a straightforward way when harms are accidental.

There is, however, an additional issue that arises when harm is uncertain: a sanction can be imposed either on the basis of the commission of an act that increases the chance of harm (such as storing chemicals in a substandard tank) or on the basis of the actual occurrence of harm (if the tank ruptures and results in a spill). In principle, either approach can achieve optimal deterrence—by setting the (expected) sanction equal to expected harm if liability is imposed whenever a dangerous act is committed, or equal to actual harm if liability is imposed only if harm occurs.

Several factors are relevant to the choice between act-based and harm-based sanctions (Shavell, 1993). First, act-based sanctions need not be as high as harm-based sanctions to accomplish a given level of deterrence (expected harm is less than actual harm), and thus offer an advantage because of parties’ limited assets. Second, because act-based sanctions can accomplish a given level of deterrence with lower sanctions, they are preferable when parties are risk averse. Third, either act-based sanctions may be simpler to impose (it might be less difficult to determine whether an oil shipper properly maintains its vessels’ holding tanks than to detect whether one of the vessels leaked oil), or harm-based sanctions may be easier to implement (a driver who causes harm might be caught without difficulty, but not one who speeds). Fourth, it may be hard to calculate the expected harm due to an act, but relatively easy to ascertain the actual harm if it eventuates, favoring harm-based sanctions.

Costs of imposing fines

The costs borne by enforcement authorities in imposing fines should be reflected in the fine. Recall that, if the probability of detection is taken as fixed and individuals are risk neutral, the optimal fine is \( h/p \), the harm divided by the probability of detection. Now suppose there is a public cost \( k \) of imposing a fine. The optimal fine then becomes \( h/p + k \); the cost \( k \) should be added to the fine that would otherwise be desirable (Becker, 1968; Polinsky and Shavell, 1992). The explanation is that, if an individual commits a harmful act, he causes society to bear not only the immediate harm \( h \) but also, with probability \( p \), the cost \( k \) of imposing the fine— that is, his act results in an expected total social cost of \( h + pk \). If the fine is \( h/p + k \), the individual’s expected fine is \( p(h/p + k) = h + pk \), leading him to commit the harmful act if and only if his gain exceeds the expected total social cost of his act.

Not only does the state bear costs when fines are imposed, so do individuals who pay the fines (such as legal defence expenses). The costs borne by individuals, however, do not affect the formula for the optimal fine. Individuals properly take these costs into account because they bear them.

Level of activity

In many settings in which harm may occur, an individual chooses not only whether to commit a harmful act when engaging in an activity, but also the level at which to engage in the activity. Drivers decide
how careful to be while driving, as well as how many miles to drive; similarly, firms choose safety precautions as well as their level of output. The socially optimal activity level is such that the actor's marginal utility from the activity just equals the marginal expected harm caused by the activity (we assume that optimal care is taken). Thus, the optimal number of miles driven is the level at which the marginal utility of driving an extra mile just equals the marginal expected harm per mile driven.

Under strict liability parties will choose the optimal level of activity because they will pay for all harm done. They will choose the optimal number of miles to drive because they will pay for all harm per mile driven. Under fault-based liability, however, parties generally do not pay for the harm they cause because they tend to behave so as not to be found at fault. As a consequence, they will choose an excessive level of activity (Shavell, 1980). Driving more miles increases expected harm, but this effect generally will be ignored under fault-based liability.

The interpretation of the preceding points in relation to firms is that under strict liability the product price will reflect the expected harm caused by production. Hence, the amount purchased, and thus the level of production, will tend to be socially optimal. However, under fault-based liability the product price will not reflect harm, but only the cost of precautions; thus, the level of output will be excessive (Polinsky, 1980b).

Relatedly, safety regulations and other regulatory requirements are often framed as standards of care that have to be met, but which, if met, free the regulated party from liability. Hence, regulations of this sort are subject to the criticism that they lead to excessive levels of the regulated activity. Making parties strictly liable for harm would be superior to safety regulation with respect to inducing socially correct activity levels.

**Mistakes**

An individual who should be found liable might mistakenly be acquitted. Conversely, an individual who should not be found liable might mistakenly be convicted. For an individual who has been detected, let the probabilities of these errors be $\epsilon_A$ and $\epsilon_C$, respectively. Given the probability of detection $p$ and the chances of these types of error, an individual will commit the wrongful act if and only if his gain $g$ net of his expected fine if he does commit it exceeds his expected fine if he does not commit it, that is, when $g - p(1 - \epsilon_A) f > - p\epsilon_C f$, or, equivalently, when $g > (1 - \epsilon_A - \epsilon_C)p f$.

As emphasized by Png (1986), both types of error reduce deterrence: the term $(1 - \epsilon_A - \epsilon_C)p f$ is declining in both $\epsilon_A$ and $\epsilon_C$. The first type of error diminishes deterrence because it lowers the expected fine if an individual violates the law. The second type of error lowers deterrence because it reduces the difference between the expected fine from violating the law and not violating it — the greater is $\epsilon_C$, the smaller is the increase in the expected fine if one violates the law.

Because mistakes dilute deterrence, they reduce social welfare. Specifically, to achieve any level of deterrence, the probability $p$ must be higher to offset the effect of errors. Mistaken convictions have the additional effect of discouraging socially desirable participation in the activity. Consequently, expenditures made to reduce errors may be socially beneficial (Kaplow and Shavell, 1994a).

Two other points regarding the implications of mistake are worth noting. First, if individuals are risk averse, the possibility of mistakes of either type generally lowers optimal sanctions (Block and Sidak,
Second, as stressed by Craswell and Calfee (1986), individuals will often have a motive to take excessive precautions under fault-based liability in order to reduce the chance of being found erroneously at fault.

**General enforcement**

In many settings, enforcement may be said to be general in the sense that several different types of violations will be detected by an enforcement agent's activity. For example, a police officer waiting at the roadside may notice a driver who litters as well as one who goes through a red light or who speeds, and a tax auditor may detect a variety of infractions when he examines a tax return. (In contrast, if enforcement is specific, the probability is chosen independently for each type of harmful act.) When enforcement is general, the optimal sanction rises with the level of harm, and is maximal only for relatively high harms (Shavell, 1991; Mookherjee and Png, 1992). To see why, assume that liability is strict, the sanction is a fine, and injurers are risk neutral. Let \( f(h) \) be the fine given harm \( h \). Then, for any general probability of detection \( p \) (that is, \( p \) applies regardless of \( h \)), the optimal fine schedule is \( h/p \), provided that \( h/p \) is feasible; otherwise the optimal fine is maximal. This schedule is obviously optimal given \( p \) because it implies that the expected fine equals harm, thereby inducing ideal behaviour whenever that is possible. That sanctions should rise with the severity of harm up to a maximum when enforcement is general also holds if the sanction is imprisonment and if liability is fault-based.

**Marginal deterrence**

In many circumstances a person may consider which of several harmful acts to commit: for example, whether to release only a small amount of a pollutant into a river or a large amount, or whether to kidnap a person or also to kill the kidnap victim. In such contexts, sanctions influence which harmful acts individuals choose to commit (as well as whether to commit any harmful act). Marginal deterrence is said to occur when a more harmful act is deterred because its sanction exceeds that for a less harmful act (Stigler, 1970; Shavell, 1992; Wilde, 1992; Mookherjee and Png, 1994).

Other things being equal, it is socially desirable that enforcement policy creates marginal deterrence so that, when harmful acts do occur, less harm is done. One way to accomplish marginal deterrence is for sanctions to rise with the magnitude of harm, which means that sanctions generally will not be maximal. However, fostering marginal deterrence may conflict with achieving overall deterrence: in order for the schedule of sanctions to rise steeply enough to accomplish marginal deterrence, sanctions for less harmful acts may have to be so low that individuals are not deterred from committing some harmful act. Note that marginal deterrence also can be promoted by increasing the probability of detection. Kidnappers can be better deterred from killing their victims if more police resources are devoted to apprehending kidnappers who murder their victims than to those who do not.

**Principal–agent relationship**

Although we have assumed that an injurer is a single actor, injurers often are more appropriately characterized as collective entities, and specifically as a principal and the principal's agent. For example,
the principal could be a firm and the agent an employee, or the principal could be a contractor and the 
ageant a subcontractor.
When harm is caused by the behaviour of principals and agents, many of our prior conclusions carry 
over to the sanctioning of principals. Notably, if a risk-neutral principal faces an expected fine equal to 
harm done, he will behave socially optimally in controlling his agents, and in particular will contract 
with them and monitor them in ways that will give the agents appropriate incentives to reduce harm 
(Newman and Wright, 1990; but see Arlen, 1994).
An issue that arises when there are principals and agents concerns the allocation of financial sanctions 
between the two parties. It is apparent that the particular allocation of sanctions does not matter when 
the parties can reallocate the sanctions through their own contract. For example, if the agent finds that he 
faces a large fine but is more risk averse than the principal, the principal can assume it; conversely, if the 
fine is imposed on the principal, he will retain it and not impose an internal sanction on the agent. Thus, 
the post-contract sanctions that the agent bears are not affected by the particular division of sanctions 
initially selected by the enforcement authority.
The allocation of monetary sanctions between principals and agents would matter, however, if some 
allocations allow the pair to reduce their total burden. An important example is when a fine is imposed 
only on the agent and he is unable to pay it (Sykes, 1981; Kornhauser, 1982). Then, he and the principal 
(who often would have higher assets) would jointly escape part of the fine, diluting deterrence. The fine 
therefore should be imposed on the principal rather than on the agent (or at least the part of the fine that 
the agent cannot pay).
A closely related point is that the imposition of imprisonment sanctions on agents may be desirable 
when their assets are less than the harm that they can cause, even if the principal's assets are sufficient to 
pay the optimal fine (Polinsky and Shavell, 1993). That an agent's assets are limited means that the 
principal may be unable to control him adequately through the use of contractually determined penalties, 
which can only be monetary. In such circumstances it may be socially valuable to use the threat of a jail 
sentence to better control agents’ misconduct.

Settlements

Settlements may have other socially undesirable consequences. First, they may result in sanctions that 
are not as well tailored to harmful acts as would be true of court-determined sanctions. For example, if 
injurers have private information about the harm that they have caused, settlements will tend to reflect 
the average harm caused, resulting in high-harm (low-harm) injurers being under-deteterred (over-
deterred), whereas trial outcomes may better approximate the actual harm. Second, settlements hinder
the amplification and development of the law through the setting of precedents. Third, if the sanction is
imprisonment and defendants are risk averse, settlements necessitate longer terms than the expected
sentence at trial in order to maintain deterrence, and thus increase public expenditures. On the social
welfare evaluation of settlement, see, for example, Shavell (1997) and Spier (1997).

Self-reporting

We have assumed that individuals are subject to sanctions only if they are detected by an enforcement
agent, but in fact parties sometimes disclose their own violations. For example, firms often report
infractions of environmental and safety regulations, individuals usually notify police of their
involvement in traffic accidents, and even criminals occasionally turn themselves in.

Self-reporting can be induced by lowering the sanction for individuals who disclose their own violations
(Kaplow and Shavell, 1994b). Moreover, the reward for self-reporting can be made small, so that
deterrence is only negligibly reduced. For example, if a risk-neutral individual commits a violation and
does not self-report, his expected fine is $pf$. If he self-reports, the fine can be set just below $pf$, say at
$pf - \varepsilon$, where $\varepsilon > 0$ is small. Then the individual will want to self-report but the deterrent effect of the
sanction will be essentially the same as if he did not self-report.

There are several social advantages of self-reporting. First, self-reporting reduces enforcement costs
because the enforcement authority does not have to identify and prove who the violator was. Second,
self-reporting reduces risk (a relatively high sanction imposed with a relatively low probability is
replaced by a certain punishment), and thus is advantageous if injurers are risk averse. Third, self-
reporting may allow harm to be mitigated (early notice of an oil spill may facilitate its containment).

Repeat offenders

In practice, the law often sanctions repeat offenders more severely than first-time offenders. This policy
cannot be socially advantageous if deterrence always induces first-best behaviour. For if the expected
sanction for an offence equals its harm, then raising the sanction because an offender has a record of
sanctions would over-deter him. Only if deterrence is inadequate is it possibly desirable to condition
sanctions on offence history to increase deterrence. But, as we observed above, it usually will be
worthwhile for the state to tolerate some under-deterrence in order to reduce enforcement expenses.

If there is under-deterrence, making sanctions depend on offence history may be beneficial. First, the use
of offence history may create an additional incentive not to violate the law: if detection results not only
in an immediate sanction but also in a higher sanction for any future violation, an individual will,
everything else equal, be deterred to a greater extent (Polinsky and Shavell, 1998). Second, making
sanctions depend on offence history allows society to take advantage of information about the
dangerousness of individuals and the need to deter them: individuals with offence histories may be more
likely than average to commit future violations, which might make it desirable to impose higher
sanctions on them (Rubinstein, 1979; Polinsky and Rubinfeld, 1991). In addition, if repeat offenders
have higher propensities to commit violations, they are more likely to be worth incapacitating by
imprisonment (see below).
Imperfect knowledge about the probability and magnitude of sanctions

Individuals might not know the true probability of a sanction because the enforcement authority refrains from publishing information about the probability (perhaps hoping that individuals will believe it to be higher than it is in fact); or because the probability depends on factors that individuals do not fully understand; or because probabilities are difficult to assess. Also, individuals may have incomplete knowledge of the true magnitude of sanctions, particularly if the levels of sanctions are discretionary. The implications of injurers’ imperfect knowledge are straightforward. First, to predict how individuals behave, what is relevant, of course, is not the actual probability and magnitude of a sanction but the perceived levels or distributions of these variables. Second, to determine the optimal probability and magnitude of a sanction, account must be taken of the relationship between the actual and the perceived variables (Bebchuk and Kaplow, 1992; Kaplow, 1990). For example, if enforcement resources are increased in order to raise the probability of detection, there might be a delay before this increase is perceived by individuals, making such an investment less worthwhile.

Incapacitation

Society may reduce harm not only through deterrence, but also by imposing sanctions that remove parties from positions in which they are able to cause harm, that is, by incapacitating them. Imprisonment is the primary incapacitative sanction, although there are other examples: individuals can lose their driver's licences, businesses can lose their rights to operate in certain markets, and the like. Suppose that the sole function of imprisonment is to incapacitate. Then it will be desirable to keep someone imprisoned as long as the reduction in criminal harm from incapacitating him exceeds the cost of imprisonment (Shavell, 1987c). Although this condition could hold for a long period, it often will not because the proclivity to commit crimes appears to decline sharply with age. As a matter of economic logic, the incapacitation rationale might imply that a person should be imprisoned even if he has not committed a crime, because the danger he poses to society makes incapacitating him worthwhile. In practice, however, the commission of a harmful act may be a good basis for predicting a person's future behaviour, in which case the incapacitation rationale would suggest imprisoning an individual only if he has committed such an act.

Two observations are worth noting about the relationship between the incapacitation goal and the deterrence goal. First, when enforcement is based on incapacitation, the optimal magnitude of the sanction is independent of the probability of apprehension, which contrasts with the case when enforcement is based on deterrence. Second, when enforcement is deterrence-oriented, the probability and magnitude of sanctions depend on the ability to deter, and if this ability is limited (as, for instance, with the insane), a low expected sanction may be optimal, whereas a high sanction still might be called for to incapacitate.

Corruption

One form of corruption in the enforcement process is bribery, in which an enforcer accepts a payment in
Bribery dilutes deterrence of violations of law because it results in a lower payment by an individual than the sanction for the offence. Framing and framing-related extortion also dilute deterrence. The reason is that framing and extortion imply that those who act innocently face an expected sanction, so that the difference between the expected sanction if an individual commits a violation and if he does not is lessened. (This point is essentially the same as the earlier observation that mistaken convictions dilute deterrence.)

One way to reduce corruption is to impose fines (or imprisonment sentences) on individuals caught engaging in bribery, extortion or framing. Corruption also can be reduced by paying enforcers rewards for reporting violations. Such payments will reduce their incentive to accept bribes because they will sacrifice their rewards if they fail to report violations. But high rewards give enforcers a greater incentive to frame innocent individuals. A third way to control corruption is to pay enforcers more than their reservation wage (that is, to pay them an efficiency wage). Then they would have more to lose if punished for corrupt behaviour and denied future employment.

A natural question is whether the deterrence-diluting effects of corruption can be offset by raising the fine on offenders. In the basic risk-neutral model of enforcement, it is not possible to raise the fine because the optimal fine is maximal. More realistically, however, the optimal fine is less than maximal for a variety of reasons, including those related to risk aversion, marginal deterrence, and general enforcement. While it would then be possible to raise the fine to offset the deterrence-diluting effects of corruption, doing so would lead to social costs (for example, by imposing greater risk).

Costly observation of wealth

Individuals and firms may be able to hide assets from government enforcers, including by hoarding cash, transferring assets to relatives or related legal entities, or moving money to offshore bank accounts. Consequently, an individual's level of wealth might not be able to be observed at all, or only after a costly audit.

Suppose first that the enforcement authority employs fines as sanctions and can audit an individual who claims that he cannot pay the fine (Polinsky, 2006). The optimal fine for misrepresenting one's wealth level equals the fine for the offence divided by the audit probability, and therefore generally exceeds the fine for the offence. This is a natural generalization of the formula for the optimal fine when the probability of detection is fixed, which is the harm divided by the probability. Auditing is valuable because it reduces misrepresentation of wealth and thereby increases deterrence.

Next, suppose that the enforcement authority cannot observe wealth because the cost of an audit is prohibitively high (Levitt, 1997; Polinsky, 2006). If the authority would have used fines alone if it could have observed wealth at no cost, it would have imposed a higher fine on higher-wealth individuals. It obviously cannot do this when wealth is unobservable. Instead, it may be desirable to use the threat of an imprisonment sentence to induce individuals capable of paying a higher fine to do so. Alternatively, the
enforcement authority might have used both fines and imprisonment if it could have observed wealth at no cost. Perhaps surprisingly, the inability to observe wealth might not be detrimental in this case. The reason is that the mix of fines and imprisonment that would be chosen when wealth is observable might impose a higher burden (though a lower fine) on low-wealth individuals. Then, high-wealth individuals will naturally want to identify themselves. Specifically, they will prefer to pay a higher fine and bear a shorter imprisonment sentence than to masquerade as low-wealth individuals, who will bear longer imprisonment sentences and a higher overall burden.

Social norms

To some extent, social norms and morality are substitutes for public law enforcement because they encourage in significant ways the attainment of desired behaviour (McAdams and Rasmusen, 2007; Posner, 1997; Shavell, 2002). Social norms influence behaviour partly through internal incentives: when a person obeys a moral rule, he will tend to feel virtuous, and if he disobeys the rule, he will tend to feel guilty. Social norms also affect behaviour through external incentives: when a person is observed by another party to have obeyed a moral rule, that party may bestow praise on the first party, who will enjoy the praise; and if the person is observed by the other party to have disobeyed the rule, the second party will tend to disapprove of the first party, who will dislike the disapproval. Because social norms channel behaviour in this way, some socially desirable conduct can be encouraged reasonably well without employing the legal system.

Notwithstanding these observations, there will, of course, often be a need for formal law enforcement. First, much conduct that society desires cannot be controlled through moral incentives alone. One reason is that the private gains from undesirable conduct are often large and dominate the moral incentives. Another reason is that external moral sanctions might be imposed only with a low probability (the robber, tax cheat or polluter might not be spotted by others). A second rationale of formal law enforcement is that the social harm from failing to control an act through moral incentives may be large. This makes the expense of law enforcement worth incurring (as in the case of controlling robbery, but not of breaking into a queue at a movie theatre).

Fairness

So far we have not considered the possibility that individuals have opinions about the fairness of sanctions or the arbitrariness of enforcement (Polinsky and Shavell, 2000b; Kaplow and Shavell, 2002). Suppose, first, that individuals believe that the magnitude of sanctions should reflect the gravity of the acts. As discussed previously, if individuals are risk neutral, the usual solution to the enforcement problem consists of the highest possible sanction and a relatively low probability of detection. When the issue of fairness is added to the analysis, however, the usual solution generally is not optimal because a very high sanction will be seen as unfair.

A consequence of the desire to keep sanctions at fair levels, meaning at quite constrained levels for acts that are not very harmful, is that the socially optimal probability of detection changes. The optimal probability could be higher than the conventionally optimal probability: to achieve a desired level of deterrence with a lower fairness-restricted sanction, the probability has to rise, perhaps significantly.
Alternatively, the optimal probability could be lower than in the conventional case: the additional deterrence from raising the probability might be relatively low because the sanction is relatively low; and the lower the deterrent benefit from raising the probability, the lower would be the social incentive to devote resources to enforcement.

Another aspect of fairness concerns the probability of detection rather than the magnitude of sanctions. Suppose that individuals consider it unfair for some lawbreakers to be sanctioned when others, who were lucky enough not to be caught, are not sanctioned. Then the optimal probability would be higher, and therefore the optimal sanction would be lower, than in the absence of this fairness concern.

A further notion of fairness involves the form of liability, whether liability is strict or based on fault. Individuals might prefer fault-based liability because sanctions are imposed on parties only if they behaved in a socially inappropriate way.

A final issue concerns the relevance of fairness considerations when firms, as opposed to individuals, are sanctioned. If what matters in terms of fairness is that the individuals responsible for harmful acts bear sanctions, as opposed to the artificial legal entity of a firm, one would want to identify the sanctions actually suffered by such persons within a firm if the firm bears a sanction. Note, too, that the imposition of sanctions on firms often penalizes individuals who are unlikely to be considered responsible for the harm, namely, shareholders and customers.

### Criminal law

The subject of criminal law may be viewed in the light of the theory of public law enforcement (Posner, 1985; Shavell, 1985). First, the fact that the acts in the core area of crime (robbery, murder, rape, and so forth) are punished by the sanction of imprisonment makes basic sense. Were society to rely on fines alone, deterrence of the acts in question would be grossly inadequate. This is because the probability of detecting many of these acts is low, making the money sanction necessary for deterrence high, but the assets of individuals who commit these acts often are insubstantial. Hence, the threat of prison is needed for deterrence. Moreover, the incapacitative aspect of imprisonment is valuable because of the difficulty of deterring individuals who are prone to commit criminal acts.

Second, many of the doctrines of criminal law appear to enhance social welfare. This seems true of the basic feature of criminal law that punishment is not imposed on all harmful acts, but instead is usually confined to those that are especially undesirable. (For example, murder is subject to criminal sanctions, but some accidental killing is not.) As we have stressed, when the socially costly sanction of imprisonment is employed, the fault system is desirable because it results in less frequent imposition of punishment than strict liability. Also, the focus on intent in criminal law as a precondition for imposing sanctions may serve to foster deterrence because those who intend to do harm are more likely to conceal their acts, and may be harder to discourage because of the benefits they anticipate. An additional example of a welfare-enhancing doctrine in criminal law concerns attempts. That attempts to do harm are punished is an implicit way of raising the likelihood of sanctions for undesirable acts.

layoffs

John Haltiwanger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Layoffs reflect employer-initiated job separations that play an important role in frictional and cyclical unemployment. The relative importance of temporary and permanent layoffs and layoffs themselves has varied over time, and understanding the factors underlying this variation is important for understanding fluctuations in frictional and cyclical unemployment over time. Modern models of labour market dynamics often emphasize the layoffs associated with endogenous job destruction at the firm level induced by the interaction of aggregate and firm-specific shocks.

Keywords

business cycles; cyclical unemployment; hold-up problem; implicit contracts; information capital; labour market search; layoffs; search and matching models; job creation and destruction

Article

The term ‘layoff’ is controversial in itself. For some the term connotes a temporary employer-initiated discharge, for others it represents any employer-initiated discharge that is without prejudice to the worker. The data on layoffs collected by the Bureau of Labor Statistics (BLS) in the United States (see, for example, various issues of the journal Employment and Earnings) takes the alternative types of layoffs into account across its firm and household surveys. Layoff data from the BLS survey of firms (the Job Openings and Labor Turnover Survey, JOLTS) provide data on employer-initiated discharges making no distinction as to whether the layoff is temporary or permanent. According to JOLTS, layoffs average about 1.1 per cent of US non-farm employment each month, which is about one-third of all worker separations. The BLS survey of households (the Current Population Survey, CPS) distinguishes between ‘temporary layoffs’ and ‘permanent job losers’ in tracking unemployment, where the former are layoffs for which recall is expected within six months and the latter are layoffs where employment ended involuntarily and the workers have begun looking for work. According to the CPS, about 50 per
cent of all unemployed are classified as job losers and temporary layoffs account for one-third of the job losers.

The controversy over the terminology is dwarfed by the controversy over the occurrence of layoffs. When General Motors announces that it is laying off 20,000 of its workers indefinitely there is widespread press coverage. This attention is well deserved since substantial variation in layoffs (both temporary and permanent) is frequently observed, and layoffs play an important role in cyclical unemployment. Empirical studies of unemployment (for example, Davis, Haltiwanger and Schuh, 1996; Bleakley, Ferris and Fuhrer, 1999) indicate that the typical increase in unemployment during a business cycle slump is primarily due to an increase in employer-initiated discharges, that is, layoffs. For example, in the sharp 1982 recession in the USA, the fraction of the unemployed due to job loss peaked at 63 per cent while in the 2001 recession this fraction peaked at 56 per cent.

The increase in layoff unemployment during recessions is closely tied to the increase in gross job destruction in recessions. Davis, Haltiwanger and Schuh (1996) show that job destruction rises substantially during recessions and is increasingly driven by establishments contracting substantially (for example, with contractions greater than 25 per cent). In turn, Davis, Faberman and Haltiwanger (2006) show that establishments that are contracting intensively use layoffs as the primary means of contraction. The structure of temporary and permanent layoffs over the cycle has varied over time. Groshen and Potter (2003) show that, in the four recessions in the USA between 1967 and 1990, both temporary layoff and permanent layoff unemployed surged in each of the recessions. However, starting with the 1990–1 recessions, temporary layoffs have played a much smaller role and the rise in job loss has been driven almost entirely by permanent layoffs.

The theory of layoff unemployment has evolved with the relative importance of temporary versus permanent layoffs. Given the important role for temporary layoffs in the 1970s, the so-called ‘implicit contract models’ (see, for example, Azariadis, 1975; Baily, 1974; and Burdett and Mortensen, 1980) were developed during that time to help account for the role of temporary layoffs. The temporary layoff models provide a basis for understanding how in a long-term employer–employee relationship it may be optimal for firms and workers to use temporary layoffs to respond to transitory shocks. However, the increased understanding and role of permanent job destruction and associated permanent job loss has pushed theoretical developments in new directions.

Recent theories that incorporate the evidence on permanent job destruction adopt the premise that the economy is subject to a continuous stream of allocative shocks – shocks that cause idiosyncratic variation in profitability among job sites and worker–job matches (see Davis and Haltiwanger, 1999; Mortensen and Pissarides, 1999; and Shimer, Rogerson and Wright, 2005 for an extensive survey of these theories). The continuous stream of allocative shocks generates the large-scale job and worker reallocation observed in the data. To explicitly model the job and worker reallocation process, these theories incorporate heterogeneity among workers and firms along one or more dimensions. Various theories also emphasize search costs, moving costs, sunk investments and other frictions that impede or otherwise distort the reallocation of factor inputs. The combination of frictions and heterogeneity gives rise to potentially important roles for allocative shocks and the reallocation process in aggregate economic fluctuations.

Theories of cyclical fluctuations in job and worker flows with such reallocation frictions can be classified into two broad types. One type treats fluctuations over time in the intensity of allocative
shocks as an important driving force behind aggregate fluctuations and the pace of reallocation activity. A second type maintains that while allocative shocks and reallocation frictions are important, aggregate shocks drive business cycles and fluctuations in the pace of worker and job reallocation. Although different in emphasis, the two types of theories offer complementary views of labour market dynamics and business cycles, and both point toward a rich set of interactions between aggregate fluctuations and the reallocation process.

One can think of allocative shocks as events that alter the closeness of the match between the desired and actual characteristics of labour and capital inputs. Adverse aggregate consequences can result from such events because of the time and other costs of reallocation activity. In considering this view, it is important to emphasize that allocative shocks affect tangible inputs to the production process (labour and physical capital) and intangible inputs. These intangible inputs include the information capital embodied in an efficient sorting and matching of heterogeneous workers and jobs, knowledge about how to work productively with co-workers, knowledge about suitable locations for particular business activities and about idiosyncratic attributes of those locations, the information capital embodied in long-term customer–supplier and debtor–creditor relationships, and the organization capital embodied in sales, product distribution and job-finding networks. These remarks make clear why the economic adjustments to these shocks are often costly and time consuming. It follows that sharp time variation in the intensity of allocative shocks can cause large fluctuations in gross job flows and in turn unemployment dynamics and layoffs in particular.

The connection between cyclical fluctuations in job destruction and layoffs may also stem from responses to adverse aggregate shocks. An adverse aggregate shock can push many declining and dying plants over an adjustment threshold. During boom times, a firm may choose to continue operating a plant that fails to recover its long-run average cost, because short-run revenues exceed short-run costs, or because of a sufficiently large option value to retaining the plant and its work force. A closely related mechanism emphasizes the changes in the incentives for reallocation over the cycle. The reallocation of specialized labour and capital inputs involves forgone production due to lost work time (for example, unemployment or additional schooling), worker retraining, the retooling of plant and equipment, the adoption of new technology, and the organization of new patterns of production and distribution. On average across firms and workers, the value of forgone production tends to fluctuate procyclically, rising during expansions and falling during recessions. This cyclical pattern generates incentives for both workers and firms to concentrate costly reallocation activity during recessions, when the opportunity cost of the resulting forgone production is relatively low. This mechanism is highlighted in the models of Davis and Haltiwanger (1999), Mortensen and Pissarides (1994) and Caballero and Hammour (1994).

A key question is whether the cyclical fluctuations in job destruction and layoffs reflect efficient or inefficient responses to shocks. Caballero and Hammour (1996) highlight the potential for labour markets to malfunction because of appropriability or hold-up problems. These problems arise whenever investment in a new production unit or the formation of a new employment relationship involves some degree of specificity for workers or employers, and there are difficulties in writing or enforcing complete contracts. In their model, Caballero and Hammour (1996) show that efficient restructuring involves synchronized job creation and destruction and relatively little unemployment. In contrast, the inefficient equilibrium restructuring process that emerges under incomplete contracts involves the decoupling of creation and destruction dynamics and relatively large unemployment responses to negative shocks. As discussed in Mortensen and Pissarides (1999), appropriability problems arise
naturally in many search and matching models. Malcomson (1999) provides a broad discussion of hold-up problems in the labour market.

Overall, understanding layoffs requires understanding of the underlying dynamics of job and worker reallocation. New theories and new data sets have emerged that provide a rich new perspective on the dynamics of the labour market at the micro level and in turn the implications of these dynamics for aggregate fluctuations. Much work remains to be done on both theoretical and empirical questions, particularly on understanding the role of market imperfections in these dynamics. Along these lines, one continuing open question is not only to understand the driving forces of job loss but also the closely related forces of the job gains. After all, the loss of a job has much lower costs to the individual and the economy if the worker in question moves quickly to another job.

Le Chatelier principle

Eugene Silberberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In the field of economics, the Le Chatelier principle refers to the differences in the responses of decision variables to changes in parameters when additional constraints are imposed on the system. In the context of demand theory, for example, the Le Chatelier principle is the ‘second law of demand’, that demand curves are more elastic in the long run than in the short run. In many models, additional constraints reduce the absolute response of a decision variable to a change in a parameter.

Keywords

comparative statics; conjugate pairs theorem; envelope theorem; Le Chatelier principle; parameter values; Samuelson, P.

Article

Henri Louis Le Chatelier was a French chemist born in Paris in 1850. In 1884, he offered the following observation:

Any system in stable chemical equilibrium, subjected to the influence of an external cause which tends to change either its temperature or its condensation (pressure, concentration, number of molecules in unit volume), either as a whole or in some of its parts, can only undergo such internal modifications as would, if produced alone, bring about a change of temperature or of condensation of opposite sign to that resulting from the external cause. (Oliver and Kurtz, 1992)

Later writers produced a more heuristic simplification: ‘If the external conditions…are altered, the equilibrium … will tend to move in such a direction so as to oppose the change in external conditions’ (Fermi, 1937, p. 111, cited in Samuelson, 1949, p. 639), or even more simply: if a stress is
applied to a system at equilibrium, then the system readjusts, if possible, to reduce the stress. The Le Chatelier principle is a firmly established proposition in classical thermodynamics, though its verbal statement is somewhat vague in operational content. In the field of economics, the law of demand, which states that as a price increases, ceteris paribus, consumers will decrease their consumption of that good, is in fact a direct application of the Le Chatelier principle. Consumers (or firms) mitigate the adverse effects of the price increase by utilizing less of that good or input.

Following up a suggestion by his professor and mentor E.B. Wilson at Harvard, Paul Samuelson showed that this principle was a simple application of maximizing behaviour (see especially Samuelson, 1949; 1960a; 1974.) Moreover, physicists and economists – among economists, principally Samuelson – came to realize that the Le Chatelier principle was being used to describe two separate phenomena. The first referred to first-order changes in response to a change in a parameter value, such as a price. The second, which is what the Le Chatelier principle is now generally understood to mean, refers to differences in the changes as additional constraints are imposed on the system.

The general case

First-order effects

The most general comparative statics model with explicit maximizing behaviour is maximize

\[ y = f(x, \alpha) \]  
subject to \[ g(x, \alpha) = 0, \] where \( x(x_1, ..., x_n) \) is a vector of decision variables, \( \alpha = (\alpha_1, ..., \alpha_m) \) is a vector of parameters (though for simplicity, we treat \( \alpha \) as a scalar in the discussion below), and \( g(\cdot) \) represents one or more constraints. Models at this level of generality, however, imply no refutable implications and are hence largely uninteresting. In particular, there are never refutable implications for parameters that enter the constraint (see, for example, Silberberg and Suen, 2000). Thus we restrict the analysis to models of the form

\[
\begin{align*}
\text{maximize } & y = f(x, \alpha), \\
\text{subject to } & g(x) = 0.
\end{align*}
\]

Since it has no effect on the analysis to follow, we consider the case of only one external constraint. Also, parameters \( \beta \), which enter the constraint but which do not enter the objective function, also do not affect the analysis, and hence we suppress them in the notation. The Lagrangian for this model is
Le Chatelier principle: The New Palgrave Dictionary of Economics

\[ L = f(x, \alpha) + \lambda g(x) \] producing the necessary first-order conditions (NFOC)

\[ L_i = f_i(x, \alpha) + \lambda g_j(x) = 0 \quad i = 1, \ldots, n \]  
(3)

\[ L_\lambda = g(x) = 0 \]  
(4)

Assuming the sufficient second-order conditions hold, we can in principle ‘solve’ for the \( n + 1 \) explicit choice functions \( x = x^*(\alpha) \) and \( \lambda^*(\alpha) \). Of course, since these choice functions are the result of solving the NFOC simultaneously, each individual \( x_i \) is a function of all the parameters, not just the ones which appear in \( L_i \).

Substituting the \( x_i^* \)'s into the objective function yields the indirect objective function

\[ \phi(\alpha) = f(x^*(\alpha), \alpha) \], the maximum value of \( f \) for given \( \alpha \), subject to the constraint. Since \( \phi(\alpha) \) is by definition a maximum value, \( \phi(\alpha) \geq f(x, \alpha) \), but \( \phi(\alpha) = f(x, \alpha) \) when \( x = x^* \). Thus the function \( F(x, \alpha) = f(x, \alpha) - \phi(\alpha) \) has a (constrained) maximum of zero, with respect to both \( x \) and \( \alpha \). Thus we consider the primal-dual model

\[ \text{maximize } F(x, \alpha) = f(x, \alpha) - \phi(\alpha) \]  
(5)

\[ \text{subject to } g(x) = 0 \]  
(6)

where the maximization runs over \( x \) and also \( \alpha \). (In the latter instance, we ask, for given \( x_i \)'s, what values of the parameters would make these \( x_i \)'s the maximizing values?) The Lagrangian for this model
The Le Chatelier principle is:

\[ L = f(x, \alpha) - \phi(\alpha) + \lambda g(x) \]  

(7)

The first-order conditions with respect to \( x \) are the same as in the original model. With respect to \( \alpha \), the NFOC yield the famous ‘envelope theorem’

\[ L_\alpha = f_\alpha - \phi_\alpha = 0 \]  

(8)

When \( \alpha \) enters the constraint also, we get the envelope theorem in its most general form,

\[ \phi_\alpha = L_\alpha = f_\alpha + \lambda g_\alpha \]  

(8a)

Importantly, however, since we have restricted the model so that the parameters \( \alpha \) do not enter the constraint, the primal-dual model is an unconstrained maximization in \( \alpha \). Hence in the \( \alpha \) dimensions, the second-order conditions are simply

\[ F_{\alpha\alpha} = f_{\alpha\alpha} - \phi_{\alpha\alpha} \leq 0. \]  

(9)

This inequality says that in the \( \alpha \) dimensions, \( f \) is relatively more concave than \( \phi \). This is the fundamental geometrical property that underlies all comparative statics relationships and also the ‘second-order’ Le Chatelier relationships.

The NFOC (8) are identities when \( x = x^* \). That is,

\[ \phi_\alpha(\alpha) \equiv f_\alpha(x^*(\alpha), \alpha) \]  

(10)
Differentiating with respect to $\alpha$,

$$
\phi_{\alpha\alpha} = \sum_{1}^{n} f_{\alpha i} \frac{\partial x_i^*}{\partial \alpha} + f_{\alpha\alpha}
$$

(11)

Rearranging terms, using (9) and invariance to the order of differentiation,

$$
\phi_{\alpha\alpha} - f_{\alpha\alpha} = \sum_{1}^{n} f_{i\alpha} \frac{\partial x_i^*}{\partial \alpha} \geq 0
$$

(12)

This is the fundamental relation of comparative statics. From it, we can derive Samuelson's famous 'conjugate pairs' theorem, namely, that refutable implications occur in maximization models when and only when a parameter enters one and only one first-order condition. For in that case, where say $\alpha$ enters only $L_j = 0$, $f_{j\alpha} = 0$, $j \neq i$, and so (12) reduces to one term:

$$
f_{i\alpha} \frac{\partial x_i^*}{\partial \alpha} \geq 0
$$

(13)

In this case we can say that the response of $x_i$ is in the same direction as the disturbance to the equilibrium (or, in the case of minimization models, in the opposite direction). These relationships constitute the 'first-order' Le Chatelier effects. Note that these results are identical to those in models with no constraints at all, or with multiple constraints, as long as those constraints do not contain the parameter that is changing.

**Second-order effects**

Suppose now the NFOC hold at the parameter value $\alpha^0$ and consider now the imposition of an
additional constraint, \( h(x) = 0 \), with the important restriction that this constraint does not change the original equilibrium, for example, a constraint holding some input fixed at the previous profit maximizing level. Then the new NFOC are solved for new explicit choice functions, \( x_i = x_i^s(\alpha) \), where the superscript ‘s’ stands for ‘short run’. Substituting these short run choice functions into the objective function produces a new indirect objective function, \( \psi (\alpha) \). Since the new constraint did not disturb the equilibrium, \( \psi(\alpha^0) = \phi(\alpha^0) \) at that point. However, since the objective function is now more constrained, for \( \alpha \neq \alpha^0, \psi(\alpha) \leq \phi(\alpha) \). Thus the function \( G(\alpha) = \psi(\alpha) - \phi(\alpha) \) has an unconstrained maximum (of zero) at \( \alpha = \alpha^0 \). The NFOC are

\[
G_\alpha(\alpha) = \psi_\alpha(\alpha) - \phi_\alpha(\alpha) = 0
\]

(14)

We note that \( \psi_\alpha(\alpha) = \phi_\alpha(\alpha) = f_\alpha \) using the same analysis leading to eq. (8), since \( \alpha \) appears in neither constraint. The second-order conditions are

\[
G_{\alpha\alpha}(\alpha) = \psi_{\alpha\alpha}(\alpha) - \phi_{\alpha\alpha}(\alpha) \leq 0
\]

(15)

That is, the more constrained indirect objective function \( \psi (\alpha) \) is tangent to \( \phi(\alpha) \) at \( \alpha = \alpha^0 \), but it is relatively more concave, or less convex. Using \( \psi_\alpha(\alpha) = \phi_\alpha(\alpha) = f_\alpha \) expressed as identities, and proceeding as in eqs. (10) through (12), inequality (15) yields the general second-order Le Chatelier effects:

\[
\sum_{i=1}^{n} f_{i\alpha} \left( \frac{\partial x_i^*}{\partial \alpha} - \frac{\partial x_i^s}{\partial \alpha} \right) \geq 0
\]

(16)

In the empirically important case where \( \alpha \) enters only the \( i \)th first-order condition, this summation reduces to one term, producing
Le Chatelier principle: The New Palgrave Dictionary of Economics

\[
f_i \frac{\partial x_i^*}{\partial \alpha} \geq f_i \frac{\partial x_i^5}{\partial \alpha}
\]

(17)

Thus \( \frac{\partial x_i^*}{\partial \alpha} / \partial \alpha \geq \frac{\partial x_i^5}{\partial \alpha} / \partial \alpha \geq 0 \) when \( f_{i\alpha} > 0 \), and \( \frac{\partial x_i^*}{\partial \alpha} / \partial \alpha \leq \frac{\partial x_i^5}{\partial \alpha} / \partial \alpha \leq 0 \) when \( f_{i\alpha} < 0 \). In either case, \( \left| \frac{\partial x_i^*}{\partial \alpha} \right| \geq \left| \frac{\partial x_i^5}{\partial \alpha} \right| \).

Examples

Profit maximization

Consider the profit-maximization model \( \text{maximize } \pi = f(x, w, p) = p\theta(x_1, ..., x_n) - \sum w_i x_i \) Each parameter \( w_i \) enters only the \( i^{th} \) NFOC, and \( \frac{\partial x_i}{\partial w_i} = -1 \), so that (13) yields the negative slope property \( \frac{\partial x_i}{\partial w_i} \leq 0 \). Moreover, (17) yields, in addition, for any additional constraint (not involving \( w_i \)) imposed on the initial equilibrium,

\[
\frac{\partial x_i^*}{\partial w_i} \leq \frac{\partial x_i^5}{\partial w_i} \leq 0
\]

(18)

The ‘long-run’ factor demand functions are more elastic than any short-run factor demands defined as above.

In the case where the additional constraint is simply \( x_n = x_n^0 \), an analysis based on ‘conditional demands’ (Pollak, 1969) is available. If we substitute this constraint directly into the objective function, the ‘short-run’ demand functions are \( x_i = x_i^5(w_1, ..., w_{n-1}, p, x_n^0) \). These functions are related to the long-run demands by the identity

\[
x_i^*(w_1, ..., w_n, p) \equiv x_i^5(w_1, ..., w_{n-1}, p, x_n^*(w_1, ..., w_n, p))
\]

(19)

Differentiating both sides of this identity with respect to \( w_i \) and \( w_n \),
Substituting (21) into (20) and using a well-known reciprocity condition yields

$$\frac{\partial x_i^*}{\partial w_j} = \frac{\partial x_i^*}{\partial w_j} + \frac{\partial x_i^*}{\partial x_n^0} \frac{\partial x_n^*}{\partial w_i}$$

(20)

$$\frac{\partial x_i^*}{\partial w_n} = \frac{\partial x_i^*}{\partial x_n^0} \frac{\partial x_n^*}{\partial w_n}$$

(21)

Since the last term in (22) is negative, we get the Le Chatelier result (18).

Cost (expenditure) minimization

The cost functions in production theory are derived from the model, minimize \( C = \sum w_i x_i \) subject to \( f(x_1, \ldots, x_n) = y \), where \( y \) is now a parameter, that is, it is an arbitrary fixed level of output. This model is directly related to the profit maximization model. Write the profit maximization model as maximize \( py - \sum w_i x_i \) subject to \( f(x_1, \ldots, x_n) = y \). When output \( y \) is a variable, this model is the profit-maximization model. If \( y \) is parametric, it is the constrained cost minimization model. Thus we see that the cost minimization model is the profit maximization model with an added constraint. Denoting the factor demands derived from cost minimization as \( x_i = x_i(y, w_1, w_n, y) \), we apply (13) and (17) to derive

$$\frac{\partial x_i^*}{\partial w_j} = \frac{\partial x_i^*}{\partial x_j} \frac{\partial x_j^*}{\partial w_i} \leq 0 \quad \frac{\partial x_i^*}{\partial w_j} = \frac{\partial x_i^*}{\partial x_j} \frac{\partial x_j^*}{\partial w_i} \leq 0$$

The profit maximizing factor demand function, which incorporates an output effect, is always more elastic with respect to its own price than the constant output factor demand functions, regardless of whether the output effect is positive or negative. We can also show by this method that, if another constraint is imposed on the factors, these cost-minimizing demand functions
become less elastic. When the additional constraint takes on the form of holding some factor fixed, as in the above profit-maximization model, a similar conditional demand process is available (see Silberberg and Suen, 2000).

### Marginal cost functions

Many – perhaps most – important economic models incorporate a constraint of the form $g(x_1, ..., x_n) = k$. The cost minimization model is an example; so are the various two-factor two-good models in which endowment levels are fixed. The Lagrangian for the cost minimization model is $L = \sum w_i x_i + \lambda (y - f(x_1, ..., x_n))$. The indirect objective function is the cost function $C = C^*(w_1, ..., w_n, y)$. The envelope theorem (8a) identifies $\lambda^*(w_1, ..., w_n, y)$ as the marginal cost function: $\frac{\partial C^*}{\partial y} = \lambda^*$. We know from the above comparative statics discussion that cost minimization does not imply a sign for the slope of the marginal cost function, that is, $\frac{\partial \lambda^*}{\partial y} / \partial y \neq 0 \rightarrow \frac{\partial \lambda^*}{\partial y} / \partial y \geq 0$. Nonetheless, we can still derive a Le Chatelier result for the marginal cost function.

Adding a new constraint $h(x) = 0$ to the cost minimization model consistent with the original equilibrium produces a new ‘short run’ cost function $C^s(w_1, ..., w_n, y)$. Since this is more constrained than $C^*$, it must be the case that $C^s \leq C^*$, but the two are equal at the original equilibrium. Thus the function $F = C^s - C^*$ has an unconstrained maximum (of zero) with respect to all the parameters, and in particular, $y$. Thus $F^s = C^s - C^* = 0$ and $F^y = C^s_y - C^*_y \leq 0$. But this latter inequality is $\frac{\partial \lambda^*}{\partial y} / \partial y \leq \frac{\partial \lambda^*}{\partial y} / \partial y$. That is, the long-run marginal cost function either falls faster or rises slower than the short-run marginal cost function. This is the mathematical foundation for the famous article by Viner (1932) and his draftsman Wong that started it all.

### Extensions

The Le Chatelier principle is a local result. Even with the usual sufficient second-order conditions, if some price changes by a finite amount, it is not an implication of the model that the long-run effects are absolutely larger than the short-run effects. However, Milgrom and Roberts (1996) showed, using lattice theory, that, for example, for the profit-maximizing firm model, if all the cross-partials of the production function are everywhere non-negative, the Le Chatelier results hold in the large. A few years later, Suen, Silberberg and Tseng (2000) provided an easier proof of this result, showing also that the global Le Chatelier result held when the factors of production and the fixed factor do not switch from being substitutes to being complements (or vice versa) over the relevant price range.

Samuelson (1960a) analysed Le Chatelier phenomena for equilibrium systems not resulting from an explicit maximization hypothesis, using the ‘well-known’ theorem of reciprocal determinants of Jacobi. (I used to joke to my classes that the theorem was well-known to Jacobi and to Samuelson.) Lady and Quirk (2004) have analysed non-maximizing systems using a theory of cycles in determinants; they prove the Le Chatelier principle applies to systems identified by Morishima (1952), which allows substitutes and complements.

Le Trosne, Guillaume François (1728–1780)

Peter Groenewegen

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Le Trosne, G. F.; Physiocracy; single tax; value

Article

French lawyer and economist. Born in Orléans, Le Trosne studied natural law philosophy with Pothier in preparation for work as a magistrate. In 1753 he was appointed Royal Councillor at the Orléans Presidial Court, whence he retired in 1773. Le Trosne joined the Physiocrats in 1764 by publishing a book defending the free trade in grain (1765) and articles in Ephémérides and other journals. His major economic work, De l'ordre social, appeared in 1777, its second volume, De l'intérêt social, having major economic content with its discussion of value, circulation, money, industry, and domestic, foreign and colonial trade, partly by way of criticism of Condillac's (1776) anti-physiocratic views on these subjects. Le Trosne died in Paris in 1780.

De l'ordre social sets out the laws required for good government designed to ensure and enhance the reproduction of subsistence and wealth. Two major laws are identified. The first demands freedom for economic activity and security of property (Le Trosne, 1777a, p. 38). The second seeks to secure sufficient government revenue to defray public expenses in providing not only security of property and defence but also public works in communication and transport most favourable to reproduction (1777a, p. 122). The second law entails an appropriate tax system ensured by gradual implementation of the single tax on net product (1777a, p. 147). The remaining discourses of the first volume develop the absolute necessity of these laws from historical examples and from their undesirable consequences when transgressed. Constitutional issues of good government defended in part by standard physiocratic arguments in lengthy footnotes (for example, on luxury, 1777a. pp. 214–19, and free trade, pp. 347–50) form the thrust of the argument in the first volume.

Le Trosne's second volume (1777b) is particularly noted for its theory of value (Meek, 1962, p. 389, n. 1), which distinguishes its various determinants such as usefulness, tastes, relative scarcity and competition but which identifies necessary expenses of production as the major influence on value, hence the name fundamental price (pp. 503–4). To analyse value effects on production and wealth Le
Trosne distinguishes various value forms linking, for example, the excess of the price received for produce by the farmer over costs, to accumulation and the increase of wealth. Other roles for these complex value relationships are illustrated in Le Trosne's perceptive discussions of exchange, money, circulation, the sterility of industry and the benefits of trade for an agricultural nation. This analysis clearly confirms the value foundations of physiocratic theory, crystallized in his demonstration of the special productivity of agriculture by means of a simple example where all payments are assumed to be in kind ('*en nature*'), thereby demonstrating the inaccuracy of interpretations which neglect the sophisticated physiocratic value analysis (p. 590).

learning and evolution in games: adaptive heuristics

H. Peyton Young
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A ‘heuristic’ is a method or rule for solving problems; in game theory it refers to a method for learning how to play. Such a rule is ‘adaptive’ if it is directed towards higher payoffs and is reasonably simple to implement. This article discusses a variety of such rules and the forms of equilibrium that they implement. It turns out that even sophisticated solution concepts, like subgame perfect equilibrium, can be achieved by relatively simple and intuitive methods.

Keywords

adaptive heuristics; commitment; correlated equilibrium; learning; Nash equilibrium; probability; regret; repeated games; strategic learning; subgame perfection

Article

‘Adaptive heuristics’ are simple behavioural rules that are directed towards payoff improvement but may be less than fully rational. The number and variety of such rules are virtually unlimited; here we survey several prominent examples drawn from psychology, computer science, statistics and game theory. Of particular interest are the informational inputs required by different learning rules and the forms of equilibrium to which they lead. We shall begin by considering very primitive heuristics, such as reinforcement learning, and work our way up to more complex forms, such as hypothesis testing, which still, however, fall well short of perfectly rational learning.

One of the simplest examples of a learning heuristic is cumulative payoff matching, in which the subject plays actions next period with probabilities proportional to their cumulative payoffs to date. Specifically, consider a finite stage game G that is played infinitely often, where all payoffs are assumed to be strictly positive. Let $a_{ij}(t)$ denote the cumulative payoff to player $i$ over all those periods $0 \leq t' \leq t$ when he played action $j$, including some initial propensity $a_{ij}(0) > 0$. The cumulative payoff matching rule stipulates that in period $t+1$, player $i$ chooses action $j$ with probability
learning and evolution in games: adaptive heuristics

The New Palgrave Dictionary of Economics

Notice that the distribution has full support given the assumption that the initial propensities are positive. This idea was first proposed by the psychologist Nathan Herrnstein (1970) to explain certain types of animal behaviour, and falls under the more general rubric of reinforcement learning (Bush and Mosteller, 1951; Suppes and Atkinson, 1960; Cross, 1983). The key feature of a reinforcement model is that the probability of choosing an action increases monotonically with the total payoff it has generated in the past (on the assumption that the payoffs are positive). In other words, taking an action and receiving a positive payoff reinforces the tendency to take that same action again. This means, in particular, that play can become concentrated on certain actions simply because they were played early and often, that is, play can be habit-forming (Roth and Erev, 1995; Erev and Roth, 1998).

Reinforcement models differ in various details that materially affect their theoretical behaviour as well as their empirical plausibility. Under cumulative payoff matching, for example, the payoffs are not discounted, which means that current payoffs have an impact on current behaviour that diminishes as $1/t$. Laboratory experiments suggest, however, that recent payoffs matter more than those long past (Erev and Roth, 1998); furthermore, the rate of discounting has implications for the asymptotic properties of such models (Arthur, 1991).

Another variation in this class of models relies on the concept of an aspiration level. This is a level of payoffs, sometimes endogenously determined by past play, that triggers a change in a player's behaviour when current payoffs fall below the level and inertial behaviour when payoffs are above the level. The theoretical properties of these models have been studied for $2 \times 2$ games, but relatively little is known about their behaviour in general games (Börgers and Sarin, 2000; Cho and Matsui, 2005).

Next we turn to a class of adaptive heuristics based on the notion of minimizing regret, about which more is known in a theoretical sense. Fix a particular player and let $\alpha(t)$ denote the average per period payoff that she received over all periods $t' \leq t$. Let $\alpha_j(t)$ denote the average payoff she would have received by playing action $j$ in every period through $t$, on the assumption that the opponents played as they actually did. The difference $r_j(t) = \alpha_j(t) - \alpha(t)$ is the subject's unconditional regret from not having played $j$ in every period through $t$. (In the computer science literature this is known as external regret; see Greenwald and Gondek, 2002.)

The following simple heuristic was proposed by Hart and Mas-Colell (2000; 2001) and is known as unconditional regret matching: play each action with a probability that is proportional to the positive part of its unconditional regret, that is,

$$p_j(t + 1) = \frac{[r_j(t)]_+}{\sum_k [r_k(t)]_+}.$$ (2)
This learning rule has the following remarkable property: when used by any one player, his regrets become non-positive almost surely as \( t \) goes to infinity \textit{irrespective of the behaviour of the other players}. When all players use the rule, their time average behaviour converges almost surely to a generalization of correlated equilibrium known as the \textit{Hannan set} or the \textit{coarse correlated equilibrium set} (Hannan, 1957; Moulin and Vial, 1978; Hart and Mas-Colell, 2000; Young, 2004). In general, a \textit{coarse correlated equilibrium} (CCE) is a probability distribution over outcomes (joint actions) such that, given a choice between (\( a \)) committing \textit{ex ante} to whatever joint action will be realized, and (\( b \)) committing \textit{ex ante} to a fixed action, given that the others are committed to playing their part of whatever joint action will be realized, every player weakly prefers the former option. By contrast, a \textit{correlated equilibrium} (CE) is a distribution such that, after a player's part of the realized joint action has been disclosed, he would just as soon play it as something else, given that the others are going to play their part of the realized joint action. It is straightforward to show that the coarse correlated equilibria form a convex set that contains the set of correlated equilibria (Young, 2004, ch. 3).

The heuristic specified in (2) belongs to a large family of rules whose time-average behaviour converges almost surely to the coarse correlated equilibrium set; equivalently, that assures no long-run regret for all players simultaneously. For example, this property holds if we let

\[
p_j(t + 1) = \frac{[r_j(t)]^\theta}{\sum_k[r_k(t)]^\theta}
\]

for some exponent \( \theta > 0 \); one may even take different exponents for different players. Notice that these heuristics put positive probability only on actions that would have done strictly better (on average) than the player's realized average payoff. These are sometimes called \textit{better reply rules}. Fictitious play, by contrast, puts positive probability only on action(s) that would have done best against the opponents’ frequency distribution of play.

Fictitious play does not necessarily converge to the coarse correlated equilibrium set (CCES); indeed, in some 2x2 coordination games fictitious play causes perpetual miscoordination, in which case both players have unconditional long-run regret (Fudenberg and Kreps, 1993; Young, 1993). By choosing \( \theta \) to be very large, however, we see that there exist better reply rules that are arbitrarily close to fictitious play and that do converge almost surely to the CCES. Fudenberg and Levine (1995; 1998; 1999) and Hart and Mas-Colell (2001) give general conditions under which stochastic forms of fictitious play converge in time average to the CCES.

Without complicating the adjustment process too much, one can construct rules whose time average behaviour converges almost surely to the \textit{correlated equilibrium set} (CES). To define this class of heuristics we need to introduce the notion of conditional regret. Given a history of play through time \( t \) and a player \( i \), consider the change in per period payoff if \( i \) had played action \( k \) in all those periods \( t' \leq t \) when he actually played action \( j \) (and the opponents played what they did). If the difference is positive, player \( i \) has conditional regret – he wishes he had played \( k \) instead of \( j \). Formally, \( i \)'s conditional regret at playing \( j \) instead of \( k \) up through time \( t \), \( r^i_{jk}(t) \), is \( 1/t \) times the increase in payoff that would have resulted from playing \( k \) instead of \( j \) in all periods \( t' \leq t \). Notice that the average is taken over all \( t \) periods to date; hence, if \( j \) was not played very often, \( r^i_{jk}(t) \) will be small.

Consider the following \textit{conditional regret matching} heuristic proposed by Hart and Mas-Colell (2000):
if a given agent played action $j$ in period $t$, then in period $t+1$ he plays according to the distribution

$$q_k(t+1) = \varepsilon r_{jk}(t) + \text{for all } k \neq j, \text{ and } q_j(t+1) = 1 - \varepsilon \sum_{k \neq j} r_{jk}(t).$$

(3)

In effect $1 - \varepsilon$ is the degree of inertia, which must be large enough that $q_k(t+1)$ is non-negative for all realizations of the conditional regrets $r_{jk}(t)$. If all players use conditional regret matching and $\varepsilon$ is sufficiently small, then almost surely the joint frequency of play converges to the set of correlated equilibria (Hart and Mas-Colell, 2000). Notice that pointwise convergence is not guaranteed; the result says only that the empirical distribution converges to a convex set. In particular, the players’ time-average behaviour may wander from one correlated equilibrium to another. It should also be remarked that, if a single player uses conditional regret matching, there is no assurance that his conditional regrets will become non-positive over time unless we assume that the other players use the same rule. This stands in contrast to unconditional regret matching, which assures non-positive unconditional regret for any player who uses it irrespective of the behaviour of the other players. One can, however, design more sophisticated updating procedures that unilaterally assure no conditional regret; see for example Foster and Vohra (1999), Fudenberg and Levine (1998, ch. 4), Hart and Mas-Colell (2000), and Young (2004, ch. 4).

A natural question now arises: do there exist simple heuristics that allow the players to learn Nash equilibrium instead of correlated or still coarser forms of equilibrium? The answer depends on how demanding we are about the long-run convergence properties of the learning dynamic. Notice that the preceding results on regret matching were concerned solely with time-average behaviour; no claim was made that period-by-period behaviour converges to any notion of equilibrium. Yet surely it is period-by-period behaviour that is most relevant if we want to assert that the players have ‘learned’ to play equilibrium. It turns out that it is very difficult to design adaptive learning rules under which period-by-period behaviour converges almost surely to Nash equilibrium in any finite game, unless one builds in some form of coordination among the players (Hart and Mas-Colell, 2003; 2006). The situation becomes even more problematic if one insists on fully rational, Bayesian learning. In this case it can be shown that there exist games of incomplete information in which no form of Bayesian rational learning causes period-by-period behaviours to come close to Nash equilibrium behaviour even in a probabilistic sense (Jordan, 1991, 1993; Foster and Young, 2001; Young, 2004; see also learning and evolution in games: belief learning).

If one does not insist on full rationality, however, one can design stochastic adaptive heuristics that cause period-by-period behaviours to come close to Nash equilibrium – indeed close to subgame perfect equilibrium – most of the time (without necessarily converging to an equilibrium). Here is one approach due to Foster and Young (2003); for related work see Foster and Young (2006) and Germano and Lugosi (2007). Let $G$ be a finite $n$-person game that is played infinitely often. At each point in time, each player thinks that the others are playing i.i.d. strategies. Specifically, at time $t$ player $i$ thinks that $j$ is playing the i.i.d strategy $p_j(t)$ on $j$'s action space, and that the opponents are playing independently; that is, their
Learning and Evolution in Games: Adaptive Heuristics

The joint strategies are given by the product distribution $P_{-i}(t) = \prod_{j \neq i} P_j(t)$. Suppose that $i$'s best response is to play a smoothed best response to $P_{-i}(t)$. Specifically, assume that $i$ plays each action $j$ with a probability proportional to $e^{\beta u_{ij}(\cdot, P_{-i})}$, where $u_{ij}(\cdot, P_{-i})$ is $i$'s expected utility from playing $j$ in every period when the opponents play $P_{-i}$, and $\beta > 0$ is a response parameter. This is known as a quantal or log linear response function. For brevity, denote $i$'s response in period $t$ by $Q_i^\beta(t)$; this depends, of course, on $P_{-i}(t)$. Player $i$ views $P_{-i}(t)$ as a hypothesis that he wishes to test against data. After first adopting this hypothesis he waits for a number of periods (say $s$) while he observes the opponents’ behaviour, all the while playing $Q_i^\beta(t)$. After $s$ periods have elapsed, he compares the empirical frequency distribution of the opponents’ play during these periods with his hypothesis. Notice that both the empirical frequency distribution and the hypothesized distribution lie in the same compact subset of Euclidean space. If the two differ by more than some tolerance level $\tau$ (in the Euclidean metric), he rejects his current hypothesis and chooses a new one.

In choosing a new hypothesis, he may wish to take account of information revealed during the course of play, but we shall also assume he engages in some experimentation. Specifically, let us suppose that he chooses a new hypothesis according to a probability density that is uniformly bounded away from zero on the space of hypotheses. One can show the following: given any $\varepsilon > 0$, if the response parameter $\beta$ is sufficiently large, the test tolerance $\tau$ is sufficiently small (given $\beta$), and the amount of data collected $s$ is sufficiently large (given $\beta$ and $\tau$), then the players’ period-by-period behaviours constitute an $\varepsilon$-equilibrium of the stage game $G$ at least $1 - \varepsilon$ of the time (Foster and Young, 2003). In other words, classical statistical hypothesis testing is a heuristic for learning Nash equilibria of the stage game. Moreover, if the players adopt hypotheses that condition on history, they can learn complex equilibria of the repeated game, including forms of subgame perfect equilibrium.

The theoretical literature on strategic learning has advanced rapidly in recent years. A much richer class of learning models has been identified since the mid-1990s, and more is known about their long-run convergence properties. There is also a greater understanding of the various kinds of equilibrium that different forms of learning deliver. An important open question is how these theoretical proposals relate to the empirical behaviour of laboratory subjects. While there is no reason to think that any of these rules can fully explain subjects’ behaviour, they can nevertheless play a useful role by identifying phenomena that experimentalists should look for. In particular, the preceding discussion suggests that weaker forms of equilibrium may turn out to be more robust predictors of long-run behaviour than is Nash equilibrium.

Article

The theory of learning and evolution in games provides models of disequilibrium behaviour in strategic settings. Much of the theory focuses on whether and when disequilibrium behaviour will resolve in equilibrium play, and, if it does, on predicting which equilibrium will be played. But the theory also offers techniques for characterizing perpetual disequilibrium play.

1 A taxonomy

Models from evolutionary game theory consider the behaviour of large populations in strategic environments. In the biological strand of the theory, agents are genetically programmed to play fixed actions, and changes in the population's composition are the result of natural selection and random mutations. In economic approaches to the theory, agents actively choose which actions to play using simple myopic rules, so that changes in aggregate behaviour are the end result of many individual decisions. Deterministic evolutionary dynamics, usually taking the form of ordinary differential equations, are used to describe behaviour over moderate time spans, while stochastic evolutionary
Learning and evolution in games: an overview

The New Palgrave Dictionary of Economics

Dynamics, modelled using Markov processes, are more commonly employed to study behaviour over very long time spans. Models of learning in games focus on the behaviour of small groups of players, one of whom fills each role in a repeated game. These models too can be partitioned into two categories. Models of heuristic learning (or adaptive learning) resemble evolutionary models, in that their players base their decisions on simple myopic rules. One sometimes can distinguish the two sorts of models by the inputs to the agents’ decision rules. In both the stochastic evolutionary model of C, Kandori, Mailath and Rob (1993) and the heuristic learning model of Young (1993), agents’ decisions take the form of noisy best responses. But in the former model agents evaluate each action by its performance against the population’s current behaviour, while in the latter they consider performance against the time averages of opponents’ past play. In models of coordinated Bayesian learning (or rational learning), each player forms explicit beliefs about the repeated game strategies employed by other players, and plays a best response to those beliefs in each period. The latter models assume a degree of coordination of players’ prior beliefs that is sufficient to ensure that play converges to Nash equilibrium. By dropping this coordination assumption, one obtains the more general class of Bayesian learning (or belief learning) models. Since such models can entail quite naive beliefs, belief learning models overlap with heuristic learning models – see Section 3 below.

2 Evolutionary game theory

The roots of evolutionary game theory lie in mathematical biology. Maynard Smith and Price (1973) introduced the equilibrium notion of an evolutionarily stable strategy (or ESS) to capture the possible stable outcomes of a dynamic evolutionary process by way of a static definition. Later, Taylor and Jonker (1978) offered the replicator dynamic as an explicitly dynamic model of the natural selection process. The decade that followed saw an explosion of research on the replicator dynamic and related models of animal behaviour, population ecology, and population genetics: see Hofbauer and Sigmund (1988).

In economics, evolutionary game theory studies the behaviour of populations of strategically interacting agents who actively choose among the actions available to them. Agents decide when to switch actions and which action to choose next using simple myopic rules known as revision protocols (see Sandholm, 2006). A population of agents, a game, and a revision protocol together define a stochastic process – in particular, a Markov process – on the set of population states.

2.1 Deterministic evolutionary dynamics

How the analysis proceeds depends on the time horizon of interest. Suppose that for the application in question, our interest is in moderate time spans. Then if the population size is large enough, the idiosyncratic noise in agent's choices is averaged away, so that the evolution of aggregate behaviour follows an almost deterministic path (Benaïm and Weibull, 2003). This path is described by a solution to an ordinary differential equation. For example, Björnerstedt and Weibull (1996) and Schlag (1998) show
that if agents use certain revision protocols based on imitation of successful opponents, then the population's aggregate behaviour follows a solution to Taylor and Jonker's (1978) replicator dynamic. This argument provides an alternative, economic interpretation of this fundamental evolutionary model. Much of the literature on deterministic evolutionary dynamics focuses on connections with traditional game theoretic solution concepts. For instance, under a wide range of deterministic dynamics, all Nash equilibria of the underlying game are rest points. While some dynamics (including the replicator dynamic) have additional non-Nash rest points, there are others under which rest points and Nash equilibria are identical (Brown and von Neumann, 1950; Smith, 1984; Sandholm, 2006).

A more important question, though, is whether Nash equilibrium will be approached from arbitrary disequilibrium states. For certain specific classes of games, general convergence results can be established (Hofbauer, 2000; Sandholm, 2007). But beyond these classes, convergence cannot be guaranteed. One can construct games under which no reasonable deterministic evolutionary dynamic will converge to equilibrium — instead, the population cycles through a range of disequilibrium states forever (Hofbauer and Swinkels, 1996; Hart and Mas-Colell, 2003). More surprisingly, one can construct games in which nearly all deterministic evolutionary dynamics not only cycle for ever, but also fail to eliminate strictly dominated strategies (Hofbauer and Sandholm, 2006). If we truly are interested in modelling the dynamics of behaviour, these results reveal that our predictions cannot always be confined to equilibria; rather, more complicated limit phenomena like cycles and chaotic attractors must also be permitted as predictions of play.

2.2 Stochastic evolutionary dynamics

If we are interested in behaviour over very long time horizons, deterministic approximations are no longer valid, and we must study our original Markov process directly. Under certain non-degeneracy assumptions, the long-run behaviour of this process is captured by its unique stationary distribution, which describes the proportion of time the process spends in each population state. While stochastic evolutionary processes can be more difficult to analyse than their deterministic counterparts, they also permit us to make surprisingly tight predictions. By making the amount of noise in agents’ choice rules vanishingly small, one can often ensure that all mass in the limiting stationary distribution is placed on a single population state. This stochastically stable state provides a unique prediction of play even in games with multiple strict equilibria (Foster and Young, 1990; Kandori, Mailath and Rob, 1993).

The most thoroughly studied model of stochastic evolution considers agents who usually play a best response to the current population state, but who occasionally choose a strategy at random. Kandori, Mailath and Rob (1993) show that if the agents are randomly matched to play a symmetric 2×2 coordination game, then taking the probability of ‘mutations’ to zero generates a unique stochastically stable state. In this state, called the risk dominant equilibrium, all agents play the action that is optimal against an opponent who is equally likely to choose each action. Selection results of this sort have since been extended to cases in which the underlying game has an arbitrary number of strategies, as well as to settings in which agents are positioned on a fixed network, interacting only with neighbours (see Kandori and Rob, 1995; Blume, 2003; Ellison, 1993; 2000). Stochastic stability has also been employed in contexts where the underlying game has a nontrivial
Learning and Evolution in Games: An Overview

The New Palgrave Dictionary of Economics

This extensive form; these analyses have provided support for notions of backward induction (for example, subgame perfection) and forward induction (for example, signalling game equilibrium refinements): see Nöldeke and Samuelson (1993) and Hart (2002).

Still, these selection results must be interpreted with care. When the number of agents is large or the rate of ‘mutation’ is small, states that fail to be stochastically stable can be coordinated upon for great lengths of time (Binmore, Samuelson and Vaughan, 1995). Consequently, if the relevant time span for the application at hand is not long enough, the stochastically stable state may not be the only reasonable prediction of behaviour.

3 Learning in Games

3.1 Heuristic Learning

Learning models study disequilibrium adjustment processes in repeated games. Like evolutionary models, heuristic learning models assume that players employ simple myopic rules in deciding how to act. In the simplest of these models, each player decides how to act by considering the payoffs he has earned in the past. For instance, under reinforcement learning (Börgers and Sarin, 1997; Erev and Roth, 1998), agents choose each strategy with probability proportional to the total payoff that the strategy has earned in past periods.

By considering rules that look not only at payoffs earned, but also at payoffs foregone, one can obtain surprisingly strong convergence results. Define a player's regret for (not having played) action \( a \) to be the difference between the average payoff he would have earned had he always played \( a \) in the past, and the average payoff he actually received. Under regret matching, each action whose regret is positive is chosen with probability proportional to its regret. Hart and Mas-Colell (2000) show that regret matching is a consistent repeated game strategy: it forces a player's regret for each action to become nonpositive. If used by all players, regret matching ensures that their time-averaged behaviour converges to the set of coarse correlated equilibria of the underlying game. (Coarse correlated equilibrium is a generalization of correlated equilibrium under which players' incentive constraints must be satisfied at the ex ante stage rather than at the interim stage: see Young, 2004.)

Some of the most striking convergence results in the evolution and learning literature establish a stronger conclusion: namely, convergence of time-averaged behaviour to the set of correlated equilibria, regardless of the game at hand. The original result of this sort is due to Foster and Vohra (1997; 1998), who prove the result by constructing a calibrated procedure for forecasting opponents' play. A forecasting procedure produces probabilistic forecasts of how opponents will act. The procedure is calibrated if in those periods in which the forecast is given by the probability vector \( p \), the empirical distribution of opponents’ play is approximately \( p \). It is not difficult to show that if players always choose myopic best responses to calibrated forecasts, then their time-averaged behaviour converges to the set of correlated equilibria.

Hart and Mas-Colell (2000) construct simpler procedures – in particular, procedures that define conditionally consistent repeated game strategies – also ensure convergence to correlated equilibrium. A repeated game strategy is conditionally consistent if for each frequently played action \( a \), the agent would not have been better off had he always played an alternative action \( a' \) in place of \( a \). As a matter of
definition, the use of conditionally consistent strategies by all players leads time-averaged behavior to converge to the set of correlated equilibria.

Another variety of heuristic learning models, based on \textit{random search and independent verification}, ensures a stochastic form of convergence to Nash equilibrium regardless of the game being played (Foster and Young, 2003). However, in these models the time required before equilibrium is first reached is quite long, making them most relevant to applications with especially long time horizons. In some heuristic learning models, players use simple rules to predict how opponents will behave, and then respond optimally to those predictions. The leading examples of such models are \textit{fictitious play} and its stochastic variants (Brown, 1951; Fudenberg and Kreps, 1993): in these models, the prediction about an opponents’ next period play is given by the empirical frequencies of his past plays. Beginning with Robinson (1951), many authors have proved convergence results for standard and stochastic fictitious play in specific classes of games (see Hofbauer and Sandholm (2002) for an overview). But as Shapley (1964) and others have shown, these models do not lead to equilibrium play in all games.

\subsection{3.2 Coordinated Bayesian learning}

The prediction rule underlying two-player fictitious play can be described by a belief about the opponent's repeated game strategy that is updated using Bayes's rule in the face of observed play. This belief specifies that the opponent choose his stage game actions in an i.i.d. fashion, conditional on the value of an unknown parameter. (In fact, the player's beliefs about this parameter must come from the family of Dirichlet distributions, the conjugate family of distributions for multinomial trials.) Evidently, each player's beliefs about his opponent are wrong: player 1 believes that player 2 chooses actions in an i.i.d. fashion, whereas player 2 actually plays optimally in response to his own (i.i.d.) predictions about player 1's behaviour. It is therefore not surprising that fictitious play processes do not converge in all games.

In models of \textit{coordinated Bayesian learning} (or \textit{rational learning}), it is not only supposed that players form and respond optimally to beliefs about the opponent's repeated game strategy; it is also assumed that the players’ initial beliefs are coordinated in some way. The most studied case is one in which prior beliefs satisfy an absolute continuity condition: if the distribution over play paths generated by the players’ actual strategies assigns positive probability to some set of play paths, then so must the distribution generated by each player's prior. A strong sufficient condition for absolute continuity is that each player's prior assigns a positive probability to his opponent's actual strategy.

The fundamental result in this literature, due to Kalai and Lehrer (1993), shows that under absolute continuity, each player's forecast along the path of play is asymptotically correct, and the path of play is asymptotically consistent with Nash equilibrium play in the repeated game. Related convergence results have been proved for more complicated environments in which each player's stage game payoffs are private information (Jordan, 1995; Nyarko, 1998). If the distributions of players types are continuous, then the sense in which play converges to equilibrium can involve a form of purification: while actual play is pure, it appears random to an outside observer.

How much coordination of prior beliefs is needed to prove convergence to equilibrium play? Nachbar (2005) proves that for a large class of repeated games, for any belief learning model, there are no prior beliefs that satisfy three criteria: learnability, consistency with optimal play, and diversity. Thus, if
players can learn to predict one another's behaviour, and are capable of responding optimally to their updated beliefs, then each player's beliefs about his opponents must rule out some seemingly natural strategies a priori. In this sense, the assumption of coordinated prior beliefs that ensures convergence to equilibrium in rational learning models does not seem dramatically weaker than a direct assumption of equilibrium play.

For additional details about the theory of learning and evolution in games, we refer the reader to the entries on specific topics listed in the cross-references below.

learning and evolution in games: belief learning

John Nachbar
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In the context of learning in games, belief learning refers to models in which players are engaged in a dynamic game and each player optimizes with respect to a prediction rule that gives a forecast of next-period opponent behaviour as a function of the current history. This article focuses on the most studied class of dynamic games, namely, two-player discounted repeated games with finite stage game action sets and perfect monitoring.

Keywords

belief learning; best-response dynamics; convergence; Cournot, A. A.; distributional strategies; dynamic games; fictitious play; folk theorem; learnable best-response property; mixed strategy equilibrium; myopia; perfect monitoring; prediction rules; purification; repeated games

Article

In the context of learning in games, belief learning refers to models in which players are engaged in a dynamic game and each player optimizes, or ε optimizes, with respect to a prediction rule that gives a forecast of next period opponent behaviour as a function of the current history. This article focuses on the most studied class of dynamic games, two-player discounted repeated games with finite stage game action sets and perfect monitoring. An important example of a dynamic game that violates perfect monitoring and therefore falls outside this framework is Fudenberg and Levine (1993). For a more comprehensive survey of belief learning, see Fudenberg and Levine (1998).

The earliest example of belief learning is the best-response dynamics of Cournot (1838). In Cournot's model, each player predicts that her opponent will repeat next period whatever action her opponent chose in the previous period.

The most studied belief learning model is fictitious play (Brown, 1951), and its variants. In fictitious play, each player predicts that the probability that her opponent will play an action, say L, next period is
a weighted sum of an initial probability on $L$ and the frequency with which $L$ has been chosen to date. The weight on the frequency is $t/(t+k)$, where $t$ is the number of periods thus far and $k>0$ is a parameter. The larger is $k$, the more periods for which the initial probability significantly affects forecasting. The remainder of this article discusses four topics: (1) belief learning versus Bayesian learning, (2) convergence to equilibrium, (3) special issues in games with payoff uncertainty, and (4) sensible beliefs.

**Belief learning versus Bayesian learning**

Recall that, in a repeated game, a behaviour strategy gives, for every history, a probability over the player's stage game actions next period. In a Bayesian model, each player chooses a behaviour strategy that best responds to a belief, a probability distribution over the opponent's behaviour strategies. Player 1's prediction rule about player 2 is mathematically identical to a behaviour strategy for player 2. Thus, any belief learning model is equivalent to a Bayesian model in which each player optimizes with respect to a belief that places probability 1 on her prediction rule, now reinterpreted as the opponent's behaviour strategy.

Conversely, any Bayesian model is equivalent to a belief learning model. Explicitly, for any belief over player 2's behaviour strategies there is a degenerate belief, assigning probability 1 to a particular behaviour strategy, that is equivalent in the sense that both beliefs induce the same distributions over play in the game, no matter what behaviour strategy player 1 herself adopts. This is a form of Kuhn's theorem (Kuhn, 1964). I refer to the behaviour strategy used in the degenerate belief as a reduced form of the original belief. Thus, any Bayesian model is equivalent to a Bayesian model in which each player's belief places probability 1 on the reduced form, and any such Bayesian model is equivalent to a belief learning model.

As an example, consider fictitious play. I focus on stage games with just two actions, $L$ and $R$. By an i.i.d. strategy for player 2, I mean a behaviour strategy in which player 2 plays $L$ with probability $q$, independent of history. Thus, if $q=1/2$, then player 2 always randomizes 50:50 between $L$ and $R$. Fictitious play is equivalent to a degenerate Bayesian model in which each player places probability 1 on the fictitious play prediction rule, and one can show that this is equivalent in turn to a non-degenerate Bayesian model in which the belief is represented as a beta distribution over $q$. The uniform distribution over $q$, for example, corresponds to taking the initial probability of $L$ to be 1/2 and the parameter $k$ to be 2.

There is a related but distinct literature in which players optimize with respect to stochastic prediction rules. In some cases (for example, Foster and Young, 2003), these models have a quasi-Bayesian interpretation: most of the time, players optimize with respect to fixed prediction rules, as in a Bayesian model, but occasionally players switch to new prediction rules, implicitly abandoning their priors.

**Convergence to equilibrium**

Within the belief learning literature, the investigation of convergence to equilibrium play splits into two branches. One branch investigates convergence within the context of specific classes of belief learning models. The best-response dynamics, for example, converge to equilibrium if the stage game is solvable by the iterated deletion of strictly dominated strategies. See Bernheim (1984) and, for a more general
learning and evolution in games: belief learning

class of models, Milgrom and Roberts (1991). For an \( \varepsilon \) optimizing variant of fictitious play, convergence to approximate equilibrium play obtains for all zero-sum games, all games with an interior ESS, and all common interest games, in addition to all games that are strict dominance solvable, with the approximation closer the smaller is \( \varepsilon \). Somewhat weaker convergence results are available for supermodular games. These claims follow from results in Hofbauer and Sandholm (2002).

In the results surveyed above, convergence is to repeated play of a single-stage game Nash equilibrium; in the case of \( \varepsilon \) fictitious play, this equilibrium may be mixed. There is a large body of work on convergence that is weaker than what I am considering here. In particular, there has been much work on convergence of the empirical marginal or joint distributions. For mixed strategy equilibrium, it is possible for empirical distributions to converge to equilibrium even though play does not resemble repeated equilibrium play; play may exhibit obvious cycles, for example. The study of convergence to equilibrium play is relatively recent and was catalysed by Fudenberg and Kreps (1993).

There are classes of games that cause convergence problems for many standard belief learning models, even when one considers only weak forms of convergence, such as convergence of the empirical marginal distributions (see Shapley, 1962; Jordan, 1993). Hart and Mas-Colell (2003; 2006) (hereafter HM) shed light on non-convergence by investigating learning models, including but not limited to belief learning models, that are decoupled, meaning that player 1's behaviour does not depend directly on player 2's stage game payoffs. A continuous time version of fictitious play fits into the framework of Hart and Mas-Colell (2003). The HM results imply that universal convergence is impossible for large classes of decoupled belief learning models: for any such model there exist stage games and initial conditions for which play fails to converge to equilibrium play.

The second branch of the literature, for which Kalai and Lehrer (1993a) (hereafter KL) is the central paper, takes a Bayesian perspective and asks what conditions on beliefs are sufficient to give convergence to equilibrium play. I find it helpful to characterize this literature in the following way. Say that a belief profile (giving a belief for each player) has the learnable best-response property (LBR) if there is a profile of best-response strategies (LBR strategies) such that, if the LBR strategies are played, then each player learns to predict the play path.

A player learns to predict the play path if her prediction of next period's play is asymptotically as good as if she knew her opponent's behaviour strategy. If the behaviour strategies call for randomization then players accurately predict the distribution over next period's play rather than the realization of next period's play. For example, consider a 2x2 game in which player 1 has stage game actions T and B and player 2 has stage game actions L and R. If player 2 is randomizing 50:50 every period and player 1 learns to predict the path of play, then for every \( \varepsilon \) there is a time, which depends on the realization of player 2's strategy, after which player 1's next period forecast puts the probability of L within \( \varepsilon \) of 1/2. (This statement applies to a set of play paths that arises with probability 1 with respect to the underlying probability model; I gloss over this sort of complication here and below.) For a more complicated example, suppose that in period \( t \) player 2 plays L with probability \( 1 - \alpha \), where \( \alpha \) is the frequency that the players have played the profile \((B, R)\). If player 1 learns to predict the play path, then for any \( \varepsilon \) there is a time, which now depends on the realization of both players' strategies, after which player 1's next period forecast puts the probability of L within \( \varepsilon \) of \( 1 - \alpha \).

Naively, if LBR holds, and players are using their LBR strategies, then, in the continuation game, players are optimizing with respect to posterior beliefs that are asymptotically correct and so
continuation behaviour strategies should asymptotically be in equilibrium. This intuition is broadly correct, but there are three qualifications.

First, in general, convergence is to Nash equilibrium play in the repeated game, not necessarily to repeated play of a single stage game equilibrium. If players are myopic (meaning that players optimize each period as though their discount factors were zero), then the set of equilibrium play paths comprises all possible sequences of stage game Nash equilibria, which is a very large set if the stage game has more than one equilibrium. If players are patient, then the folk theorem applies and the set of possible equilibrium paths is typically even larger.

Second, convergence is to an equilibrium play path, not necessarily to an equilibrium of the repeated game. The issue is that LBR implies accurate forecasting only along the play path. A player's predictions about how her opponent would respond to deviations may be grossly in error, for ever. Therefore, posterior beliefs need not be asymptotically correct and, unless players are myopic, continuation behaviour strategies need not be asymptotically in equilibrium. Kalai and Lehrer (1993b) shows that behaviour strategies can be doctored at information sets off the play path so that the modified behaviour strategies are asymptotically in equilibrium yet still generate the same play path. This implies that the play path of the original strategy profile was asymptotically an equilibrium play path.

Third, the exact sense in which play converges to equilibrium play depends on the strength of learning. See KL and also Sandroni (1998).

KL shows that a strong form of LBR holds if beliefs satisfy an absolute continuity condition: each player assigns positive probability to any (measurable) set of play paths that has positive probability given the players' actual strategies. A sufficient condition for this is that each player assigns positive, even if extremely low, probability to her opponent's actual strategy, a condition that KL call grain of truth. Nyarko (1998) provides the appropriate generalization of absolute continuity for games with type space structures, including the games with payoff uncertainty discussed below.

Games with payoff uncertainty

Suppose that, at the start of the repeated game, each player is privately informed of his or her stage game payoff function, which remains fixed throughout the course of the repeated game. Refer to player i's stage game payoff function as her payoff type. Assume that the joint distribution over payoff functions is independent (to avoid correlation issues that are not central to my discussion) and commonly known. Each player can condition her behaviour strategy in the repeated game on her realized payoff type. A mathematically correct way of representing this conditioning is via distributional strategies (see Milgrom and Weber, 1985).

For any belief about player 2, now a probability distribution over player 2's distributional strategies, and given the probability distribution over player 2's payoff types, there is a behaviour strategy for player 2 in the repeated game that is equivalent in the sense that it generates the same distribution over play paths. Again, this is essentially Kuhn's theorem. And again, I refer to this behaviour strategy as a reduced form.

Say that a player learns to predict the play path if her forecast of next period's play is asymptotically as good as if she knew the reduced form of her opponent's distributional strategy. This definition specializes to the previous one if the distribution over types is degenerate. If distributional strategies are
in equilibrium then, in effect, each player is optimizing with respect to a degenerate belief that puts probability one on her opponent's actual distributional strategy and in this case players trivially learn to predict the path of play.

One can define LBR for distributional strategies and, as in the payoff certainty case, one can show that LBR implies convergence to equilibrium play in the repeated game with payoff types. More interestingly, there is a sense in which play converges to equilibrium play of the realized repeated game – the repeated game determined by the realized type profile. The central paper is Jordan (1991). Other important papers include KL (cited above), Jordan (1995), Nyarko (1998), and Jackson and Kalai (1999) (which studies recurring rather than repeated games).

Suppose first that the realized type profile has positive probability. In this case, if a player learns to predict the play path, then, as shown by KL, her forecast is asymptotically as good as if she knew both her opponent's distributional strategy and her opponent's realized type. LBR then implies that actual play, meaning the distribution over play paths generated by the realized behaviour strategies, converges to equilibrium play of the realized repeated game. For example, suppose that the type profile for matching pennies gets positive probability. In the unique equilibrium of repeated matching pennies, players randomize 50:50 in every period. Therefore, LBR implies that, if the matching pennies type profile is realized, then each player's behaviour strategy in the realized repeated game involves 50:50 randomization asymptotically.

If the distribution over types admits a continuous density, so that no type profile receives positive probability, then the form of convergence is more subtle. Suppose that players are myopic and that the realized stage game is like matching pennies, with a unique and fully mixed equilibrium. Given myopia, the unique equilibrium of the realized repeated game calls for repeated play of the stage game equilibrium. In particular, it calls for players to randomize. It is not hard to show, however, that in a type space game with a continuous density, optimization calls for each player to play a pure strategy for almost every realized type. Thus, for almost every realized type profile in a neighbourhood of a game like matching pennies, actual play (again meaning the distribution over play paths generated by the realized behaviour strategies) cannot converge to equilibrium play, even if the distributional strategies are in equilibrium. Foster and Young (2001) provides a generalization for non-myopic players.

There is, however, a weaker sense in which play nevertheless does converge to equilibrium play in the realized repeated game. For simplicity, assume that each player knows the other's distributional strategy and that these strategies are in equilibrium. One can show that to an outsider observed play looks asymptotically like equilibrium play in the realized repeated game. In particular, if the realized game is like repeated matching pennies then observed play looks random. Moreover, to a player in the game, opponent behaviour looks random because, even though she knows her opponent's distributional strategy, she does not know her opponent's type. As play proceeds, each player in effect learns more about her opponent's type, but never enough to zero in on her opponent's realized, pure, behaviour strategy. Thus, when the distribution over types admits a continuous density, convergence to equilibrium involves a form of purification in the sense of Harsanyi (1973), a point that has been emphasized by Nyarko (1998) and Jackson and Kalai (1999).

Sensible beliefs
A number of papers investigate classes of prediction rules that are sensible in that they exhibit desirable properties, such as the ability to detect certain kinds of patterns in opponent behaviour (see Aoyagi, 1996; Fudenberg and Levine, 1995; 1999; Sandroni, 2000). Nachbar (2005) instead studies the issue of sensible beliefs from a Bayesian perspective. For simplicity, focus on learning models with known payoffs. Fix a belief profile, fix a subset of behaviour strategies for each player, and consider the following criteria for these subsets.

- **Learnability** – given beliefs, if players play a strategy profile drawn from these subsets then they learn to predict the play path.

- **Richness.** Informally (the formal statement is tedious), richness requires that if a behaviour strategy is included in one of the strategy subsets then certain variations on that strategy must be included as well. Richness, called CSP in Nachbar (2005), is satisfied automatically if the strategy subsets consist of all strategies satisfying a standard complexity bound, the same bound for both players. Thus richness holds if the subsets consist of all strategies with \( k \)-period memory, or all strategies that are automaton implementable, or all strategies that are Turing implementable, and so on.

- **Consistency** – each player's subset contains a best response to her belief.

The motivating idea is that, if beliefs are probability distributions over strategy subsets satisfying learnability, richness, and consistency, then beliefs are sensible, or at least are candidates for being considered sensible. Nachbar (2005) studies whether any such beliefs exist.

Consider, for example, the Bayesian interpretation of fictitious play in which beliefs are probability distributions over the i.i.d. strategies. The set of i.i.d. strategies satisfies learnability and richness. But for any stage game in which neither player has a weakly dominant action, the i.i.d. strategies violate consistency: any player who is optimizing will not be playing i.i.d.

Nachbar (2005) shows that this feature of Bayesian fictitious play extends to all Bayesian learning models. For large classes of repeated games, for any belief profile there are no strategy subsets that simultaneously satisfy learnability, richness, and consistency. Thus, for example, if each player believes the other is playing a strategy that has a \( k \)-period memory, then one can show that learnability and richness hold but consistency fails: best responding in this setting requires using a strategy with a memory of more than \( k \) periods. The impossibility result generalizes to \( \varepsilon \) optimization and \( \varepsilon \) consistency, for \( \varepsilon \) sufficiently small. The result also generalizes to games with payoff uncertainty (with learnability, richness, and consistency now defined in terms of distributional strategies) (see Nachbar, 2001).

I conclude with four remarks. First, since the set of all strategies satisfies richness and consistency, it follows that the set of all strategies is not learnable for any beliefs: for any belief profile there is a strategy profile that the players will not learn to predict. This can also be shown directly by a diagonalization argument along the lines of Oakes (1985) and Dawid (1985). The impossibility result of Nachbar (2005) can be viewed as a game theoretic version of Dawid (1985). For a description of what subsets are learnable, see Noguchi (2005).

Second, if one constructs a Bayesian learning model satisfying learnability and consistency then LBR holds and, if players play their LBR strategies, play converges to equilibrium play. This identifies a
potentially attractive class of Bayesian models in which convergence obtains. The impossibility result says, however, that if learnability and consistency hold, then player beliefs must be partially equilibrated in the sense of, in effect, excluding some of the strategies required by richness.

Third, consistency is not necessary for LBR or convergence. For example, for many stage games, variants of fictitious play satisfy LBR and converge even though these learning models are inconsistent. The impossibility result is a statement about the ability to construct Bayesian models with certain properties; it is not a statement about convergence per se.

Last, learnability, richness, and consistency may be too strong to be taken as necessary conditions for beliefs to be considered sensible. It is an open question whether one can construct Bayesian models satisfying conditions that are weaker but still strong enough to be interesting.

**How to cite this article**

The ESS concept, developed in the 1970s to predict through static fitness comparisons the evolutionary outcome of individual behaviours in a biological species, emerged as the cornerstone of evolutionary game theory. This theory is now as central to the analysis of strategic interactions in the social and management sciences as in the life sciences. The ESS also addresses stability questions for dynamics describing how individual behaviours evolve over time. Here, we summarize ESS theory as originally developed for symmetric two-player games and then discuss generalizations to population games, extensive form games, games with continuous strategy spaces, asymmetric and bimatrix games.

Article

1. Introduction

According to John Maynard Smith in his influential book Evolution and the Theory of Games (1982, p.10), an ESS (that is, an evolutionarily stable strategy) is ‘a strategy such that, if all members of the population adopt it, then no mutant strategy could invade the population under the influence of natural selection’. The ESS concept, based on static fitness comparisons, was originally introduced and developed in the biological literature (Maynard Smith and Price, 1973) as a means to predict the eventual outcome of evolution for individual behaviours in a single species. It avoids the complicated dynamics of the evolving population that may ultimately depend on spatial, genetic and population size effects. To illustrate the Maynard Smith (1982) approach, suppose individual fitness is the expected payoff in a random pairwise contest. The ESS strategy $p^*$ must then do at least as well as a mutant strategy $p$ in their most common contests against $p^*$ and, if these contests yield the same payoff, then $p^*$ must do better than $p$ in their rare contests against a mutant. That is, Maynard Smith's definition applied to a symmetric two-player game says $p^*$ is an ESS if and only if, for all $p \neq p^*$,

\begin{align*}
(i) \quad & \pi(p, p^*) \leq \pi(p^*, p^*) \\
(ii) \quad & \text{if } \pi(p, p^*) = \pi(p^*, p^*), \pi(p, p) < \pi(p^*, p) \quad \text{ (stability condition)}
\end{align*}
where \( \pi(p, \hat{p}) \) is the payoff of \( p \) against \( \hat{p} \). One reason the ESS concept has proven so durable is that it has equivalent formulations that are equally intuitive (see especially the concepts of invasion barrier and local superiority in Section 2.1).

By (1) (i), an ESS is a Nash equilibrium (NE) with the extra refinement condition (ii) that seems heuristically related to dynamic stability. In fact, there is a complex relationship between the static ESS conditions and dynamic stability, as illustrated throughout this article with specific reference to the replicator equation. It is this relationship that formed the initial basis of what has come to be known as ‘evolutionary game theory’.

ESS theory (and evolutionary game theory in general) has been extended to many classes of games besides those based on a symmetric two-player game. This article begins with ESS theory for symmetric normal form games before briefly describing the additional features that arise in each of several types of more general games. The unifying principle of local (or neighborhood) superiority will emerge in the process.

2. ESS for symmetric games

In a symmetric evolutionary game, there is a single set \( S \) of pure strategies available to the players, and the payoff to pure strategy \( e_i \) is a function \( \pi_i \) of the system’s strategy distribution. In the following subsections we consider two-player symmetric games with \( S \) finite in normal and extensive forms (Sections 2.1 and 2.2 respectively) and with \( S \) a continuous set (Section 2.3).

2.1. Normal form games

Let \( S = \{ e_1, \ldots, e_n \} \) be the set of pure strategies. A player may also use a mixed strategy \( p \in \Delta^n \equiv \{ p = (p_1, \ldots, p_n) | \sum p_i = 1, \ p_i \geq 0 \} \) where \( p_i \) is the proportion of the time this individual uses pure strategy \( e_i \). Pure strategy \( e_i \) is identified with the \( i \)th unit vector in \( \Delta^n \). The population state is \( \hat{p} \in \Delta^n \) whose components are the current frequencies of strategy use in the population (that is, the strategy distribution). We assume the expected payoff to \( p \) is the bilinear function \( \pi(p, \hat{p}) = \sum_{i,j=1}^{n} p_i \pi(e_i, e_j) \hat{p}_j \) resulting from random two-player contests.

Suppose the resident population is monomorphic at \( p^* \) (that is, all members adopt strategy \( p^* \)) and a monomorphic sub-population of mutants using \( p \) appears in the system. These mutants will not invade if there is a positive invasion barrier \( \varepsilon_0(p) \) (Bomze and Pötscher, 1989). That is, if the proportion \( \varepsilon \) of mutants in the system is less than \( \varepsilon_0(p) \), then the mutants will eventually die out due to their lower replication rate. In mathematical terms, \( \varepsilon = 0 \) is a (locally) asymptotically stable rest point of the corresponding resident-mutant invasion dynamics. For invasion dynamics based on replication, Bomze and Pötscher show \( p^* \) is an ESS (that is, satisfies (1)) if and only if every \( p \neq p^* \) has a positive invasion barrier.

Important and somewhat surprising consequences of an ESS \( p^* \) are its asymptotic stability for many evolutionary dynamics beyond these monomorphic resident systems invaded by a single type of mutant. For instance, \( p^* \) is asymptotically stable when simultaneously invaded by several types of mutants and when a polymorphic resident system consisting of several (mixed) strategy types whose average strategy is \( p^* \) is invaded (see the ‘strong stability’ concept developed in Cressman, 1992). In particular, \( p^* \) is asymptotically stable for the replicator equation (Taylor and Jonker, 1978; Hofbauer, Schuster and Sigmund, 1979; Zeeman, 1980)

\[
\hat{p}_j = p_j(\pi(e_j, \hat{p}) - \pi(p, \hat{p}))
\]

when each individual player is a pure strategist.

Games that have a completely mixed ESS (that is, \( p^* \) is in the interior of \( \Delta^n \)) enjoy further dynamic stability properties since these games are strictly stable (that is,

π(ρ, ρ) < π(ρ*, ρ).

(3)

It is this last characterization, called ‘local superiority’ (Weibull, 1995), that proves so useful for other classes of games (see below). Heuristically, (3) suggests ρ* will be asymptotically stable since there is an incentive to shift towards ρ* whenever the system is slightly perturbed from ρ*.

Unfortunately, there are many normal form games that have no ESS. These include most three-strategy games classified by Zeeman (1980) and Bomze (1995). No mixed strategy ρ* can be an ESS of a symmetric zero-sum game (that is, for all ρ, ρ' ∈ Δn) since π(ρ*, ρ) = π(ρ* - ρ, ρ) ≤ 0 = π(ρ, ρ) for all ρ ∈ Δn in some direction from ρ*. Thus, the classic zero-sum Rock–Scissors–Paper Game in Table 1 has no ESS since its only NE \(\left\{\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right\}\) is interior. An early attempt to relax the ESS conditions to rectify this replaces the strict inequality in (1) (ii) by π(ρ, ρ) ≤ π(ρ*, ρ). The NE ρ* is then called a neutrally stable strategy (NSS) (Maynard Smith, 1982; Weibull, 1995). The only NE of the Rock–Scissors–Paper Game is a NSS.

The payoff matrix for the Rock–Scissors–Paper Game

<table>
<thead>
<tr>
<th></th>
<th>Rock</th>
<th>Scissors</th>
<th>Paper</th>
</tr>
</thead>
<tbody>
<tr>
<td>Rock</td>
<td>0</td>
<td>1</td>
<td>-1</td>
</tr>
<tr>
<td>Scissors</td>
<td>-1</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>Paper</td>
<td>1</td>
<td>-1</td>
<td>0</td>
</tr>
</tbody>
</table>

Each entry is the payoff to the row player when column players are listed in the same order.

Also, the normal forms of most interesting extensive form games have no ESS, especially when NE outcomes do not specify choices off the equilibrium path and so correspond to NE components. In general, when NE are not isolated, the ESSet introduced by Thomas (1985) is more important. This is a set E of NSS so that (1) (ii) holds for all \(\tilde{\rho} \in E\) and \(\rho \in \overline{E}\). An ESSet is a finite union of disjoint NE components, each of which must be an ESSet in its own right. Each ESSet has setwise dynamic stability consequences analogous to an ESS (Cressman, 2003). The ES structure of a game refers to its collection of ESSs and ESSets.

There are then several classes of symmetric games that always have an ESSet. Every two-strategy game has an ESSet (Cressman, 2003) which generically (that is, unless \(\pi(\tilde{\rho}, \tilde{\rho}) = \pi(\rho, \rho)\) for all \(\rho, \tilde{\rho} \in \Delta^2\)) is a finite set of ESSs. All games with symmetric payoff function (that is, \(\pi(\tilde{\rho}, \rho) = \pi(\rho, \tilde{\rho})\) for all \(\rho, \tilde{\rho} \in \Delta^2\)) have an ESSet corresponding to the set of local maxima of \(\pi(\rho, \rho)\) which generically is a set of isolated ESSs). These are called partnership games (Hofbauer and Sigmund, 1998) or common interest games (Sandholm, 2006).

Symmetric games with payoff, \(\pi(\tilde{\rho})\), of pure strategy \(e_i\), nonlinear in the population state \(\tilde{\rho}\) are quite common in biology and in economics (Maynard Smith, 1982; Sandholm, 2006), where they are called playing-the-field models or population games. With \(\pi(\tilde{\rho}, \rho) = \Sigma_i \rho_i \pi_i(\tilde{\rho})\), nonlinearity implies (1) is a weaker condition than (3), as examples in Bomze and Pötscher (1989) show. Local superiority (3) is then taken as the operative definition of an ESS \(\rho^*\) (Hofbauer and Sigmund, 1998) and it is equivalent to the existence of a uniform
invasion barrier for \( p^* \).

2.2. Extensive form games

The application of ESS theory to finite extensive form games has been less successful (see Figure 1). Every ESS can have no other realization equivalent strategies in its normal form (van Damme, 1991) and so, in particular, must be pervasive strategy (that is, it must reach every information set when played against itself). To ease these problems, Selten (1983) defined a direct ESS in terms of behaviour strategies (that is, strategies that specify the local behaviour at each player information set) as a \( b^* \) that satisfies (1) for any other behaviour strategy \( b \). He showed each such \( b^* \) is subgame perfect and arises from the backward induction technique applied to the ES structure of the subgames and their corresponding truncations.

Figure 1
The extensive form tree of the van Damme example. For the construction of the tree of a symmetric extensive form game, see Selten (1983) or van Damme (1991)
Consider backward induction applied to Figure 1. Its second-stage subgame has mixed ESS and, when the second decision point of player 1 is replaced by the payoff 0 from \( b_2^* \), the truncated single-stage game also has a mixed ESS \( b_1^* = \left( \frac{1}{2}, \frac{1}{2} \right) \). Since both stage games have a mixed ESS (and so a unique NE since they are strictly stable), \( (b_1^*, b_2^*) \) is the only NE of Figure 1 and it is pervasive. Surprisingly, this example has no direct ESS as Selten originally hoped since \( (b_1^*, b_2^*) \) can be invaded by the pure strategy that plays \( Rr \) (van Damme, 1991).

The same technique applied to Figure 1 with second-stage subgame replaced by yields \( b_2^* = \left( \frac{1}{2}, \frac{1}{2} \right) \) and truncated single-stage game with \( b_1^* = \left( \frac{3}{5}, \frac{2}{5} \right) \).

This is an example of a two-stage War of Attrition with base game where a player remains \( (R) \) at the first stage in the hope the opponent will leave \( (L) \) but incurs a waiting cost of one payoff unit if both players remain. This \( (b_1^*, b_2^*) \) is a direct ESS since all \( N \)-stage War of Attrition games are strictly stable (Cressman, 2003).

The examples in the preceding two paragraphs show that, although backward induction determines candidates for the ES structure, it is not useful for determining which candidates...
Learning and evolution in games: ESS - The New Palgrave Dictionary of Economics

are actually direct ESSs. The situation is more discouraging for non-pervasive NE. For example, the only NE outcome of the two-stage repeated Prisoner’s Dilemma game (Nachbar, 1992) with cumulative payoffs is mutual defection at each stage. This NE outcome cannot be an isolated behaviour strategy (that is, there is a corresponding NE component) and so there is no direct ESS. Worse, for typical single-stage payoffs such as
\[
\begin{pmatrix}
\text{Defect} & -1 & 10 \\
\text{Cooperate} & -2 & 5
\end{pmatrix},
\]
this component does not satisfy setwise extensions of the ESS (for example, it is not an ESS).

Characterization of NE found by backward induction with respect to dynamically stable rest points of the subgames and their truncations shows more promise. Each direct ESS \(b^*\) yields an ESS in the game's normal form (Cressman, 2003) and so is dynamically stable. Furthermore, for the class of simultaneity games where both players know all player actions at earlier stages, Cressman shows that, if \(b^*\) is a pervasive NE, then it is asymptotically stable with respect to the replicator equation if and only if it comes from this backward induction process. In particular, the NE for Figure 1 and for the N-stage War of Attrition are (globally) asymptotically stable. Although the subgame perfect NE for the N-stage Prisoner’s Dilemma game that defects at each decision point is not asymptotically stable, the eventual outcome of evolution is in the NE component (Nachbar, 1992; Cressman, 2003).

2.3. Continuous strategy space

Evolutionary game theory for symmetric games with a continuous set of pure strategies \(S\) has been slower to develop. Most recent work examines static payoff comparisons that predict an \(x^* \in S\) is the evolutionary outcome. There are now fundamental differences between the ESS notion (1) and that of local superiority (3) as well as between invasion by monomorphic mutant sub-populations and the polymorphic model of the replicator equation. Here, we illustrate these differences when \(S\) is a subinterval of real numbers and \(\pi(x, y)\) is a continuous payoff function of \(x, y \in S\).

First, consider an \(x^* \in S\) that satisfies (3). In particular,
\[
\pi(x, x) < \pi(x^*, x)
\]
(4)
for all \(x \in S\) sufficiently close (but not equal) to \(x^*\). This is the \textit{neighbourhood invader strategy} (NIS) condition of Apaloo (1997) that states \(x^*\) can invade any nearby monomorphism \(x\). On the other hand, from (1), \(x^*\) cannot be invaded by these \(x\) if it is a \textit{neighbourhood strict NE}, that is
\[
\pi(x, x^*) < \pi(x^*, x^*)
\]
(5)
for any other \(x\) sufficiently close to \(x^*\). Inequalities (4) (5) are independent of each other and combine to assert that \(x^*\) strictly dominates \(x\) in all these two-strategy games \(\{x^*, x\}\).

In the polymorphic model, populations are described by a \(P\) in the infinite dimensional set \(\Delta(S)\) of probability distributions with support in \(S\). When the expected payoff \(\pi(x, P)\) is given through random pairwise contests, Cressman (2005) shows that strict domination implies \(x^*\) is \textit{neighbourhood superior} (that is,
\[
\pi(x^*, P) > \pi(P, P)
\]
(6)
for all other $p \in \Delta(S)$ with support sufficiently close to $x^*$ and conversely, neighbourhood superiority implies weak domination. Furthermore, a neighborhood superior monomorphic population $x^*$ (that is, the Dirac delta probability distribution $\delta_{x^*}$) is asymptotically stable for all initial $P$ with support sufficiently close to $x^*$ (and containing $x^*$) under the replicator equation. This is now a dynamic on $\Delta(S)$ (Oechssler and Riedel, 2002) that models the evolution of the population distribution.

In the monomorphic model, the population is a monomorphism $x(t) \in S$ at all times. If a nearby mutant strategy $\forall \in S$ can invade $x$, the whole population is shifted in this direction. This intuition led Eshel (1983) to define a continuously stable strategy (CSS) as a neighbourhood strict NE $x^*$ that satisfies, for all $x$ sufficiently close to $x^*$,

$$
\pi(y, x) > \pi(x, x)
$$

for all $y$ between $x^*$ and $x$ that are sufficiently close to $x$. Later, Dieckmann and Law (1996) developed the canonical equation of adaptive dynamics to model the evolution of this monomorphism and showed a neighbourhood strict NE $x^*$ is a CSS if and only if it is an asymptotically stable rest point. Cressman (2005) shows $x^*$ is a CSS if and only if it is neighbourhood half-superior (that is, there is a uniform invasion barrier of at least $\frac{1}{2}$ in the two-strategy games $\{x^*, x\}$) (see also the half-dominant concept of Morris, Rob and Shin, 1995).

For example, take $S = \mathbb{R}$ and payoff function

$$
\pi(x, y) = -x^2 + byy
$$

that has strict NE $x^* = 0$ for all values of the fixed parameter $b$. $x^*$ is a NIS (CSS) if and only if $b < 1 \ (b < 2)$ (Cressman and Hofbauer, 2005). Thus, there are strict NE when $b > 2$ that are not ‘evolutionarily stable’.

### 3 Asymmetric games

Following Selten (1980) and van Damme (1991), in a two-player asymmetric game with two roles (or species), pairwise contests may involve players in the same or in opposite roles. First, consider ESS theory when there is a finite set of pure strategies $S = \{e_1, \ldots, e_n\}$ and $T = \{f_1, \ldots, f_m\}$ for players in role 1 and 2 respectively. Assume payoff to a mixed strategist is given by a bilinear payoff function and let $\pi_1(p; \tilde{p}, \tilde{q})$ be the payoff to a player in role one using $p \in \Delta^n$ when the current state of the population in roles 1 and 2 are $\tilde{p}$ and $\tilde{q}$ respectively. Similarly, $\pi_2(q; \tilde{p}, \tilde{q})$ is the payoff to a player in role 2 using $q \in \Delta^m$. For a discussion of resident-mutant invasion dynamics, see Cressman (1992), who shows the monomorphism $(\tilde{p}^*, \tilde{q}^*)$ is uninvadable by any other mutant pair $(p, q)$ if and only if it is a two-species ESS, that is, for all $(p, q)$ sufficiently close (but not equal) to $(\tilde{p}^*, \tilde{q}^*)$,

$$
\text{either } \pi_1(p; p, q) < \pi_1(p^*; p, q) \text{ or } \pi_2(q; p, q) < \pi_2(q^*; p, q).
$$

The ESS condition (9) is the two-role version of local superiority (3) and has an equivalent formulation analogous to (1) (Cressman, 1992). This ESS also enjoys similar stability properties to the ESS of Subsection 2.1 such as its asymptotic stability under the (two-species) replicator equation (Cressman, 1992; 2003).
A particularly important class of asymmetric games consists of truly asymmetric games that have no contests between players in the same role (that is, there are no intraspecific contests). These are bimatrix games (that is, given by an $n \times n$ matrix whose $ij$th entry is the pair of payoffs $(\pi_1(e_i, f_j), \pi_2(e_i, f_j))$ for the interspecific contest between $e_i$ and $f_j$). The ESS concept is now quite restrictive since Selten (1980) showed that $(p^*, q^*)$ satisfies (9) if and only if it is a strict NE. This is also equivalent to asymptotic stability under the (two-species) replicator equation (Cressman, 2003). Standard examples (Cressman, 2003), with two strategies for each player include the Buyer–Seller Game that has no ESS since its only NE is in the interior. Another is the Owner–Intruder Game that has two strict NE Maynard Smith (1982) called the bourgeois ESS where the owners defend their territory and the paradoxical ESS where owners retreat.

Asymmetric games with continuous sets of strategies have recently received a great deal of attention (Leimar, 2006). For a discussion of neighbourhood (half) superiority conditions that generalize (6) and (7) to two-role truly asymmetric games with continuous payoff functions, see Cressman (2005). He also shows how these conditions are related to NIS and CSS concepts based on (9) and to equilibrium selection results for games with discontinuous payoff functions such as the Nash Demand Game (Binmore, Samuelson and Young, 2003).

‘Social learning’ is a process whereby economic agents learn by observing the behaviour of others. ‘Social learning in networks’ requires sophistication because individuals draw inferences from the behaviour of agents they cannot directly observe. Theoretical research suggests that, even if networks are very incomplete, social learning leads to uniform behaviour. Experimental evidence suggests that learning in networks conforms quite well to theoretical predictions. It also illustrates how the network architecture influences the pattern of learning and the efficiency of information aggregation.

Article
‘Social learning’ is a process whereby economic agents learn by observing the actions (but not the payoffs) of others; ‘social learning in networks’ applies this idea to situations in which individuals observe the other individuals to whom they are connected in a social network.

Griliches (1957) first studied the gradual adoption of corn planted with hybrid seed in the USA, a new agricultural technique, from the early 1930s to mid-1950s. He observed that at first farmers learned from salespersons; later they learned from their neighbours. The result was an S-shaped time profile of adoption. A number of recent papers, including Foster and Rosenzweig (1995), Conley and Udry (2001), Kremer and Miguel (2003) and Munshi (2004) examine how agents in developing countries learn from their social contacts when deciding whether to adopt new technologies.

The classical model of social learning, first studied by Banerjee (1992) and Bikhchandani, Hirshleifer
and Welch (1992), and extended by Smith and Sørensen (2000), assumes a pure information externality. An agent's payoff $u(a, w)$ depends only on his own action $a$ and an unknown state of nature $w$. Each agent $i$ has private information about the state and his choice of action $a$ will reflect that information. By observing an agent's action, it is possible to learn something about his information and make a better decision. The problem is that agents may rationally ignore their own information and 'follow the herd', that is, imitate the actions they see others choose. So-called herd behaviour and informational cascades can arise very rapidly, before much information has been revealed, and often result in inefficient choices. A number of experimental studies replicate herd behaviour in the laboratory.

The classical models assume that agents make decisions sequentially and observe the action chosen by each of their predecessors. In reality, individuals are bound together by a social network, the complex of relationships that brings them into contact with other agents, such as neighbours, co-workers, family, and so on. A specific framework, introduced by Gale and Kariv (2003), henceforth GK, assumes that individuals are bound together by a social network and can observe the agents to whom they are connected only through the network. The social network is represented by a directed graph in which nodes correspond to agents and agent $i$ can observe agent $j$ if there is an edge leading from node $i$ to node $j$. In order to model the diffusion of information through the network, GK assume that agents choose actions simultaneously and revise their decisions as new information is received. More precisely, an agent whose current information is $I$ chooses an action $a$ to maximize his short-run payoff $E[u(a, w)]$. GK rationalize non-strategic behaviour by assuming there is a large number of agents of each type, so a single agent's decision has no impact on the future play of the game.

An agent's beliefs can be represented by a random sequence of probability distributions $P_t(\omega)$. At date $t$, an agent derives a posterior $P_{t+1}(w)$ from the prior $P_t(\omega)$ and the new information received. These beliefs satisfy the martingale property $E[P_{t+1}(\omega) | P_t] = P_t$, and the martingale convergence theorem implies that these beliefs converge to a constant with probability one. The limiting beliefs are not necessarily uniform (different agents may have different beliefs) and need not be fully revealing. However, in connected networks, where every agent is connected directly or indirectly with every other agent, the initial diversity of actions is eventually replaced by uniformity. More precisely, except in cases of indifference, agents will choose the same action. This is the network-learning analogue of the herd behaviour found in the classical social learning model. The proof of uniformity makes use of the imitation principle. If agent $i$ can observe the actions of agent $j$, agent $i$ must be able to do as well as $j$ on average (because one feasible strategy is to choose the same action $j$). In a connected network, all agents get the same payoff on average and this implies that they choose different actions only if they are indifferent.

Learning in a network is ‘simply’ a matter of Bayesian updating, but a rational agent must take account of the network architecture in order to update correctly. For example, suppose there are three (types of) agents, $A$, $B$, and $C$, arranged in a circle: $A$ observes $B$, $B$ observes $C$, and $C$ observes $A$. At the first decision, $A$ has not yet had a chance to observe $B$, so he makes his decision based on his private information. Before the second decision, $A$ observes $B$'s first decision and uses it to update his beliefs about the true state of nature. Before the third decision, $A$ observes $B$'s second decision and realizes that any change from the first must be based on $B$'s observation of $C$'s first decision. So now $A$ can make some inference about $C$'s private information and update his beliefs accordingly. This learning can go on for some time. Eventually, $A$ may observe changes in $B$'s action that were prompted by changes in $C$'s
action that were prompted by C's observation of A. Even this is informative because it reveals how strong C's information is relative to A's. In any case, exploiting fully the information revealed in a network requires agents to consider not only what they observe, but also what their neighbours observe, what their neighbours’ neighbors observe, and so on. The chains of inferences that rational individuals make naturally involve hierarchies of beliefs, that is, beliefs about a neighbour's beliefs about a neighbour's beliefs about ....

The complexity of Bayesian learning in networks has led some authors to suggest that models of \textit{bounded rationality} are more appropriate for describing learning in networks. Bala and Goyal (1998) examine the decisions of boundedly rational agents, who try to extract information from the actions and payoffs of the agents they observe, but without taking account of the fact that those agents also observe other agents. Hence, there is private information in the Bala–Goyal model, but agents are assumed to ignore it. In the Bala–Goyal model, at each date, an agent chooses one of several available actions with unknown payoff distributions. Agents can observe the actions and payoffs of their neighbours (those to whom they are directly connected by the network) and use this information to update their beliefs about the payoff distribution. Thus, agents learn by observing the outcome (payoff) of an experiment (choice of action) rather than by inferring another agent's private information from his action. This is a model of \textit{social experimentation}, in the sense that it generalizes the problem of a single agent experimenting with a multi-armed bandit to a social setting, rather than social learning. A model of social experimentation is quite different from a model of social learning because there is an informational externality but there is no informational asymmetry. As with Bayesian learning, boundedly rational learning implies convergence of beliefs and uniformity of actions in the limit.

Laboratory experiments provide the cleanest test for the theory since subjects’ neighbourhoods and private information can be controlled. Choi, Gale and Kariv (2004; 2005) describe the results of an experimental investigation of learning in networks based on the model of GK. The experiments involve three-person, connected social networks. The experimental design uses three representative networks: the \textit{complete network}, in which each agent can observe the actions chosen by the other agents; the \textit{star network}, in which one agent, the centre, can observe the actions of the other two peripheral agents, and the peripheral agents can observe only the centre; and the \textit{circle network}, in which each agent can observe only one other agent and each agent is observed by one other agent. Despite the small number of players in each game, it can be shown that myopic payoff maximization is rational: there is no gain to strategic behaviour. Nonetheless, larger-scale experiments might be informative.

The experimental data from these studies exhibit a strong tendency toward herd behaviour, but despite this tendency the efficiency of information aggregation is quite good. Although convergence to a uniform action is quite rapid, frequently occurring within two to three turns, there are significant differences between the behaviour of different networks. Most herds entail correct decisions, which is consistent with the predictions of the parametric model underlying the experimental design. Comparing the behaviour of different individuals indicates that there is indeed high variation in individual behaviour across subjects, but the error rates (the proportion of times a subject deviates from the best response) are uniformly fairly low.

These results suggest that the theory adequately accounts for large-scale features of the data, but in some situations the theory does less well in accounting for subjects’ behaviour. It is likely that the theory fails in those situations because the complexity of the decision problem exceeds the bounded rationality of the subjects. Clearly, because of the lack of common knowledge in the networks, the decision problems
faced by subjects require quite sophisticated reasoning. Subjects’ success or failure in the experiment results from the appropriateness of the heuristics they use as much as the inherent difficulty of the decision-making. Thus, an important subject for future research is to identify ‘black spots’ where the theory does least well in interpreting the data and ask whether additional ‘behavioural’ explanations might be needed to account for the subjects’ behaviour.

Many important questions about social learning in networks remain to be explored. While small networks can be very insightful, especially in experimental contexts, the development of the theory depends on properties of networks that can be generalized. The recent discovery of Barabási and Albert (1999) that many networks are scale-free, in the sense that a few nodes are hubs, which have a very large number of links to other nodes whereas most nodes have just a few, has significant implications for the efficiency of information aggregation. Once information reaches a hub it passes to numerous other nodes and spreads rapidly throughout the entire population, but if the hub’s information is of poor quality its disproportionate influence becomes a disadvantage. Thus, the impact of hubs on the efficiency of information aggregation is not clear. Perhaps the most important subject for future research is to identify the impact of network architecture on the efficiency and dynamics of social learning. Progress in this area requires both new theory and new experimental data.

learning in macroeconomics

George W. Evans and Seppo Honkapohja
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Expectations play a key role in macroeconomics. The assumption of rational expectations has been recently relaxed by explicit models of forecasting and model updating. Rational expectations can be assessed for stability under various types of learning, with least squares learning playing a prominent role. In addition to assessing the plausibility of an equilibrium, learning also provides a selection criterion when there are multiple equilibria. Monetary policy should be designed to avoid instability under learning and to facilitate coordination on desirable equilibria. Learning can also help to explain macroeconomic fluctuations as arising through either instabilities, stable indeterminacies or persistent learning dynamics.

Article

Learning in macroeconomics refers to models of expectation formation in which agents revise their forecast rules over time, for example in response to new data. Expectations of future income, prices and sales play key roles in theories of saving and investment. Many other examples of the central role of expectations could be given.
1 Introduction

The current standard methodology for modelling expectations is to assume that the economy is in a rational expectations equilibrium (REE). REE is a model-consistent equilibrium in the two-way relationship between the influence of expectations on the economy and the dependence of expectations on the time path of the economy.

The standard formulation of REE makes strong assumptions on the information of economic agents. The true stochastic process of the economy is assumed known, with unforecastable random shocks constituting the remaining uncertainty. This assumption presupposes that the economic agents know much more than, say, the economists who in practice do not know the true stochastic structure and instead must estimate its parameters.

Recently, macroeconomic theory has been moving beyond the strict rational expectations (RE) hypothesis. Explicit models of imperfect knowledge and associated learning processes have been developed. In models of learning economic agents try to improve their knowledge of the stochastic process of the economy over time as new information becomes available.

Different approaches to modelling learning behaviour have been employed. Perhaps the most common has been ‘adaptive learning’, which views economic agents as econometricians who estimate the parameters of their model and make forecasts using their estimates. In adaptive learning economic agents have limited common knowledge since they estimate their own perceived laws of motion.

A second approach, called ‘eductive learning’, assumes common knowledge of rationality: economic agents engage in a process of reasoning about the possible outcomes knowing that other agents engage in the same process. Eductive learning takes place in logical time. A third approach has been ‘rational learning’, which employs a Bayesian viewpoint. Full knowledge of economic parameters is then replaced by priors and Bayesian updating under a correctly specified model, including common knowledge that all agents share this knowledge. Rational learning thus retains a form of REE at each point of time.

Basic theories of learning were developed largely in the 1980s and 1990s. See Sargent (1993, 1999), Evans and Honkapohja (2001), Guesnerie (2005) and Beck and Wieland (2002) for references. Recently, models of learning have been applied to issues of macroeconomic, and especially monetary, policy. In this overview, we focus on adaptive learning as it has been the most widely used approach. (For references to the pre-2001 literature, see Evans and Honkapohja, 2001.)

2 Least squares learning

In adaptive learning it is commonly assumed that agents estimate their model of the dynamics of economic variables, called the perceived law of motion (PLM), by recursive least squares (RLS), arguably the most common estimation method in econometrics.

2.1 Overview

We illustrate the key concepts using the Cagan model of the price level
learning in macroeconomics: The New Palgrave Dictionary of Economics

\( \hat{m} - p_t = -\psi(p^\epsilon_{t+1} - p_t) + \phi'w_t + \varepsilon_t \), where \( p_t \) and \( \hat{m} \) are logarithms of the price level and (constant) nominal money supply. Here \( \psi > 0 \) and \( p^\epsilon_{t+1} \) denotes the expectations of \( p_{t+1} \) formed at time \( t \). \( w_t \) is a vector of observable exogenous variables, assumed to follow a stationary vector autoregression (VAR) process \( \bar{w}_t = F\bar{w}_{t-1} + \nu_t \), in which \( F \) is taken as known for simplicity. \( \varepsilon_t \) is an unobservable i.i.d. shock.

The reduced form of the Cagan model is

\[
\begin{align*}
p_t &= \alpha_0 + \alpha_1 p^\epsilon_{t+1} + \beta'w_t + \nu_t \\
(1)
\end{align*}
\]

where \( \nu_t = -(1 + \psi)^{-1} \varepsilon_t \) and \( \alpha_0, \alpha_1 \) and \( \beta \) depend on \( \hat{m}, \psi \) and \( \phi \). The model has a unique REE of the form \( p_t = \bar{a} + \bar{b}'w_t + \nu_t \), where \( \bar{a} = (1 - \alpha_1)^{-1} \alpha_0, \bar{b} = (1 - \alpha_1 F')^{-1} \beta \).

Agents are assumed to use the PLM \( p_t = a + b'w_t + \eta_t \), where \( \eta_t \) is a disturbance term. The PLM has the same functional form as the REE but possibly different coefficients since agents do not know the REE. To estimate the PLM, agents use data \( \{ p_t, w_t \}_{0}^{T-1} \) and forecast using the estimated model \( E_t^np^\epsilon_{t+1} = a_{t-1} + b'_{t-1}Fw_t \).

These forecasts lead to a temporary equilibrium or actual law of motion (ALM) \( \bar{p}_t = T(\varphi_{t-1})'z_t + \nu_t \), where \( T(\varphi) = (\alpha_0 + \alpha_1 a, \alpha_1 b'F + \beta') \). The REE \( (\bar{a}, \bar{b}') \) is a fixed point of the mapping \( T(\varphi) \) from the PLM to the ALM. If we let \( \varphi'_t = (a_t, b'_t) \) and \( z'_t = (1, w'_t) \), RLS estimation is given by

\[
\begin{align*}
\varphi_t &= \varphi_{t-1} + t^{-1}R_{t-1}z_t(p_t - \varphi'_{t-1}z_t)R_t = R_{t-1} + t^{-1}(z_tz'_t - R_{t-1}). \\
(2)
\end{align*}
\]

where \( p_t \) is given by the ALM. We say that the REE is stable under RLS learning if \( (a_{t-1}, b'_{t-1}) \rightarrow (\bar{a}, \bar{b}') \) over time.

This model of learning involves bounded rationality. Each period agents maximize their objective, given their forecasts. However, agents treat the economy as having constant parameters, which is true only in the REE. Outside the REE the PLMs are misspecified, but misspecification vanishes as learning converges to the REE.

A key result, which holds in numerous models, is that RLS learning converges to RE under certain
conditions on model parameters. Thus, the REE can be learned even though economic agents initially have limited knowledge and are boundedly rational. *Expectational stability* (E-stability) is a convenient way for establishing the convergence conditions for RLS learning. Define the differential equation \( \frac{d\varphi}{dT} = T(\varphi) - \varphi \), which describes partial adjustment in virtual time \( T \). The REE is E-stable if it is locally stable under the differential equation. For models of the form (1), convergence is guaranteed if \( 0 < \alpha_1 < 1 \), which is satisfied in the Cagan model since \( \alpha_1 = \psi(1 + \psi)^{-1} \). Evans and Honkapohja (2001) contains a detailed discussion of convergence of RLS learning.

### 2.2 The roles of learning

Adaptive learning has several other important roles besides being a stability theory for REE. RE models can have multiple stationary equilibria, that is, indeterminacy of equilibrium. In such situations learning stability acts as a selection criterion to determine the plausibility of a particular REE. As an example consider the non-stochastic Cagan model with government spending financed by seigniorage, with nonlinear reduced form \( x_t = G(x_t^e + 1) \), where \( x_t \) denotes inflation (see Evans and Honkapohja, 2001, chs. 11 and 12, for details). This model has two (interior) steady state solutions \( \hat{x} = G(\hat{x}) \). The low-inflation steady state \( x_L \) is stable under learning and the high-inflation steady state \( x_H \) is not. Learning selects a unique REE \( x_L \) in this model. In more general models, learning stability does not necessarily select a unique REE, but the set of ‘plausible’ REE is usually significantly smaller than the set of all REE.

The roles of RLS learning are not restricted to stability of REE and equilibrium selection. Learning can also provide new forms of dynamics as discussed below.

### 3 Monetary policy design

Indeterminacy of equilibria and instability of REE under RLS learning mean that the economy can be subject to persistent fluctuations. These instabilities can arise in the New Keynesian (NK) model (Woodford, 2003), which is widely used for studying monetary policy. Policy design has an important role in eliminating these instabilities and facilitating convergence to ‘desirable’ equilibria.

Consider the linearized NK model. The IS and PC curves \( x_t = -\phi(i_t - E_t^n \pi_{t+1}) + E_t^n x_{t+1} + g_t \) and \( \pi_t = \lambda x_t + \beta E_t^n \pi_{t+1} + u_t \) summarize private sector behaviour. Here \( x_t, \pi_t \) and \( i_t \) denote the output gap, inflation and the nominal interest rate. \( \phi \) and \( \lambda \) are positive parameters while \( 0 < \beta < 1 \) is the discount factor. The shocks \( g_t \) and \( u_t \) are assumed to be observable and follow a known VAR(1) process.

Central bank (CB) behaviour is described by an interest-rate rule. CB may use an instrument rule that is not based on explicit optimization. Examples are Taylor rules that depend on current data or forecasts, \( i_t = x_\pi \pi_t + x_\chi x_t \) or \( i_t = x_\pi E_t^n \pi_{t+1} + x_\chi E_t^n x_{t+1} \), where \( x_\pi, x_\chi > 0 \).

The IS and PC equations, together with either Taylor rule, lead to a bivariate reduced form in \( (x_t, \pi_t) \),
which can be examined for determinacy (uniqueness of equilibrium) and E-stability. Bullard and Mitra (2002) show that current-data Taylor rules yield both E-stability and determinacy iff $\lambda (\chi \pi -1)+(1-\beta ) \chi x >0$. Under forward-looking rules $\chi \pi >1$ and small $\chi x$ yield E-stability and determinacy.

Optimal monetary policy under discretion and commitment has been examined by Evans and Honkapohja (2003a; 2003b; 2006). Various ways to implement optimal policy have been suggested. Some commonly suggested interest-rate rules, based on fundamental shocks and variables, can lead to E-instability and/or indeterminacy. Evans and Honkapohja advocate appropriate expectations-based rules that deliver both E-stability and determinacy.

Other aspects of learning are also important for monetary policy. One practical concern is the observability of private forecasts needed for forecast-based rules. Results by Honkapohja and Mitra (2005) show that using internal CB forecasts in place of private sector expectations normally delivers E-stability.

Another difficulty for optimal monetary policy is that it requires knowledge of structural parameters, which are in practice unknown. CB can learn the values of $\phi$ and $\lambda$ by estimating IS and PC equations. Expectations-based optimal rules continue to deliver stability under simultaneous learning by private agents and the CB (see Evans and Honkapohja, 2003a; 2003b).

### 4 Fluctuations

A major issue in macroeconomics is economic fluctuations, for example, business cycles and asset price movements. Can learning help to explain these phenomena?

#### 4.1 Stable sunspot fluctuations

One theory of macroeconomic fluctuations interprets them as rational ‘sunspot’ equilibria. Although many macroeconomic models – for example, the real business cycle (RBC) model or Taylor's overlapping contracts model – have a unique stationary solution under RE, other models can have indeterminacy. Examples include the overlapping generations (OLG) model and RBC models with increasing returns and monopolistic competition or tax distortions.

When multiple equilibria are present, some solutions may depend on variables, ‘sunspots’, that are completely extraneous to the economy. Such stationary sunspot equilibria (SSEs) exhibit self-fulfilling prophecies with the sunspot acting as a coordinating device: if expectations depend on a sunspot variable, then the actual economy, since it depends on expectations, can also depend rationally on the sunspot.

As already noted, learning stability is a selection device. Suppose agents’ forecasts are a linear function of both the macroeconomic state and a sunspot variable. If the forecast functions have coefficients close to but not equal to SSE values, and if agents update the estimated coefficients using RLS, can the coefficients converge to SSE values? If not, this casts doubt on the plausibility of SSEs. SSEs appear not to be stable under learning in indeterminate RBC models but are learnable in some other models. We first describe results for the NK model and then discuss the possibility of stable SSE in other models.
4.1.1 SSEs in the NK model

Consider again the linearized NK model augmented by either the current-data or forward-looking Taylor rule. As noted above, indeterminacy is likely when the ‘Taylor principle’ $\chi \pi > 1$ is violated. In practice CBs are said to use forward-looking rules, and Clarida, Gali and Gertler (2000) argue that empirical estimates of $\chi \pi$ are less than 1 in the period before 1984, while they are greater than 1 for the subsequent period. Could SSEs explain the higher economic volatility in the earlier period? Honkapohja and Mitra (2004) and Evans and McGough (2005) approach this question by asking when SSEs are stable under learning in the NK model. Surprisingly, SSEs appear never to be stable under learning for current-data Taylor rules. When the forward-looking Taylor rule is employed, stable SSEs occur not when $\chi \pi < 1$, but rather when $\chi \pi > 1$ and $\chi \pi$ and $\chi x$ are sufficiently large, that is, overly aggressive rules lead to learnable SSEs. However, this does not rule out the Clarida, Gali, Gertler explanation for pre-1984 instability because, if $\chi \pi < 1$ leads to indeterminacy, no REE is stable under learning and aggregate instability would presumably result.

4.1.2 Stable SSEs in other models

Stability under learning is a demanding test for SSEs that is met in only some cases in the NK model. There are, however, other examples of stable SSEs, such as the basic OLG model. Some nonlinear models can have multiple steady states that are locally stable under RLS learning. In this case there can also be SSEs that take the form of occasional random shifts between neighbourhoods of the distinct stable steady states. Examples of this are the ‘animal spirits’ model of Howitt and McAfee (1992), based on a positive search externality, and the ‘growth cycles’ model of Evans, Honkapohja and Romer (1998) based on monopolistic competition and complementarities between capital goods. Two stable steady states also play a role in some important policy models. This can arise in a monetary inflation model with a fiscal constraint, developed by Evans, Honkapohja and Marimon (2001), and in the liquidity trap model of Evans and Honkapohja (2005). In these set-ups policy has an important role in eliminating undesirable steady states.

4.2 Dynamics with constant gain learning

An alternative route to explaining economic fluctuations is to modify RLS learning so that more recent observations are given a higher weight. A natural way to motivate this is to assume that agents are concerned about the possibility of structural change. In the RLS formula (2) this can be formally accomplished by replacing $r^{-1}$ with a small ‘constant gain’ $0 < \gamma < 1$, yielding weights that geometrically decline with the age of observations. This apparently small change leads to ‘boundedly rational’ fluctuations, with sometimes dramatic effects. Three main phenomena have emerged. First, as shown by Sargent (1999) and Cho, Williams and Sargent (2002), even when there is a unique equilibrium, occasional ‘escape paths’ can arise with learning dynamics temporarily driving the economy far from the equilibrium. Sargent shows how the reduction of inflation in the 1982–99 period might be due to such an escape path in which policymakers
are led to stop attempting to exploit a perceived (but misspecified) Phillips curve trade-off. Second, in models with multiple steady states, learning dynamics can take the form of periodic shifts between regimes as a result of intrinsic random shocks interacting with learning dynamics. This is seen in the ‘increasing social returns’ example of Evans and Honkapohja (2001), the hyperinflation model of Marcet and Nicolini (2003), the exchange rate model of Kasa (2004) and the liquidity trap model of Evans and Honkapohja (2005).

Third, even when large escapes do not arise, there can be policy implications, because constant gain learning differs in small but persistent ways from full rationality. Orphanides and Williams (2005) show that policymakers attempting to implement optimal policy should be more hawkish against inflation than under RE.

5 Other developments

There continue to be many new applications of learning dynamics in macroeconomics, with closely related work in asset pricing and game theory.

One recent topic concerns the possibility that agents use a misspecified model. Under RLS learning agents may still converge, but to a restricted perceptions equilibrium, rather than to an REE (see Evans and Honkapohja, 2001). Another recent development is to allow agents to select from alternative predictors. In the Brock and Hommes (1997) model agents choose, based on recent past performance, between a costly sophisticated and a cheap naive predictor. This can lead to complex nonlinear dynamics. Branch and Evans (2006) combine dynamic predictor selection with RLS learning and show the existence of ‘misspecification equilibria’ when all forecasting models are underparameterized.

Other topics and applications include empirical work on expectation formation, calibration and estimation of learning models to data, interaction of policymaker and private-sector learning, learning and robust policy, experimental studies of expectation formation, the role of calculation costs, expectations over long horizons, alternative learning algorithms, expectational and structural heterogeneity, transitional learning dynamics, consistent expectations and near-rationality.

learning-by-doing

Spyros Vassilakis
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
capital–labour ratio; externalities; firm size, theory of; learning spillovers; learning-by-doing; partial equilibrium

Article

Empirical studies of the production process in various industries have demonstrated a positive association between current labour productivity and measures of past activity like past cumulative output or investment (see Wright, 1936; Hirsch, 1956; Alchian, 1963; Hollander, 1965; Sheshinski, 1967; Boston Consulting Group, 1972; 1974; 1978; and Lieberman 1984). A hypothesis advanced to explain this is that labour learns through experience and that experience is obtained during the production process. In other words, learning-by-doing is one of the reasons giving rise to dynamic economies of scale, because a firm knows that increasing current production reduces future average costs. If knowledge obtained within one firm cannot be communicated to other firms, we speak of learning without spillovers. There is some empirical evidence, though, that firms cannot totally exclude outsiders from their stock of knowledge, mainly because of labour turnover (see Boston Consulting Group, 1978, and Lieberman, 1984). Learning spillovers are a special case of positive externalities. The study of learning-by-doing, therefore, is a special case in the study of economies characterized by dynamic economies of scale and positive externalities.

Empirical studies of growth have demonstrated that increases in per capita output cannot be attributed solely, or even mainly, to increases in the capital–labour ratio (see Abramovitz, 1956; Solow, 1957; Kendrick, 1976). On the other hand, Verdoorn (1956) observed a positive relationship between past cumulative output and current labour productivity in the aggregate. This seems to suggest that the part of growth unexplained by increases in the capital–labour ratio could be accounted for by learning-by-doing. Once income per head increases for any reason, say because of an increase in the capital–labour ratio, it will keep on increasing for ever because the initial increase will improve labour productivity and income per head in the next period; after that, the chain of output increases resulting in productivity
increases and vice versa is repeated for ever and for the right values of the coefficients it will generate unbounded growth even with stationary population.

Formal models of this process were constructed by Arrow (1962), Levhari (1966), Romer (1986), and Stokey (1986). None of these authors model the process of learning explicitly but consider a world of perfect information with features that are supposed to emerge from a process of learning going on behind the scenes. Here we analyse Romer's model, which is the more general and pays particular attention to existence.

Romer considers a continuous time model with infinitely lived agents who produce and consume a single final good out of a fixed, inexhaustible supply of primary factors. At any given moment in time, the final good can be either consumed or added to the indestructible stock of capital. There is an exogenously given number of firms; each firm's output at any moment in time depends on the amount of capital accumulated by the firm up to that moment, on the amount of natural resources it employs and on the total amount of capital accumulated by all firms up to that moment. In other words, knowledge can be communicated across firms and is incorporated in the capital stock. There are diminishing returns in private capital accumulation but increasing returns when the effect of a firm's accumulation on the total capital stock is taken into account. Notice that the assumption of diminishing returns in private capital accumulation implies that the technical process generated by new learning is capital-augmenting, not land-augmenting. Firms maximize profit and consumers maximize utility taking prices as given.

Existence of Walrasian equilibria is demonstrated under the following assumptions: (a) firms do not recognize that their accumulation affects the total capital stock; (b) the growth rate of each firm's capital stock is uniformly bounded above and is a concave function of each firm's investment; (c) the production function is majorized by a constant plus a constant-elasticity function of the capital stock; (d) the discount factor is larger than the product of the above elasticity times the upper bound in the growth rate of the capital stock. Under some additional conditions, the equilibrium capital stock and consumption per head grow without bound. Equilibria are Pareto inefficient because firms do not take into account the fact that their private accumulation adds to the aggregate capital stock and therefore reduces everybody's future costs. Romer and Sasaki (1985) have generated unbounded growth with constant population and a fixed supply of exhaustible resources under more restrictive conditions on the coefficients.

Clearly, the main achievement of Romer's competitive model is to generate unbounded growth without assuming exogenous improvements in technology. The applicability and generality of the model, though, are restricted by the price-taking assumption and the related assumptions that all economies of scale are external to the firm and that the number of firms is fixed. Suppose for a moment that we accept the last two assumptions. Then, as Fudenberg and Tirole (1983) showed, if returns with respect to private capital accumulation are constant, no price-taking equilibrium exists; in other words, the assumption that technical progress is not land-augmenting is crucial. Also, there is no reason why firms should fail to recognize the effect of their actions on the capital stock. Spence (1981) and Fudenberg and Tirole (1983) constructed dynamic partial equilibrium models of learning without spillovers in which a fixed number of firms compete in quantities with Cournot expectations. Industry output may decline over time at a subgame perfect equilibrium, depending on how large is the discount factor relative to the number of firms. Stokey (1986) investigated the same model with spillovers and found that industry output increases over time. Given the importance of spillovers in generating growth, therefore, it seems
worthwhile to study their determinants. The next step is to remove the assumption that all dynamic economies of scale are external to the firm and that the number of firms is fixed. Even if one begins with a situation of purely external economies of scale, there are powerful economic incentives to internalize these economies by reductions in the number of firms, either by collusion or by competition that drives some firms out of business. The tendency to collude to internalize externalities is checked by the incentive of each firm to shirk (underinvest in learning) given that others have done their share of investment. The tendency of competition to reduce the number of firms is checked by entry when the number of firms is so small that a new entrant's gains by wiping out excess profits exceed losses due to lost economies of scale. The learning-by-doing model coupled with such a theory of firm size could generate more predictions about growth, concentration and distribution of income over time.

Finally, one has to address the issue of the evolution of the externalities themselves over time. The extent of learning spillovers is limited by concentration and by the creation of markets in order to transform the external effects into ordinary goods; both of these magnitudes are endogenous, and so the extent of learning spillovers should also be an endogenous variable. The current formulation of learning spillovers assumes a stable, exogenous relationship between measures of past activity and future productivity, but in a long-run model one would not expect such a relationship to hold, exactly because the number of firms and completeness of markets are variable in the long run.

Article
Emil Lederer was a prominent economist and sociologist in the German Weimar Republic. He was born in the Bohemian town of Pilsen in 1882 and died in political exile in New York City in 1939. In Vienna and Berlin, where he studied both law and economics, Lederer participated in advanced seminars conducted by Menger, Böhm-Bawerk and Schmoller. From 1918 to 1931 he served as professor in Heidelberg and then succeeded Sombart in Berlin from 1931 to 1933. In collaboration with E. Jaffé, Schumpeter and Sombart as well as Max and Alfred Weber, he edited the Archiv für Sozialwissenschaft und Sozialpolitik, the renowned social science journal which ceased publication under the Nazi regime. After emigrating to New York in 1933 he became the first Dean of the New School for Social Research's Faculty of Political and Social Sciences, which was comprised of outstanding Continental scholars who had also sought asylum in the United States.

Lederer made pioneering contributions towards understanding the social, political and economic significance of large-scale, bureaucratic private enterprise. In a major theoretical and empirical study based on his Habilitation, Lederer undertook the first comprehensive analysis of the working conditions and political attitudes of salaried employees (Lederer, 1912). Subsequent work together with Jacob Marschak showed how rationalization of production along with bureaucratic division of labour in administration formed the basis for the rise of the new middle class (Lederer and Marschak, 1926). They concluded that the evolution of class structure in advanced capitalist societies undermines political stability and raises the spectre of fascism. Anxiety stemming from economic insecurity and abhorrence of collective action with organized labour weakens the growing middle class's support for democratic forms of government and strengthens its tolerance of authoritarian institutions to suppress the demands of the proletariat.
Lederer's advanced economics textbook contains an authoritative exposition and critique of objective and subjective value theories (Lederer, 1931a). The laws of the market economy, as depicted in the marginalist doctrine, are no longer in effect, since economies of large-scale production prevail. Adoption of modern technologies requires vertical integration, high proportion of fixed capital and substantial fixed costs for sales and general administrative overhead. Complementarities and decreasing marginal costs are the rule in basic industries (coal, steel, chemicals and utilities).

Increasing returns to scale is not only an anomaly which cannot be subsumed under the marginalist paradigm; it forms the starting point for business cycle theory (Lederer, 1924; 1927). Disproportionalities in growth of demand for investment and consumer goods are due to unavoidable price inflexibilities and absence of strong equilibrating tendencies. Cartels which administer prices and set production quotas are the natural outcome of the technically determined drive to realize economies of scale. The self-contained planning of separate industrial bureaucracies lacks inter-industry coordination and thus cannot prevent misallocation, underutilization and periodic decumulation of capital.

Rapid labour-saving technical change is regarded by Lederer as a key factor in explaining the severity of unemployment during the Great Depression (Lederer, 1931b; 1936a). In an upswing, dynamic enterprises exploit opportunities to realize above-normal returns on investment offered by introduction of highly mechanized techniques. Labour is displaced not only by rationalization of operations but also by diversion of capital from static enterprises which do not employ the new techniques. As productivity and productive capacity in dynamic enterprises increases, monopolistic market structures prevent prices from falling faster than wages. Redistribution of income from labour to capital decreases consumer goods demand, which in turn reduces the derived demand for capital goods and brings about excess capacity in capital goods production. Without incentives for accelerating the form of technical progress which creates new products, opens up new markets and stimulates labour-absorbing investment, technological unemployment persists.

Stressing the distinction between labour-saving and labour-absorbing forms of technical progress, Lederer criticized Keynes for his failure to analyse long-run dynamics (Lederer, 1936b). Investment in plant and equipment embodies new techniques. Not the lack of profitable investments, but rather an abundance of abnormally profitable rationalization investments creates structural unemployment in addition to the cyclical unemployment treated by Keynes. Government spending is necessary to stimulate the economy, but it is not sufficient to overcome mass unemployment. Democratic national planning is also necessary to attract capital to new industries offering additional employment opportunities.

Lederer's conviction that a mix of market and planned economies based on political consensus is practicable may be traced to his close association with the industrialist and statesman, Walther Rathenau, who was the architect of German economic mobilization in the First World War (Lederer, 1933; 1934).

Along with Schumpeter, Lederer cultivated an undogmatic Austrian style of theorizing. Both emphasized the significance of uncertainty, entrepreneurship (or its absence as a consequence of bureaucratization), disequilibrating forces, such as technical change, and underlying instability of capitalism. Schumpeter (1939; 1942) defended neoclassical equilibrium theory by asserting that the price system it represents moves automatically, but not without friction, towards a new equilibrium following the ‘creative destruction’ of an old equilibrium. Similarly, Lederer (1931b) wrote: ‘The capitalist dynamic is not only “development” but also “destruction” ’. However, Lederer combined neo-
Ricardian (von Bortkiewicz, 1907) and Austro-Marxian (Hilferding, 1910) approaches to focus on the production system; accordingly, in his view there was no automatic mechanism to assure that investment brings about a rate and direction of technical change consistent with full employment equilibrium.

legal institutions and the ancient economy

Dennis P. Kehoe
From The New Palgrave Dictionary of Economics Online, 2008,
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This brief survey suggests some of the issues that can be investigated by a careful analysis of the relationship between legal institutions and the economy in the ancient world. By investigating legal institutions, we can better understand the relationships that shaped the economy and the likely implications of these relationships for economic performance. It covers institutions in the Ancient Greek world, in the Ancient Roman world, and more briefly in Ptolemaic Egypt.

Keywords

government; ancient Greece; ancient Rome; ancient Egypt; law and economics; new institutional economics

Article

Within the broad constraints imposed by population and technology (Scheidel, Morris and Saller, 2007), law and legal institutions played an important role in ancient economies. The overriding question concerns how formal institutions, including courts and contractual types, and informal ones, such as social conventions or ideology, affected incentives to enter into mutually beneficial contractual arrangements. The alternative is that the laws and legal institutions surrounding an ancient economy served primarily to protect the privileges or interests of certain well-connected groups. Understanding the role of legal institutions in an ancient economy is complex because the available evidence usually makes it impossible to verify hypotheses about the likely incentives resulting from various property rights regimes. Still, analysing ancient legal institutions can shed light on the basic relationships among the principal actors in an ancient economy, including the state, elite property owners, urban residents, and farmers.

Legal institutions in the Greek world
One key issue is the role that legal institutions played in promoting commerce. The Greek world in the classical (480–323 BCE) and Hellenistic periods (323–31 BCE) was politically fragmented, and individual city-states (poleis) had their own legal systems. Consequently, we can speak of a unified system of Greek law only to a limited degree. This made it difficult to develop governance structures to enforce the types of contractual arrangements essential to commerce. In the Hellenistic period, the emergence of larger monarchies may have promoted a more unified system of commercial law between states. Eventually, the incorporation of the Greek world into the Roman Empire greatly enhanced the possibilities for developing a more uniform set of legal institutions. In the absence of unified formal institutions to govern commerce, we should expect merchants to have developed their own private ways of enforcing contractual obligations and resolving disputes (cf. Greif, 2006).

At the level of the polis, we are best informed about the way in which commercial law functioned in classical Athens, particularly in the fourth century BCE (Todd, 1993; Cohen, 2005). At this time, Athens had become a commercial hub, and its involvement in commerce was vital to its survival, since it depended on imported grain from the Black Sea region. Certainly the economy of Athens, as much as any place in the ancient world, required legal mechanisms to develop and enforce complex commercial arrangements. The state intervened in commerce directly only to protect the grain supply by imposing severe sanctions on Athenians who exported grain to other cities. Even so, institutions developed in Athens to promote trade. Banks played a crucial role in assembling the capital necessary for maritime commerce. Often these commercial undertakings might be complex, with multiple investors supplying cargoes to the same ship, so that a single voyage might involve a wide variety of contracts and loans (Cohen, 1992). The question is how merchants involved in this commerce, many of whom came from locations overseas, could enforce the obligations of their trading partners. In most city-states, the local courts were open only to citizens, unless two states negotiated a bilateral commercial treaty. The Athenians endeavored to meet a more general need for a forum to resolve disputes by developing courts in which lawsuits involving overseas commerce, dikai emporikai, could be heard (Todd, 1993, pp. 333–7; Cohen, 2005, pp. 299–300). These courts were open to anyone doing business in Athens, not just Athenian citizens. Their success in encouraging commerce depended on their treating foreign traders in Athens impartially. Foreign traders, when sued in the court, had to post bond, but at the same time the courts discouraged frivolous lawsuits by imposing financial penalties on plaintiffs who failed to gain at least one-sixth of the jury's votes (Cohen, 2005, pp. 299–302).

Another issue is the role that private contract law played in the economy. In contrast to Roman law, the mutual consensus of the two parties to a contract did not in and of itself create contractual obligations; rather, a real act, such as the exchange of property, was required (Todd, 1993, pp. 262–8; Rupprecht, 2005, p. 337). The apparent simplicity of this type of contract would seem to preclude certain complex commercial arrangements, such as sales of real estate on credit or sales of crops in advance of the harvest, but this was manifestly not the case. In Athens, one part of the solution to the problem was the freedom of procedure in courts; this flexibility made it possible to sue regardless of whether a business arrangement corresponded to an accepted contractual form.

The Hellenistic period saw legal developments potentially significant for the economy (Rupprecht, 2005). Typically, multiple legal systems functioned side by side. In Egypt, for example, the Ptolemies, a Macedonian dynasty, introduced Greek law for the immigrant Greek population, while the native Egyptians continued to rely on their own legal traditions and contract forms. The substantial Jewish
population in Egypt could also use its own laws. In Greek law, written documents were increasingly common in private business arrangements. They tended to be written in standard language, and so they would have served to make contracting in business simpler. The widespread use of written contracts means that there were scribes well versed in the basics of commercial law. The trend of using written documents to record what had originally been oral contracts accelerated in Roman times (Meyer, 2004).

A second development in Ptolemaic Egypt was the increasing registration of documents in state archives. In the early Roman imperial period in Egypt, the state developed a registry of real property and the rights assigned to it, the *bibliotheke enkteseon*, which helped to eliminate some of the uncertainty surrounding the ownership of real property that is characteristic of pre-modern economies.

The development of commerce in the Greek world, and in the Roman world later, depended on property owners having reliable agents to manage their businesses. Part of the solution in both the Greek and Roman worlds was to employ agents who were social dependants. In fourth-century Athens, this can be seen especially in the banking industry. The general prohibition against the ownership of land in Attica by non-Athenian citizens surely made banking an attractive business undertaking for resident aliens (metics), many of whom were quite wealthy. The foreign owners of these banks commonly employed slaves as their managers. A highly trained slave could operate a bank independently, but there was no threat that he would take advantage of his training to set up a rival bank to compete with that of his former employer (Cohen, 1992, pp. 61–110, 133–6). In Rome, property owners employed slaves and freedmen in similar functions, as will be discussed below.

**Legal institutions in the Roman world**

The development of Roman law as a legal system with wide application in the Mediterranean world had potentially enormous consequences for the Roman economy. Roman society had a professional class of jurists who interpreted the law in a rigorous fashion and, in effect, created a science of jurisprudence. The jurists originally provided legal advice in private trials, but beginning with the reign of Augustus (31 BCE – 14 CE) they gained a state-sanctioned role in providing authoritative interpretations of the law. In economic matters, one of the jurists' main contribution was to interpret contract law. By the second century BCE, the Roman praetors (the officials in charge of the administration of private law) had developed the concept of consensual contracts, including sale (*emptio-venditio*), lease and hire (*locatio-conductio*), mandate (*mandatum*), and partnership (*societas*). The contract types defined legal relationships crucial for the Roman economy, and they provided a basis for Roman commercial law for centuries to come. Although this is a controversial subject, it is now increasingly accepted that the jurists endeavored to respond to social needs as they interpreted contract law.

The Roman Empire was also successful in developing legal institutions that were accessible to a broad segment of the population. One key to this was the petition process. The Roman emperor received such a volume of petitions that the Roman government had an office, headed by an official of equestrian rank, the *a libellis*, whose responsibility was to receive petitions and issue answers, or rescripts, in the emperor's name (Peachin, 1996). Petitioners would receive an authoritative response about the law applicable to their case, and they could then take these responses to local courts, whose judges would be obliged to follow them. People also sent petitions to officials of lower rank, from local magistrates to provincial governors. The petition process was so widespread that it suggests that the empire's subjects
viewed it as a reasonably reliable way to protect their interests. Responding to petitions, moreover, provided the state with one way, albeit reactive, to intervene in the economy. Such intervention can be discerned in legal policies concerning farm tenancy, in such issues as the tenant's security of tenure and the allocation of the risks associated with agriculture (Kehoe, 2007).

To consider agency again, the Romans, like the Greeks, often relied on social dependants, particularly slaves and freedmen, to serve as business agents. To some extent, this resulted from the basic organizing principles of the Roman household. In Roman society, the head of a Roman household, the *pater familias*, exercised a great deal of power over the members of his *familia*. These included his agnatic descendants as well as his slaves and freedmen. In economic terms, he was the ultimate owner of all the property in the hands of anyone in his power, or *patria potestas* (Saller, 1994: 102–32). The *familia* provided the basic structure for organizing much of economic life in the Roman world. It was a setting in which people were trained in specialized skills important for the economy, and it also influenced the organization of commercial enterprises. When employing social dependants as agents, Roman property owners tended to give them a great deal of freedom. The slave would operate with a *peculium*, funds and property under his control but ultimately belonging to the owner. The slave agent had every incentive to manage the business well, since he could earn his freedom in doing so, whereas the owner could impose sanctions in the event of his misbehaviour more easily than would be possible with a free employee (Frier and Kehoe, 2007, pp. 130–4). Often freedmen who gained their initial training as slaves could establish businesses of their own, training their own slaves, and continuing the cycle.

Merchants dealing with agents had to be assured that they would be able to enforce their claims in the event of a dispute. Part of the solution was a series of remedies, the so-called *actiones adiecticiae qualitatis*, created in the late third or second centuries BCE. These established the circumstances under which a property owner could be liable for obligations taken on by an agent. In many cases, the principal's liability was limited to the size of the *peculium* granted the slave agent. This legal regime may have carried a substantial social cost, since in theory at least, the limited liability of the principal will have deterred some people from entering into otherwise productive business arrangements. At the same time, it responded to the needs of an upper class that was cautious in its approach to investing wealth (Kehoe, 1997). The formal regime surrounding agency in Roman law can be contrasted with the type of agency that characterized Ptolemaic Egypt (Von Reden, 2007, pp. 239–50). There, property owners who also held official posts relied on private, individual agents, who collected debts or made loans on their behalf. The activities of the agent, however, created no formal legal relationship between the property owner and a third party who was either a debtor or a creditor. This system of agency clearly revolved around the personal reputations of the individuals involved.

In interpreting Roman contract law, the Roman jurists seem to envision a class of independent contractors who had sufficient resources to undertake major jobs, such as leasing farms or construction projects. In the contractual relationship covering major construction projects, called *locatio-conductio operis* (Martin, 1989), the builders were expected to organize tasks and finance operations until they were paid by their principals. Again, this situation can be contrasted usefully with the corresponding contract arrangement in Ptolemaic Egypt, called *ergolabia*. In such contracts from the third century BCE, for example, the property owner employing the contractor generally had to pay the latter up front. The contractor still had a great deal of responsibility, but the payment up front created potential monitoring problems, and it was probably necessary because at this time contractors did not have ready
This brief survey suggests some of the issues that can be investigated by a careful analysis of the relationship between legal institutions and the economy in the ancient world. By investigating legal institutions, we can better understand better the relationships that shaped the economy and the likely implications of these relationships for economic performance.

The idea of a leisure class was popularized by Thorstein Veblen, whose *Theory of the Leisure Class* (1899) developed the social categories of pecuniary competition, conspicuous leisure and conspicuous consumption. Bukharin's *Economic Theory of the Leisure Class* (1919) argued that marginal utility theory was the theoretical expression of the class of rentiers who had been eliminated from the process of production and were interested only in disposing of their incomes. In *The Age of Uncertainty* (1977) J. K. Galbraith argued for the continuing relevance of Veblen's analysis. Modern sociologists, however, show little interest in the idea of a leisure class.

**Article**

This term became popular after Thorstein Veblen's book, *The Theory of the Leisure Class* (1899). In that book the author gives a historical and socio-economic explanation of the development of that wealthy class in the society of his time whose main characteristic was leisure. By ‘leisure’ Veblen means the non-productive spending of time which originates from a sense of the worthlessness of productive work and from the need to show pecuniary ability to afford a life of idleness. The basic social categories of Veblen's theory of the leisure class are pecuniary competition, conspicuous leisure and conspicuous consumption.

The leisure class is an old institution. The emergence of a leisure class coincides, according to Veblen, with the beginning of ownership. These two institutions (leisure class and ownership) are different aspects of the same general facts of social structure. The conditions for the appearance of the leisure
class as a permanent form are: (1) the community has to be of a predatory type; and (2) the means of life must be affordable in a relatively easy way, so that part of the population can be liberated from routine work. It is necessary to make a proper distinction between the leisure and the labouring class. For the lower classes, as Veblen explains, since labour is their accepted and only mode of life, an emulative pride in a reputation for efficiency in their work becomes the only emulation that is open to them. For the ‘superior pecuniary class’ the most imperative secondary demand for emulation is the abstention from productive work. It is not sufficient to possess wealth or power. It becomes important to show that you have no need to do productive work. From the days of the Greek philosophers to the present a life of leisure is, as Veblen says, in a great part of secondary and derivative value (1936, p. 231).

Leisure does not usually bring about a material product; the result takes the form of non-material goods. Good examples of occupations that members of the leisure class choose to pursue are the knowledge of dead languages and the occult sciences, of correct spelling, of the various forms of music and other household arts, fashionable dress, furniture, games, sports, dogs and racehorses. Elegant speech shows the level of a speaker's emancipation from productive work. The leisure class is not interested in technological innovations and it is an obstruction to social and economic progress.

Veblen's critique of ‘absentee ownership’ is the next step in his analysis of modern civilization. The members of the leisure class do not want to have any connection with a production process and they leave the managing and guiding of this process to so-called ‘captains of industry’. The last group is for Veblen the only positive power interested in technological development.

Veblen's critique of ownership and his opinion that the modern type of ownership is not compatible with industrial efficiency has been and still is unacceptable to many of his fellow economists. Like Marx, Max Weber and Karl Polanyi, Veblen had demonstrated the importance of studying primitive economies for general economic history and the interaction between economics and the society in general. Veblen's leisure class seems very much like Marx's ruling capitalist class. Both of them see the bitter struggle between capital and labour. But they differ very much according to the methods of solving this contradiction. Marx's solution is, as is well known, a socialist revolution. In *The Theory of the Leisure Class* Veblen was not explicit about this issue. He was not sure about the end of this struggle, but he was very positive about the existence of the struggle. This goes very well with his Darwinian philosophy. A kind of trade unionism could be closer to Darwinism and is more acceptable for Veblen than neo-Hegelianism or Marxism.

Although his theory is based on Darwinian philosophy and although he argues for evolutionary socialism, in some of his later writings he was closer to the attitude that certain radical social movements could be the solution for breaking with old social institutions. In his search for emancipation of man, Veblen, together with other great humanists, had to become a socialist. His analysis of private ownership and the leisure class necessarily pushed him into this direction.

Nikolai Bukharin's *Economic Theory of the Leisure Class* (1919) is quite different from Veblen's book. This is not an economic account of the conditions which give rise to the existence of a leisure class in the manner of Veblen. The leisure class is not the central category in this work, as the title may suggest. Bukharin mentions the leisure class in the context of his critique from a Marxist point of view of the theory of marginal utility, especially that of the Austrian school. He gives no reference to Veblen. Bourgeois political economy, according to Bukharin, seeks to justify the capitalist system and therefore it loses its scientific role, contrary to the Marxist theory which claims its general validity precisely for the reason that it is the theoretical expression of the most advanced class – the working class.
In the critique of marginal utility theory Bukharin points out that this theory is the theoretical expression of the class of rentiers who have been eliminated from the process of production and are interested in disposing of their income from holdings of securities and bonds only. This marginal utility theory is, according to Bukharin, unhistorical: it starts with consumption not the production process. His critique of the logic and the method of subjective value theory is settled in direct confrontation with the labour theory of value.

J.K. Galbraith refers to Veblen's work, suggesting that the concepts 'conspicuous leisure' and 'conspicuous consumption' are still of significance (Galbraith, 1977). In the United States, as Galbraith explains, class as described by Veblen still exists: the members of the leisure class are still buying their social status.

It might have been expected that contemporary sociologists would have been more concerned with the concept of the leisure class. But this is not the case. They are very much occupied with leisure itself: it is common for sociologists to define leisure as the portion of time which remains when time for work and the basic requirements for existence have been satisfied, and this issue is related to the problem of how to spend leisure time. But this is a different problem and does not have a substantial relation to the problem of the leisure class.

leisure

Lars Osberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economists have typically defined ‘leisure’ residually, as equal to ‘non-work time’, and, despite the problematic classification of enjoyable jobs, commuting time and unemployment, presumed that individuals derive utility from non-work time and disutility from working time. However, a recent literature now emphasizes ‘social leisure’ and coordination problems in leisure time. Since longer working hours by some individuals make arranging a social life more difficult for others (thereby decreasing the utility of their non-work time), externalities in time use may create multiple possible equilibria in time use, which may explain the sharp divergence in working hours between Europe and the United States.

Article

What is ‘leisure’? The Merriam-Webster Online Dictionary defines it as ‘freedom provided by the cessation of activities; especially: time free from work or duties’, while the Oxford English Dictionary suggests it is ‘The state of having time at one's own disposal; time which one can spend as one pleases; free or unoccupied time’. (Both note that the adjective ‘leisurely’ describes an action that is done without haste, in a relaxed way.) In common parlance, attendance at a relative's funeral or time spent voting would therefore not generally be seen as ‘leisure’, because time spent on an activity due to a sense of civic or familial duty cannot qualify.

‘Leisure’ is therefore a problematic concept for economists, because the context and subjective interpretation of an activity is crucial to deciding whether it should be counted as work, duty or leisure –
cooking or driving are, for example, activities that may be performed as parts of a paid occupational role, as a duty or for personal enjoyment. It is, in fact, not easy to think of an activity or time use that is not done sometimes for pay, sometimes for duty and sometimes for pleasure – perhaps by different people, but sometimes also by the same people. In many universities, the subtleties of such distinctions are explored in departments of ‘Leisure Studies’, which is now a recognized area of academic teaching and research. Peer-reviewed journals such as *Annals of Leisure Research* or *Leisure Sciences* report the latest research on leisure activities, and conferences are organized on such topics as ‘Serious and Casual Leisure’.

**Leisure as a residual category: the standard approach**

However, for many economists, ‘leisure’ is simply the $L$ in labour supply theory. This approach starts, in a one-period model, with each individual maximizing a utility function, where $U$ is the individual’s utility level, $C$ represents consumption goods and $L$ is leisure time, as in eq. (1):

$$\max U = u(C, L) \ [u' > 0 \ u'' < 0]$$  
(1)

The wage rate available in the paid labour market ($w$) and total time ($T$) are seen as the fundamental constraints facing individuals. In this framework, the problem of utility maximization can be equivalently seen as one of ‘labour supply’ or ‘leisure demand’ since total time is divided between hours of paid work ($H$) and leisure time ($L$).

$$H + L = T$$  
(2)

$$C \leq wH.$$  
(3)

From this perspective, ‘leisure’ is whatever ‘work’ isn’t – that is, leisure is a residual category, which is rarely examined directly or defined explicitly. Standard practice in economics journals is to focus on the hours of work decision – and ‘work’ is usually interpreted to mean ‘paid employment’. In the JSTOR
database of the top 26 economics journals, a keyword search, conducted in July 2005, for ‘leisure’ in archived articles published since 1995 yielded 823 ‘hits’. Of the top 100, sorted for ‘relevance’, only 25 had an explicit verbal definition of leisure – in most cases leisure was defined implicitly, as in eq. (2). If one discards the three articles discussing consumer demand for ‘leisure goods’ and focuses on time use, one finds the overwhelming majority of articles used leisure as a synonym for ‘non-market time’ – only three per cent recognized the possibility of ‘on the job leisure’ (but the definition was similarly residual – a lack of work effort – and implicit – for example, Dickinson, 1999, p. 639). Relatively few articles (about 15 per cent) considered the possibility that home production (such as shopping time) may be a form of ‘work’, while a similar number (about 13 per cent) argued that time spent in schooling or training preparatory to paid employment is not leisure. For a very few articles (three per cent), leisure was the residual time available after paid work and some other alternative, such as criminal activity. When working time is defined as equal to hours of paid employment, commuting time is implicitly defined as part of leisure, although it is plausibly an intermediate input into paid employment. Commuting time is an important percentage of time use in modern societies – Putnam (2000, p. 212), for example, has ascribed much of the decline in civic engagement in the United States to increased commuting time and commented that ‘American adults average seventy-two minutes every day behind the wheel….more than we spend cooking or eating and more than twice as much as the average parent spends with the kids.’ However, commuting time is strangely absent from most labour–leisure models. As well, although ‘retirement’ is the particular form of non-work time consumed at the end of the life cycle, most economics articles implicitly exclude it from analysis, by concentrating on the working-age population.

All the same, although \( L = T - H \) remains the dominant approach in economics, it has long been recognized that classifying time use as ‘work’ (painful) or ‘leisure’ (pleasurable) can be a bit oversimplified. A large body of research indicates, for example, that the unemployed are typically quite unhappy (Frey and Stutzer, 2002; Di Tella, McCulloch and Oswald, 2003) – time spent in unemployment seems to be qualitatively different from non-work time spent in other ways (that is, unpleasant). In general, people tend to rank their jobs fairly highly when asked to compare the satisfaction derived from specific activities (including jobs and types of housework and leisure). Juster and Stafford (1985) argued long ago that, in general, activities that involve social interaction – whether paid or unpaid – tend to be highly valued by individuals. Gary Becker (1965, p. 504) commented even earlier that ‘Not only is it difficult to distinguish leisure from other non-work, but also even work from non-work’.

‘Time-intensive commodities’ and the disappearance of ‘leisure’: the Becker approach

Becker's solution to the time classification problem was to posit that ‘commodities’ (like dinner, or a sailing excursion) are what enters individuals’ utility functions, and that the production of these commodities requires the input of both material goods and time. In this approach, ‘leisure’ therefore disappears as a distinct category, somewhat replaced by the concept of a ‘time-intensive commodity’. The Becker perspective has important implications for the type of leisure activities that people are predicted to choose. Personal time is, essentially, the only input into commodities like contemplation or conversation or the pure enjoyment of peace and quiet – so their cost is just the opportunity cost of time.
leisure: The New Palgrave Dictionary of Economics

(that is, the wage rate). The cost of goods-intensive non-work commodities (like speedboat racing) depends partly on the cost of those material goods. When (if) the wage rate rises, time-intensive leisure commodities increase in relative price compared with goods-intensive commodities. Hence, the Becker prediction is for greater materialism over time.

As well, consuming more ‘commodities’ in the same time period – for example, squeezing a tennis game and a sail and dinner and a night at the opera into the same day – is seen in the Becker model as representing an increase in the ‘productivity of consumption time’ (and more is always better), but some would also describe this as a more frenetic lifestyle. Winston (1987, p. 160) has commented that ‘the most serious casualty [in Becker's approach] was loss of the sense of a leisurely and controlled pace that produces genuine satisfaction’.

However, Becker's approach has not, in fact, been much used. The straightforward work–leisure dichotomy continues to dominate economics journals. The pleasures of non-work time and the marginal disutility of labour were stressed by Marshall (1920, p. 117) many decades ago, and they continue to be the dominant framework today. Can one – should one – expect this constancy of perspective among economists to persist?

Social leisure and the coordination problem

One of the peculiarities of the traditional ‘leisure demand–labour supply’ perspective is its individualism. If utility really did depend only on the quantity of consumption goods and number of non-work hours experienced by individuals, a person's level of utility would be unaffected by solitary confinement, or by any other configuration of social interaction. However, time spent in isolation is, for most people, pleasurable only in small doses. Although one can choose to be alone, relatively few leisure activities are intrinsically asocial. Most leisure activities can be arranged on a continuum of ‘teamness’, and the vast majority of them are distinctly more pleasurable if done with others. Playing softball or soccer are activities that make no sense if done alone. Singing to oneself may be something done in the shower, but singing with a choir is generally a different level of experience. Travelling to exotic foreign places or going for a walk are activities which are usually more pleasurable if done with a companion. Reading a novel is certainly solitary, but many people also like to talk about it afterwards, either formally in a book club or informally with friends over dinner.

To list these different possible leisure activities is to underscore the variety of leisure tastes that individuals have. This variety creates, for each individual, the problem of locating somebody congenial to play with, and scheduling the simultaneous free time to do so. The basic problem with wanting to have a social life is that individuals cannot do it unilaterally – arranging a social life involves a search process which is constrained by the social contacts available to each person, and by the availability of other people. This interdependence of leisure has generated a new literature, with a set of new insights. Corneo (2005), for example, contrasts privately consumed leisure time (watching television) and socially enjoyed leisure (which requires investment in relationships). Across nations, average hours of television watching are positively correlated with average working time. Corneo explains this in terms of the strategic complementarities that arise in the organization of social leisure. If these complementarities are strong enough, equilibria with little social leisure but long hours of work and television viewing, and equilibria in which there is much social leisure along with short hours of work and television viewing,
are both possible. Although workers will prefer the higher wages and lower hours of work of the latter, capitalists will prefer the former, since they realize a higher rate of return on their capital stock when total hours of work increase. And if desired working hours are conditional on what others do, individuals need coordination devices to ensure that social leisure is feasible – such as public holidays, a common weekend or working hours regulation – which implies a potentially crucial role for the state and for the relative power of workers and capitalists in influencing public policy. Jenkins and Osberg (2005) argue that, although solo television watching is certainly feasible, companionship may nonetheless increase the utility derived from the activity. Their emphasis is on modelling more explicitly the constraints involved in locating leisure companions. They argue that the leisure time choices of household members depend on the opportunities for associational life that exist outside the household, and they show that the likelihood of associational activity for persons of a given age group depends on the percentage of persons in other age groups that also engage in that activity. They note that economic models of marriage have discussed the interdependence of spouses in income and material consumption, but it is also plausible that an important reason for marriage is that couples may like spending time together. Like Hamermesh (1998; 2002), they provide evidence on the synchronization and scheduling of spousal work and leisure time.

What are the implications of these new models of social leisure? From a theoretical perspective, the emphasis on the social nature of leisure opens up a whole new set of coordination issues – there is certainly no presumption that individualistic decision making will automatically produce a socially optimal equilibrium. However, the new models of social leisure nest the old labour–leisure choice perspective, since the option of ‘solo leisure’ is always there (albeit now one of several alternatives). Kuhn (1970) argued that paradigms are replaced when they confront an important empirical anomaly that they are unable to resolve and when a more encompassing alternative theoretical perspective becomes available. The empirical fact which is now forcing a reconsideration of the analysis of leisure is the huge size of cross-national differences in the trend and level of non-work time. From 1980 to 2000, for example, average annual working hours per adult (ages 15–64) rose by 234 hours in the United States to 1,476 hours, but fell by 170 hours in Germany to 973, and by 210 hours in France to 957 (see Osberg, 2003a). By 2000, the cross-sectional difference was huge – non-work time per adult per week was some 9.7 hours greater in Germany, and 9.9 more hours greater in France, than in the United States. In principle, an increase in hourly wages increases both potential income and the opportunity cost of leisure, so the demand for a normal good (like leisure) may rise or fall depending on the relative size of income and substitution effects. However, why should one be larger in Europe and the other larger in America? It is just not very satisfactory to say that ‘tastes differ’.

Cross-country differences in average leisure time are due in part to inter-country differences in probability of employment, in part to differences in common entitlements to paid vacations and public holidays, and in part to differences in the usual hours of work of employees. Trends in these three components are driven by distinctly different processes – the number of paid public holidays is, for example, determined by a set of political processes quite different from the determinants of individual decisions to enter the workforce and to work specific hours. A robust debate has emerged over the causes of these differences in total leisure time (for example, Bell and Freeman, 2001; Alesina, Glaeser and Sacerdote, 2005) – but it is clear that these differences are large enough to motivate both a concern over their implications and a discontent with the traditional labour–leisure choice model.
It has long been acknowledged that one reason why GDP per capita is a poor measure of economic well-being is that it does not recognize that leisure time has any value at all. If, as in the comparison of the United States with Germany or France, greater per capita GDP is obtained primarily from greater average working time, a comparison of economic well-being should measure both the cost of forgone individual leisure and the cost of the externality on the marginal utility of each individual's leisure as the decrease in the leisure time of everyone else impedes the feasibility of leisure time matches. When (by increasing the availability of potential leisure matches) the choice of more leisure time by some individuals has a positive externality for other persons, there can be multiple equilibria in labour supply, in which the ‘high work’ equilibrium has unambiguously lower total utility. Societies which are better able to coordinate the level and timing of paid working hours may be better off in aggregate, because they enable their citizens to enjoy more satisfying social lives. To be specific, the leisure externality hypothesis suggests that Americans may work more hours than Europeans partly because they are more likely to have less satisfying social lives – because other Americans are also working more hours – and that they are worse off as a result. Moreover, if authors such as Putnam (1993; 2000) and the OECD (2001) are correct in stressing the dependence of social capital on associational life and the importance of social capital for social and economic development, the costs of a high-work/low-social life equilibrium may be substantial, in terms of market income as well as utility. Knack and Keefer (1997) are representative of an empirical literature which argues that localities with an active civic society and associational life (and more generally a dense network of social ties among individuals, and a high level of trust) have higher growth rates of GDP per capita. This relationship has been argued to be due to a number of possible influences: for example lower transactions costs in capital, labour and product markets, more effective governance, lower costs of crime, labour conflict and political uncertainty, better health outcomes, and so on (see Osberg, 2003b). Whatever the channel of influence, it suggests that, although working longer hours may accelerate growth in GDP per capita in the short run, both income and social life may suffer in the longer run. There may be some wisdom in the old saying that: ‘All work and no play makes Jack a dull boy.’

Article

Vladimir Ilyich Ulyanov, who wrote and gained fame under the pseudonym Lenin, was born in April 1870, the second son of a Russian provincial official in Simbirsk (now Ulyanovsk). After the arrest and execution of his elder brother Alexander, in 1887 for alleged terrorist activity, Lenin became increasingly active in political study groups at Kazan, Samara and St Petersburg. He came to identify himself with the Marxist rather than the populist (Narodniki) stream in these study groups. He played an active part in the early theoretical debates between these two streams on the future course of Russia's economic and political development. At the time of the founding of the Russian Social Democratic Labour Party (RSDLP) in 1898, he was already known as its best young theorist. A split in the RSDLP took place in 1902 and Lenin became identified as the leader of the majority (Bolshevik) faction. He spent much of the early years of the 20th century in exile in London, Paris and Zurich. He returned to Russia in April 1917 after the February Revolution had initiated the post-tsarist phase of Russian politics. Lenin, unlike his fellow party members, correctly foresaw the instability of the political situation in which an unelected liberal democratic cabinet uneasily shared power with the federation of popularly elected factory committees (Soviets). He launched the Bolsheviks on a strategy of revolutionary rejection of the government and a platform of peace in the World War at any price. His analysis proved correct when in November 1917 the Bolsheviks won a majority in the All Russian Congress of Soviets and took power. Lenin led the communist government from that day until illness forced his withdrawal from active politics in March 1923. He died in January 1924.

Lenin's economic writing is extensive, comprising books, pamphlets, newspaper articles and occasional speeches (see Desai, 1986, for a full bibliography). His contributions can be placed under three headings: analysis of Russia's capitalist development in the period 1880–1900; the analysis of the developments in world capitalism in the period 1900–1916, where his concept of imperialism as a form
of monopoly capitalism was an innovation; and lastly as a Marxist policy maker during the period 1917–23.

The development of capitalism in Russia

Lenin's book of this title published in 1898 is a substantial piece of work which traces the growth of commercial relations and specialization in agriculture leading to an erosion of the traditional communal forms. On the industrial side, Russia's late arrival entailed an active role for the tsarist state in fostering industrialization and an influx of foreign capital to finance the development. This meant that Russia, although a newly industrializing country in the 1890s, had a larger proportion of its industrial labour force in large factories than older industrialized countries like Britain. Lenin saw these as predictable consequences of rapid capitalist growth which made any going back to pre-capitalist communal forms of village organization impossible. The growth of large factories also meant concentration of workers in a few places, facilitating their combination in trade union activities. These economic circumstances – the growth of commercial relations in the countryside and of concentrations of the urban proletariat – dictated for Lenin the political strategy of a socialist party which hoped to win power by mass organization. Lenin's theory of the development of the democratic political movement follows the economic stages quite closely. In this sense he can be said to have developed an economic framework for a Marxist political theory. The Development of Capitalism in Russia is even to this day the only comprehensive economic history of a country from a Marxist perspective.

Imperialism, the highest stage of capitalism

In 1916, Lenin wrote his well-known economic pamphlet of this title. The background was provided by the First World War, which had broken out two years previously with enthusiastic participation by the working people of various combatant nations and the connivance of the socialist parties. The ‘betrayal’ by the workers and their political leaders was one factor in Lenin's urge to explain these events. The second urge was perhaps provided by a desire to integrate the facts of a war into a Marxist theory of the long-run development and eventual breakdown of capitalism. Marx had predicted a tendency for the rate of profit to fall as capitalist development proceeded. Among the forces which may counteract this tendency was an increasing concentration in industry and the emergence of larger industrial units. In 1907, Hilferding in his Finance Capital had provided a theory and empirical evidence for the increasing integration of bank finance and industrial capital. The formation of trusts and cartels was helped by banks willing to finance mergers and controlling and interlocking equity holdings. Marxist economists saw the 20th century as entering a monopoly phase of capitalism in contrast to the competitive phase that Marx had written about.

Lenin's achievement is to add to the Marx–Hilferding account an international economic and political element. One part of his theory came from Hobson's Imperialism. As an underconsumptionist, Hobson linked the fight over African and Asian territory in the last decades of the 19th century among European nations to the search for outlets for surplus which could not be sold at home. Hobson took the view that this imperial search was irrational. Lenin, as a Marxist, saw the irrationality as a systematic functional element in a world of monopoly capital economies each of which was trying to stave off the falling rate of profit by exporting. The battle for markets could not however take place in a politically neutral
context as envisaged by competitive economic theory. Large cartels and monopolies gave a few leading bankers and industrialists influence with the political governments of their country. The battle for markets thus became a struggle between developed capitalist nations for territory. It was the struggle for territory as a surrogate for markets which led to military confrontation between the major industrial nations and hence war. War was not however predicted to be a satisfactory solution to the problem of markets or of profitability. It was likely in Lenin's view to be the harbinger of proletarian uprising against the system in these countries which would end it.
Thus Lenin blends international political developments into a Marxian theory of capitalist development. Imperialism in Lenin's definition is the entire set of unequal economic relations between capitalist countries – between rival mature capitalist countries fighting for markets as well as between mature countries and developing economies which become their markets. Formal political control by one nation over another is not a necessary element in Lenin's view of imperialism. Although immensely influential in the interwar years due to Comintern orthodoxy, this theory has come under some attack recently (Warren, 1980). It lacks a coherent analytical theory of how monopoly capital differs from competitive capitalism and its empirical predictions proved only temporarily true when a series of political uprisings took place in Europe after the First World War. These uprisings did not mature into a full-scale collapse of capitalism, which continues many decades after Lenin foresaw its highest phase as having been achieved.

Socialist economic policy

As the first Marxist to lead a government, Lenin had to formulate practical economic policy. Given the notorious lack of discussion of socialist economic policy in Marx's writings, Lenin had to improvise. Two notions stand out as his distinctive contribution to this area. First, in his description of the post-revolutionary Russia as a transitional state from capitalism to socialism. During this transition, state capitalism was seen by Lenin as an advance upon private capitalism in as much as the political state was not a capitalist one but a workers’ state. Lenin used the wartime German economic organization as the ideal of a fully integrated single economic unit which a planned socialist economy could beneficially emulate. Second, in the return to normality after the Civil War – in his pamphlet ‘The Tax in Kind’ – Lenin sketched a theory for the role of trade in reviving economic activity. The key was to move from a forced requisition of food surpluses to a policy of tax in kind and encouraging exchange. A revival of agriculture was required for an industrial revival but the terms of trade between the two sectors was a crucial policy variable in this respect. Trade is seen as an antidote to economic bureaucracy in this pamphlet. It was this pamphlet that inaugurated the New Economic Policy which could be said to have lasted from 1921 to 1929.

Leontief paradox

Edward E. Leamer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Using 1947 US input–output tables and data on exports and imports, Leontief (1953) found, to the
surprise of the profession, that the capital per worker of US exports was less than the capital per worker
of US import substitutes. The response to this empirical ‘paradox’ was the formulation of theory that
might explain why a capital abundant country had labour-intensive exports. These were the first
(confused) steps in an ongoing process of making the theory and data conform sufficiently to enable us
comfortably to claim to understand the basis for international trade.

Keywords

factor content of trade; factor mobility; Heckscher–Ohlin–Samuelson trade model; Leontief paradox

Article

The Heckscher–Ohlin–Samuelson (HOS) model of international trade with two factors of production
and two commodities implies that a country will export the commodity that is produced intensively with
the relatively abundant factor. Leontief (1953) discovered, to the surprise of the profession, that 1947
US exports were more labour-intensive than US imports in the sense that the capital per man required to
produce a $1 million of exports was less than the capital per man required to produce a $1 million in
import substitutes. This seemed to conflict sharply with the presupposition that the USA was abundant
in capital compared with labour. Leontief’s finding was so startling that it has been called a ‘paradox’,
even though the result amounted to at most a single contradiction of the theory and even though no
alternative model could be said to conform better with the facts.

Leontief’s finding preceded and apparently stimulated a search of great breadth and intensity for a new
theory of trade that could account for his result. It is in fact difficult to find another empirical result that
has had as great an impact on the intellectual development of the discipline. Among the explanations of
the finding are: (a) high productivity of US workers; (b) capital-biased consumption; (c) factor-intensity
The Leontief paradox refers to the apparent contradiction that the factor content of US trade revealed the United States to be scarce in capital compared with labour, though a clear theory of the factor content of trade was not laid out until Vanek (1968).

Vanek's model of the factor content of trade was first used in an overlooked article by Williams (1970) to criticize Leontief's inference. The very simple theoretical foundation for the Leontief calculation was clearly laid out in Leamer (1980), which shows that Leontief's data in fact reveal the United States to have been abundant in capital compared with labour.

Theoretical relationships that can serve as a foundation for studying the relative factor abundance revealed by international trade are the Heckscher–Ohlin–Vanek equations. These equations are derived from the simple identity that net exports of the services of a factor f are the difference between home supply and home demand:

\[ T_f = X_f - M_f = S_f - D_f, \]

where \( T_f \) is the amount of factor \( f \) embodied in net exports, \( X_f \) is the amount of factor \( f \) required to produce the exported commodities, \( M_f \) is the amount required to produce the imported commodities, \( S_f \) is the domestic supply and \( D_f \) is the domestic demand.

This identity is given empirical content by assuming identical homothetic tastes which implies that domestic demand for factor \( f \) is proportional to world supply:

\[ D_f = sW_f, \]

where \( W_f \) is the world supply and \( s \) is the country's share of world consumption. With the use of this assumption, the net export equation can be written as

\[ \frac{T_f}{S_f} = 1 - s \left( \frac{W_f}{S_f} \right). \]

In words, net exports as a share of domestic supply is positively related to factor abundance defined as the share of the world's total supply \( S_f / W_f \). Accordingly, the relative scarcity of the factors is revealed by the ordering of the net export ratios \( T_f / S_f \). Leamer (1980) shows that, although the net export of both capital and labour services were positive in 1947, the share of domestic supply of capital that was exported exceeded the share of labour exported, and consequently the United States was revealed by trade to be relatively abundant in capital compared with labour. In addition, Leamer (1980) shows that Leontief's finding that the exports were more capital intensive than imports is compatible with either ordering of factor abundance.

This fully resolves the apparent paradoxical ordering of capital and labour abundance, but a new problem arises. Brecher and Choudhri (1982) note that, if net exports are positive, the overall consumption share \( s \) must be less than the abundance ratio \( S_f / W_f \). If trade is balanced, the consumption share is the ratio of home to world GNP, \( s = GNP / GNP_w \). The inequality

\[ S_f / W_f > s = GNP / GNP_w, \]

can be rewritten as

\[ GNP_w / W_f > GNP / S_f. \]

Thus the United States is revealed by its positive net exports of labour services embodied in commodities to have had a per-capita GNP that is less than the rest of the world. Even after adjusting for the trade surplus, this is impossible to
square with the facts. Another way of expressing this new paradox is that the positive export of labour services reveals that labour is abundant compared with other resources on the average since the consumption share \( s \) is an average of the abundance ratios.

It is ironic that this is one of the few empirical findings that can be said to have had a decided impact on the course of the profession and at the same time is based on a simple conceptual misunderstanding. The error that is implicit in Leontief's paradox is the use of an intuitive but false theorem which states that the ordering of capital per man in exports compared with imports reveals the relative abundance of capital and labour. This is true for the simple two-good model, but it is not the case for a multi-commodity reality. There is a lesson to be learned from this experience. Empirical work requires a fully articulated theoretical foundation. Intuition alone is not enough.

Although the precise form that Leontief's calculations took is inappropriate, the calculation of flows of factor services embodied in trade remains an interesting activity since these flows can be used to form a proper test of the Heckscher–Ohlin–Samuelson theorem and since the net effect of trade on the demand for factors of production can be an important input into trade policy that is intended to affect the distribution of income.

As it turns out, measurements of 1967 factor contents of trade reported in Bowen, Leamer and Sveikauskas (1987) rather badly violate the HOS model, thus reinvigorating the message of the Leontief paradox: there is something wrong with this model. One thing that is wrong is emphasized by Trefler's (1995) title: ‘The Case of the Missing Trade’. Given the world's apparent unequal geographic distribution of capital, labour and land, the HOS model suggests that there should be much more trade than actually occurs. Trefler's solution to this puzzle is to allow in the model both home bias in consumption and also international productivity differences (for example, the United States is not so labour-scarce when allowance is made for the intensity of work). Also, Conway (2002) finds problems with the measurement of factor scarcity and calls for the model to include factor-specific differences in domestic factor mobility. It seems likely that we have not seen the end of the search for a model that most fully explains the nature of international trade.

Wassily Leontief was born on 5 August 1906 in St Petersburg, the only child of an academic family. He studied first at the University of Leningrad, earning the degree of ‘Learned Economist’ in 1925, and then at the University of Berlin (Ph.D., 1928). While working on his doctorate, he was appointed a research economist at the University of Kiel, where he remained for about three years, with a year out to serve as adviser to the Chinese Ministry of Railways in Nanking.

In 1931 he went to the United States to join the staff of the National Bureau of Economic Research, but after only a few months accepted an appointment at Harvard University, where he remained for the following 44 years. During those years he attained worldwide eminence, particularly for the invention and application of input–output analysis. Prominent among the honours he received during those years were election as President of the American Economic Association in 1970 and the Nobel Memorial Prize in Economics in 1973. In 1975 he accepted a chair at New York University, where he spent the remainder of his career.

Leontief had an exceptionally strong training in mathematics and a marked flair for mathematical and geometric reasoning. These qualities were displayed in his earliest papers, in the late 1920s and early 1930s, in which he applied his technical talents to a variety of topics including the estimation of elasticities of supply and demand, the measurement of industrial concentration, the use of indifference maps at a time when they were still novelties to explain patterns of international trade in a two-commodity, two-country model, analysis of the conditions under which cobweb cycles would converge or would expand explosively, and several others. These papers established his reputation as an economic theorist of first rank.

During this same period, he struck a theme that he was to emphasize repeatedly throughout his career: the thesis that economic concepts were meaningless and misleading unless they could be observed and
measured. Thus, in 1936 he studied the significance of index numbers that purported to measure composite concepts such as the aggregate output of an economy or the general price level, and the following year published his famous diatribe against ‘implicit theorizing’, that is, explaining phenomena by introducing ill-defined concepts (the economist’s version of Molière’s doctor who attributed the effect of sleeping potions to their dormative propensities). Eleven years later, he returned to the measurement of aggregates much more profoundly and fruitfully in his ‘Introduction to a Theory of the Internal Structure of Functional Relationships’, which developed the mathematical conditions in which a single aggregate or index could replace a mass of detailed data without loss of information. And much later he devoted his presidential address to the American Economic Association to decrying ‘Theoretical Assumptions and Nonobserved Facts’ (1971).

These two characteristics – adroitness at mathematical expression and analysis and insistence that theoretical concepts be implementable – congealed in Leontief’s major achievement, the invention, development, and application of input–output analysis. As a purely theoretical construct, input–output analysis had a long genealogy before Leontief began his work on it, around 1933. In the 18th century, François Quesnay used his *Tableau économique* to illustrate the relationships between agriculture and other sectors of the economy. A hundred years later, Marx demonstrated the relationships between the capital-goods and consumers’ goods departments of an economy by a very similar two-sector table. The most important predecessor, however, was Walras’s formulation of the general equilibrium of an economy, which employed a concept that is very similar to Leontief’s input–output coefficients. In addition, as Leontief discovered after input–output analysis was well known, H.E. Bray had published essentially the same equations in 1922, and R. Remak had discovered them again in 1929.

The algebraic theory of input–output analysis had been explored by a number of late 19th-century algebraists, particularly by E. Frobenius and O. Perron, for whom the basic theorems have come to be named. All of these preceding theories expressed fundamental, abstract theoretical concepts; none could be used to specify the relationships among the sectors of an actual economy.

But throughout his career, Leontief has insisted that the task of a theorist only begins with the proposal of a well-formulated theory; the central task is to show that the theory can be applied to real economies, that it leads to interesting predictions about the behaviour of those economies, and that those predictions can be checked and found to be reasonably accurate. This radically operational point of view led Leontief to his critical contribution: the perception that the coefficients that express the relationships among the sectors of an economy can be estimated statistically, and that they are sufficiently stable so that they can be used in comparative static analyses to give quantitative estimates of the effects of different economic policies, taking into account their reverberations throughout the economy along with their effects on the industries affected in the first instance.

It is almost impossible now to appreciate the task of confirming these conjectures in the early 1930s. Input–output computations depend on inverting large matrices; the most powerful computing machines in existence then were punch-card machines that could multiply, after a fashion, but could not divide. Solving a half-dozen simultaneous linear equations was a formidable calculation; Leontief envisaged systems that numbered in the hundreds.

Input–output analysis also required data of an unfamiliar type – coefficients specifying the amounts of various raw materials and intermediate goods required per unit of product in each sector. The US Census of Manufactures included many of these coefficients, but by no means all. The remainder had to be compiled laboriously from trade journals and scattered sources.
Furthermore, the underlying assumption of the method, that the input–output coefficients remained essentially constant for substantial periods, was hard to reconcile with one of the main tenets of the theory of production – that factors of production were substituted for one another quite sensitively in response to price changes.

Beginning around 1933–4, Leontief concentrated on overcoming these difficulties by compiling coefficients for a 44-sector input–output table – about 2,000 coefficients – and making plans for their analysis. Since the solution of 44 simultaneous equations was far beyond the realm of the possible, the 44 sectors were consolidated into a scant ten for computational purposes. To check on the stability of the coefficients, tables were to be compiled for 1919 and 1929. The first result of this study, ‘Quantitative Input and Output Relations in the Economic System of the United States’, appeared in 1936. Its centrepiece was a 41-sector input–output table for the United States in 1919, presenting the intersectoral flow coefficients along with sources and methods of estimation. The next year, Leontief published ‘Interrelation of Prices, Output, Savings and Investment’. In the interim, he had made contact with Professor John B. Wilbur of the Massachusetts Institute of Technology, who had just invented an analog computer that could solve systems of up to nine linear equations. Accordingly, Leontief aggregated his 41-sector table into ten sectors and used Wilbur’s computer to calculate the inverse. This was the first Leontief-inverse ever computed, and probably the first use of a large computer in economics or other social science.

By 1941, a parallel 41-sector table had been compiled for 1929 and the inverse of a ten-sector aggregation of it had been computed. The two tables were presented and compared in Leontief's first monograph, *The Structure of American Economy, 1919–1929*. The comparisons were intended to test whether the input coefficients were stable enough to yield useful empirical predictions. The comparisons were indecisive, in part for lack of a clear standard for judging the stability of the estimated coefficients. The monograph did establish, however, that it was feasible to compile the raw data needed for an input–output table and to compute coefficients and an inverse table that appeared to make good economic sense. The importance of such tables for economic planning was recognized almost immediately. Within a few years, the US Bureau of Labour Statistics, with Leontief as a consultant, constructed a 400-sector table for projecting post-war employment by major industries, and the method was being applied all over the world for constructing economic development plans.

Leontief remained in the forefront of these developments. By 1944 he had calculated a table of input coefficients for 1939, comparable with the earlier two tables, and found a satisfactory degree of stability for most of the coefficients extending over two decades. Using this up-to-date table, he published a sequence of three important papers in the *Quarterly Journal of Economics* for 1944 and 1946 exemplifying the use of input–output analysis for estimating the effects of exogenous disturbances on output, employment, wages, and prices in individual sectors.

In 1948, Leontief established the Harvard Economic Research Project as a centre for applying and extending input–output analysis. He became director of the Project, and headed it for the next 25 years. He was particularly active in developing interregional input–output analysis and in introducing capital–coefficient matrices to derive the investment implications of changes in final demand and, thereby, to use input–output analysis to generate growth paths as well as static equilibriums of economic systems. This work led to two books, *The Structure of American Economy 1919–1939*, in 1951, and *Studies in the Structure of the American Economy*, in 1953, as well as several international conferences and a score of papers and articles. Probably the most striking discovery of this period of work has come to be called
‘the Leontief paradox’, the finding that, when indirect as well as direct input requirements are taken into account, American exports are more labour-intensive and less capital-intensive than American imports, although the United States is exceptionally well endowed with capital and has exceptionally high real wages.

Leontief and the staff of the Harvard Economic Research Project devised and implemented numerous other applications of input–output analysis. They included estimates of the inflationary impact of wage settlements, calculations of the direct and indirect effects of armament expenditures on the individual sectors of the economy, and methods for projecting the growth-paths of the sectors in a developing economy and for estimating capital requirements for economic development.

In the middle 1970s, Leontief became persuaded that, while competitive markets might guide an economy to a socially efficient equilibrium if given sufficient time, the process would be likely to be very protracted and unduly wasteful of mistakenly invested resources. Economic growth and efficient adjustments would be promoted better by establishing an economic planning board that would work out a number of detailed growth possibilities based on input–output analyses. The ultimate choice among these possibilities would be made by a political process. He advocated this type of indicative planning in a number of articles in *The New York Review of Books*, the *New York Times* ‘op-ed page’, and other general interest periodicals.

Leontief subsequently turned to the problems of worldwide economic growth, its environmental impact, its demands on the world's base of natural resources, and particularly on its implications for relations between the economies of the so-called First and Third Worlds. Under the sponsorship of the United Nations, he directed a study of the evolution of the world economy until the year 2000, based on a multiregional input–output model consisting of 15 regions, each comprised of 45 sectors, and linked by balanced trading relationships. This is, perhaps, the most ambitious input–output study yet undertaken. The results were published as *The Future of the World Economy* (1977). It found that, under a wide range of plausible assumptions, little progress would be made in closing the gap between the industrial and the developing regions unless current policies concerning international trade and finance were changed drastically in the directions of increased multinational aid and an increased flow of imports from the Third World to the First.

Leontief was a leader in improving the computational methods of economics, beginning with his use of Wilbur's analog equation solver in 1936. Subsequently he inverted input–output matrices on Howard Aiken's early Mark I and Mark II computers, the immediate predecessors of the electronic computer. In the 1980s the very large matrices required by his world economic models led him to be the first economist to use the so-called supercomputers and to apply parallel-processors and other highly efficient methods of computation.

Throughout his career, Leontief took an active interest in the education of the next generation of scholars. While at Harvard he served for 11 years as chairman of the Society of Fellows, the foundation that provides three-year, duty-free fellowships to promising young scholars, to enable them to reside at Harvard and pursue whatever interests they choose. He delighted in presiding over the weekly dinner meetings of the Society and leading conversations that range over all the fields of interest represented at the table.

Article

Lerner was one of the last of the great non-mathematical economists and certainly one of the most original, versatile and prolific members of the profession. Born in Rumania, raised from early childhood in the Jewish immigrant quarter of London's East End, he went to rabbinical school, started work at 16, working as tailor, capmaker, Hebrew School teacher, typesetter, and then founded his own printing shop. When that went bankrupt at the onset of the Great Depression, he enrolled as an evening student at the London School of Economics to find out the reason for his shop's failure. There, his outstanding logical faculties soon became evident and won him all the available prizes and fellowships, one of which took him to Cambridge to study with Keynes. He published many major articles already as an undergraduate, was appointed temporary assistant lecturer at the London School of Economics in 1935, assistant lecturer in 1936, and in 1937 a Rockefeller fellowship took him to the United States, where he remained, although his restlessness kept him from settling at any one university for more than a few years.

Lerner was a lifelong socialist, advocate of market pricing for its allocative efficiency, and believer in private enterprise, whose offer of private employment he considered an essential safeguard of individual freedom. That unusual combination of principles accounts for Lerner's loneliness and political isolation. In his economics, however, he knew how to reconcile those principles. His reconciliation of the first two made him into one of the founders (along with Oskar Lange) of the theory of market pricing in the
decentralized socialist economy, and he sought to reconcile the first and third principles by advocating what he called socialist free enterprise: ‘the freedom of both public and private enterprise to enter any industry on fair terms which, in each particular case, permit that form to prevail which serves the public best.’
Although Lerner's ambition was to improve the economy, not economics, he made many, often fundamental contributions to economic theory, mainly in the fields of welfare economics, international trade and macroeconomics but also in the theories of production, capital, monopoly, duopoly, spatial competition and index numbers. Furthermore, and hardly less important, he made generous use of his geometrical skill and genius for exposition in tidying up and clarifying other people's ideas. As a result, a number of important economic theorems and ideas, though first stated by others, became the profession's common property in Lerner's simpler and clearer formulations. An important example of that is the well-known rule that marginal cost pricing is a condition of welfare optimality. Another example is his definitive proof (Lerner, 1936a) that in the two-country, two-commodity model, export and import duties have identical consequences if their proceeds are spent in the same way.
In welfare economics, one of his first articles (Lerner, 1934a) not only introduced the notion that monopoly is a matter of degree, whose extent is best measured by the excess of price over marginal cost, but in the process also provided the first complete, comprehensive and clear statement and discussion of the nature and limitations of Pareto optimality, and of the equality between price and marginal cost and between price and marginal value product as necessary conditions of optimality. All that, along with Lerner's many papers on market pricing under socialism, was restated, elaborated and extended in his 1944 The Economics of Control: Principles of Welfare Economics.
That work, Lerner's best book, became and remains the most comprehensive non-mathematical text on welfare economics. Although written in the style of a handbook, with its propositions presented as rules for the planners and plant managers of a decentralized socialist economy to follow, the book is better described by the second than by the first half of its title. For most of those rules are nothing but the first-order conditions of optimality, presented with great care, clarity and completeness but without a hint at the practical obstacles in the way of putting them into actual practice. As a text on welfare economics, however, it is exceptionally meticulous and complete, it extends the scope of the welfare principle from resource allocation narrowly defined to taxation, macroeconomics and international trade and finance, and it contains the first logically based analysis of distributional optimality. Moreover, since a socialist economy, for Lerner, meant the use of private enterprise in some sectors, state-owned plants in others, depending on which was the more efficient in each, his guidebook for socialist planners also discusses why and when perfect competition leads to optimality and why and when real-life competition falls short of being perfect.
In the field of international trade theory, Lerner derived Samuelson's celebrated factor-price equalization theorem 15 years before Samuelson in a 1933 unpublished seminar paper printed only 19 years later (Lerner, 1952a). His elegant and ingenious resolution of a 19th-century controversy over the identity of import and export duties has already been mentioned; he devised (Lerner, 1932; 1934b) the standard geometry of the two-country, two-commodity model, which is well known from a whole generation of textbooks; and he was the first to raise and deal with the question of ‘optimum currency areas’ in his 1944 Economics of Control.
Most of Lerner's innovations in microeconomics and international trade theory were so basic and so useful that they promptly became integral parts of every economist's standard equipment. That is why it
is hard to appreciate, at this late stage, the striking originality and elegant simplicity of his logic. One gets a glimpse of that by looking at his almost unknown proposal of how to counter OPEC's raising of the price of oil (Lerner, 1980a). He proposed the imposition of a variable import duty on oil (which he called extortion tax), whose level would always match the producer's profit margin, thereby rising and falling with the oil price and being higher on imports from high-priced and lower on those from low-priced producers. Since such a tariff would make consumers face much larger price changes than those decided upon by OPEC and much greater price differentials than those set by the different oil exporters, it would also make consumers’ responses to those price changes and differentials correspondingly greater, thereby raising the price elasticity of demand for oil as it appears to producers. That would lower OPEC's monopoly power and so its profit maximizing monopoly price, and it would increase the rewards and the temptation for OPEC members to break up the coalition by defecting from it.

In macroeconomics, Lerner did as much as anyone to clarify, extend and popularize Keynes's *General Theory*; he was the first to recognize the inflationary implications of employment policies, the first to analyse in depth and in detail the causes and nature of inflation, and to propose a remedy for stagflation. Lerner wrote the first article (1936b) to make Keynes's employment theory simple and generally intelligible, and in two short papers clarified Keynes's ‘user cost’ and ‘marginal efficiency of capital’ concepts (1943b; 1953). He wrote an interesting book (1951) to summarize and significantly extend Keynes's employment theory; he published an enlightening paper to explain the *General Theory* 's obscure Chapter 17 (1952b), thereby clearing up the complex role wage rigidity plays in rendering underemployment equilibrium possible; and he was the person best to elucidate the relation between macroeconomics and microeconomics by representing them as the two limiting cases of a more general type of economic analysis (1962).

Next to his work on welfare economics and international trade theory, Lerner's best known and most shockingly new contribution was his introduction of the idea of ‘functional finance’ (1943a; also restated in 1951, and in his 1944 *Economics of Control*), whose advocacy of Keynesian employment policies exposed the latter's logical implications and revolutionary nature. To careless readers, it also seemed like a wildly inflationary doctrine, although Lerner's concern over inflation and over the inflation effects of employment policies antedate everybody else's by many years.

Lerner's extensive work on inflation began with his distinguishing between low and high full employment (Lerner, 1951). High full employment is that beyond which further demand expansion presses against supply limitations and creates overspending (demand-pull) inflation; low full employment is the employment level below which the price level is stable. Levels of employment between the low and high full-employment levels create administered (cost-push) inflation, owing to labour's excessive bargaining strength. His ‘low full employment’ therefore is a forerunner (by 17 years) of Friedman's ‘natural rate of unemployment’.

Lerner's theoretical papers on inflation contain many pioneering insights. One is his sharp analytic distinction between overspending or excess-demand inflation and administered or excess-claims inflation (1958; 1972), of which the former does, but the latter (according to him) does not, call for fiscal and/or monetary restraint. He later added a third category, expectational inflation (1972), which he also called defensive inflation to differentiate it from the aggressive nature of excess-claims inflation – arguing that incomes policy is effective against the former but ineffective against the latter. Another and well-known distinction which Lerner was the first to draw was that between expected and unexpected inflation (1949).
Since Lerner's heart was in reform, not in analytic niceties, his many discussions of inflation were just a preamble for working out a plan to control the main economic problem of his time, stagflation, that is, the combination of unemployment and inflation, which he considered characteristic of administered or excess-claims inflation. Restrictive policies were to him an inadmissible cure for that type of inflation, because he considered the creation of unemployment a prohibitive cost. Incomes policies he judged ineffective against all but expectational inflation, and he was too ardent a believer in the pricing mechanism to argue for wage and price controls. He wanted to stabilize the general price level without impeding the free movement of individual prices and wages. To accomplish that, he devised and, with David Colander's help, worked out in detail a scheme, called Market Anti-Inflation Plan, better known as MAP (1980b), for rationing the right of firms to raise the ‘effective price’ of their output, that is, the sum of profits and wages entering the price of their products (value added). The scheme would give every firm the right to increase its value added in the proportion of the estimated rise in the economy's overall productivity, but it would also allow them to sell their unused rights or the unused portion of their rights (in a market created for the purpose) to those other firms that want to increase their wages and/or profits (value added) in greater proportion.

Lerner developed his Market Anti-Inflation Plan gradually and published it at several stages and in several versions before it reached its final form in 1980. It was his last major contribution to economics and a fitting end to his career, because it well illustrates both the strengths and the weaknesses of his extraordinarily fertile and original mind. It is bold, elegant, ingenious and impeccably logical, with meticulous attention to every conceivable detail and exception, but combines those qualities with a slightly utopian flavour, all of which have characterized just about all of Lerner's many proposals for reform.

For the sheer novelty and stark logic of Lerner's arguments and policy proposals usually took people aback, but he was utterly unwilling and perhaps also unable to soften their impact in the interests of their easier acceptability. He was well aware of the reasons for the hostile reception of virtually all his recommendations but believed, with some justification, that, as time wore off their shocking novelty, they would become more acceptable and politically feasible. Lerner's MAP could well be the best remedy for stagflation but many less good remedies will first have to be tried and prove ineffective in order to render MAP politically acceptable.

Article

French economist and journalist, Leroy-Beaulieu was born at Paris in 1843; he died there in 1916. His father was a Prefect and a Deputy under Louis-Philippe, his older brother a famous historian and a director of the Ecole des Sciences Politiques. His son Pierre, with whom he is sometimes confused, was also an economist. Initially trained in law, Paul Leroy-Beaulieu turned to economics in his early twenties, launching this new career with a prize-winning essay in 1867 on the effects of the moral and intellectual conditions of the working class on the rate of wages. Soon thereafter, he began collaborating on the Revue des deux mondes, and in 1871 he became editor of the Journal des débats. Two years later he founded the Economiste française, for which, as editor, he wrote weekly articles, missing only once in 43 years.

When Emile Boutmy established the Ecole Libre des Sciences Politiques in 1872, Leroy-Beaulieu accepted the chair of public finance. He later succeeded his father-in-law, Michel Chevalier, in the chair of political economy at the Collège de France. His ideas found wide exposure in countless journal articles and over a dozen books. A member of the French Institute and of the American Philosophical Society, he also received honorary degrees from the universities of Cambridge, Edinburgh, Dublin and Bologna.

Leroy-Beaulieu belonged to the French Liberal School of individualism and free trade. His major work, the Traité théorique et pratique d’économie politique (1896) is largely an exposition of classical theory. However, he rejected the pessimistic conclusions of Ricardo and Malthus, having argued in his Essai sur la répartition des richesses (1881) that there was no factual basis to either the Ricardian theory of rent or the ‘iron law of wages’. Moreover, he sought to defuse the population bomb by arguing that the progress of civilization must always bring a declining birth rate because the altered demands and increased expenditures that accompany it are incompatible with the duties and responsibilities of parentage. In value theory, he followed the marginal analysis of the Austrians. Even as Walras was proselytizing on
its behalf, however, Leroy-Beaulieu reviled the mathematical method as ‘pure delusion and a hollow mockery … [without] scientific foundation and … practical use’. Showing equally poor judgement, he rejected the demand curve on frivolous grounds.

Leroy-Beaulieu’s most enduring work was his treatise on public finance (1877), an effort that examines both public revenues and public credit. The second volume of this work rose somewhat above the first, remaining authoritative well into the 20th century.

Abstract

Level accounting (more recently known as development accounting) consists of a set of calculations whose purpose is to find the relative contributions of differences in inputs and differences in the efficiency with which inputs are used to cross-country differences in GDP. It is therefore the cross-country analogue of growth accounting.

Keywords

development accounting; growth accounting; level accounting; technical change; total factor productivity

Article

Suppose that country A is observed to produce more output than country B: is this because it employs a larger amount of labour, a larger amount of capital or a larger amount of some other input? Or because it somehow succeeds (or endeavours) to make more effective use of given inputs? Level accounting refers to a particular approach to attacking these questions. In this approach, one computes indices of the quantities of each input participating in production in different countries, as well as the shares of each input in total income. The contribution of inputs (or of a subset of the inputs) to differences in output is then given by a geometric average of the inputs, with the shares acting as weights. The difference between the cross-country difference in output and the cross-country differences in inputs, a residual, is interpreted as a cross-country difference in the efficiency with which the inputs are employed, or in total factor productivity (TFP). Level accounting is therefore the cross-country analogue of growth accounting.

The earliest level-accounting exercises are a five-country study by Denison (1967) and a two-country comparison by Walters (1968). In the late 1970s Jorgenson and Nishimizu (1978) and Christensen, Cummings, and Jorgenson (1981) adapted the growth-accounting framework of Jorgenson’s work with Griliches and Christensen to level comparisons between the United States and eight other advanced
level accounting: The New Palgrave Dictionary of Economics

They found substantial TFP differences. More recently, level accounting has been a popular technique in addressing the sources of the enormous differences in income observed between the richest and poorest economies of the world (King and Levine, 1994; Klenow and Rodriguez-Clare, 1997; Hall and Jones, 1999). This trend has caused several authors to begin referring to it as ‘development accounting’. While details vary, a consensus emerging from the development-accounting literature is that observed inputs of labour and capital account for at best 50 per cent of the observed variation in aggregate value added across a large sample (numbering about 100) of developed and developing countries. It is often argued that this evidence points to the need for developing countries to underemphasize saving and investment, and emphasize technical change and technology adoption.

Unfortunately, residual variation in development accounting poses at least as many problems of interpretation as residual variation in growth accounting. The problems are compounded by the appalling coarseness of the data. Instead of accounting for compositional differences amongst a large number of education, gender, race, and age categories, as mandated by the Jorgensonian framework, development accountants to date have mostly had to limit themselves to a rough correction for average years of schooling. Perhaps more importantly, instead of allowing for imperfect substitutability among different types of capital, again as prescribed by best accounting practice, measures of the capital stock are based on linear aggregation. Caselli and Wilson (2004) show that this could be a fatal flaw. Finally, most development-accounting exercises assume constant capital (and hence labour) shares across countries.

Creative improvements in the measurement of labour quality have recently been proposed by Weil (2007) and Jones and Schneider (2007). Weil proposes a way to account for differences in the productive capacity of the labour force caused by differences in health, while Jones and Schneider bring to bear cross-country differences in IQ. Both succeed in reducing residual variation considerably. These appear to be two (rare) instances where level accounting has introduced innovations that could potentially also be usefully incorporated into growth accounting, instead of the other way around.

Another recent extension of the development-accounting framework is due to Caselli and Coleman (2006), who show how to decompose the cross-country residual into differences in the efficiency with which different inputs are used. Caselli (2005) uses this technique to show that most differences in efficiency are differences in the efficiency with which labour is used. Caselli and Coleman (2006) further trace these differences to differences in the efficiency of skilled labour.

Cross-country level accounting can also be performed at the industry level, and indeed this seems a necessary step towards shedding light on the sources of large residual variation at the aggregate level. Conrad and Jorgenson (1985), and Jorgenson, Kuroda and Nishimizu (1987) presented industry-level productivity comparisons for the United States, Japan, and Germany. Despite the richness of their data they found surprisingly large TFP differences. The more recent development-accounting literature has only attempted an agriculture–nonagriculture decomposition. The most convincing effort to date is possibly due to Vollrath (2006), who appears to be able to eliminate a significant amount of residual variation in aggregate GDP by accounting for the allocation of factors across these two sectors.

Abstract

This article provides an outline of the career and contributions of W. Arthur Lewis, who was awarded the Nobel Prize for Economics in 1982. Born in 1915 on the Caribbean island of St Lucia, Lewis began his career at the London School of Economics before moving to Manchester University and then to Princeton University. While The Theory of Economic Growth (1955) and Growth and Fluctuations 1870–1913 (1978) have both been regarded as classics since they were first published, it is the 1954 article, ‘Economic Development with Unlimited Supplies of Labour’, that will probably remain as Lewis's most famous and influential single contribution.

development economics; dual economies; Lewis, W. A.; Nurkse, R.; periphery; surplus labour; terms of trade

Article

W. Arthur Lewis was born on the island of St Lucia in the British West Indies on 23 January 1915. His early education was at St Mary's College on the island, where he completed a rigorous high school curriculum by the age of 14. This school is remarkable for having been attended not only by Lewis but also, 15 years later, by St Lucia's other Nobel Laureate, the poet Derek Walcott. A scholarship took Lewis to the London School of Economics in 1933, where he obtained a BA in Commerce with first class honours in 1937 and then went on to do a Ph.D. under the supervision of Arnold Plant, who incidentally was also the supervisor of Ronald Coase. In 1938 he was appointed as a junior member of the faculty, the first black man to receive such a position in the history of the institution. His very active teaching at the LSE on a very broad range of subjects undoubtedly prepared him well for his future work on economic development. He moved to Manchester University in 1947, where he held the Stanley Jevons Chair, previously occupied by J.R. Hicks, and where he was himself to be succeeded by Harry Johnson. It was here that he did some of his most seminal work on development economics, the
Manchester School article on ‘Economic Development with Unlimited Supplies of Labor’ (1954) and the treatise on The Theory of Economic Growth (1955). In the 1950s he was a senior official in agencies of the United Nations, and was for a time Vice Chancellor of the University of the West Indies. He went to Princeton in 1963, where he remained until his retirement in 1983: just as at the LSE, he was the first person of African descent ever to be appointed to the faculty. He held many part-time advisory positions with international organizations and governments in developing countries, particularly in West Africa and the Caribbean. He was awarded the Nobel Prize for Economics in 1979, together with T.W. Schultz, for their contributions to economic development. He died at his summer home in Barbados on 15 June 1991.

His earliest original research, including his Ph.D. thesis, was on the application of price theory to problems of industrial organization and public utilities. A number of studies published during the 1940s, such as ‘The Two Part Tariff’ (1941), ‘Competition in Retailing’ (1945), ‘Fixed Costs’ (1946), and other related topics, were brought together in a volume entitled Overhead Costs, published in 1949. Two other books published in the same year, based on his LSE lectures, were Economic Survey 1919–1939 and Principles of Economic Planning. The first of these was an examination of the troubled economic history of the world economy in the interwar period, notable in particular for the way in which he linked together the experiences of the ‘core’ industrial countries with those of the primary producing ‘periphery’ of the world economy. The pessimism about the possibility of international trade to serve as a sustained ‘engine of growth’ for the developing countries, that has marked his subsequent writings on development economics down to his Nobel Prize Lecture in 1980 (entitled the ‘The Slowing Down of the Engine of Growth’), can perhaps be traced to his study of the inter-war period, an interesting parallel with the case of Ragnar Nurkse, who also came to the study of development problems after writing his International Currency Experience on the breakdown of the international monetary system in the 1930s. The book on planning, though written at an introductory level, was a penetrating early examination of the problems of coordinating government intervention and the market in a mixed economy.

Lewis’s most famous and influential contribution to economics is undoubtedly the 1954 paper on development with ‘unlimited supplies’ of labour. He presents a stylized model in which the typical poor country is divided into a ‘traditional’ and a ‘modern’ sector. The former consists of peasant agriculture as well as self-employment of various sorts in urban areas, where the primary objective of economic activity is to maintain consumption. The ‘modern’ sector comprises commercial farming, plantations and mines and manufacturing, in all of which there is hired labour and profit is the motive for production organized by a class of capitalists and entrepreneurs. Lewis adopts a strictly classical viewpoint on two crucial features of his model. First, the real wage of unskilled labour in the modern sector is exogenously given, with employment and profits then being determined by the demand for labour corresponding to the fixed stock of capital in the short run. The second classical feature is that the accumulation of capital is governed by saving out of profits. The process of economic development is viewed as the expansion of the modern relative to the traditional sector until such time as the ‘surplus labour’ pool in the traditional sector is drained and an integrated labour market emerges with a neoclassically determined equilibrium real wage, rising steadily over time as growth proceeds. The model as a whole thus has two distinct phases, an initial ‘classical’ one with a fixed real wage, that is the main focus of the analysis, and a subsequent ‘neoclassical’ one with a rising real wage. The concept of a ‘dual economy’ in the first phase of the model has generated considerable controversy and an extensive polemical literature, to which references can be found in Findlay (1980), together with an appraisal, extensions and critique of...
the model itself. The most sophisticated and thorough theoretical defence of the dual economy and the associated notion of ‘surplus labour’ remains that provided by Sen (1966). The Manchester School in 2004 appropriately marked the 50th anniversary of the most celebrated article it ever published by a special issue, which contains a valuable survey of subsequent developments by Kirkpatrick and Barrientos (2004).

Another notable, but much less well-known, contribution of this seminal (1954) paper, in a neglected section on the open economy, is a model of the terms of trade between manufactures and primary products that is developed further, with empirical applications, in his (1969) Wicksell Lectures. The key idea is that the world price of manufactures, relative to the prices of tropical products such as coffee, tea, sugar, rubber and jute, is determined by the relative opportunity costs of labour in food production. Thus the Pittsburgh steel worker's wage is governed by the Kansas farmer's productivity, while the Brazilian coffee plantation wage is determined by the much lower productivity of peasant subsistence agriculture, which explains why a unit of steel in the world market commands so many more units of coffee. Since the transformation curves between steel and food and coffee and food are assumed to be linear, demand only determines quantities produced, consumed and traded, not relative prices, exactly as in the approach of the classical economists. Lewis applied this model in a very imaginative way to illuminate several key aspects of the history of the world economy in his last major work, Growth and Fluctuations 1870–1913, published in (1978). This volume extended his examination of the world economy in the inter-war period in Economic Survey 1919–1939 back to the ‘golden age’ of globalization from 1870 to 1913, and is a deeply original piece of theoretical, statistical and historical research in the manner of Schumpeter and Kuznets. Both volumes are still essential reading for any serious student of the evolution of the world economy.

The reader can find an extensive collection of Lewis's articles and shorter monographs in the volume edited by Mark Gersovitz (1983). A measure of his influence on the field of development economics can be gathered from the volume of essays in his honour edited by Gersovitz and others (1982). Robert L. Tignor (2006) is a very valuable account of the life and inspiring achievements of this great pioneer of development economics, rightly drawing attention to the stoic courage and steely resolution with which he confronted and overcame the racial prejudice that was so virulent even in Western academic circles during his early career. The effect of these experiences may have made him appear to many as reserved, aloof and ‘prickly’ but to all who knew him well he was always kind, courteous and considerate, with a puckish sense of humour. The writer Pico Iyer (1997) described Derek Walcott, the other Nobel Laureate of St Lucia, as a ‘Tropical Classical’ because of the deep influence of Homer and other classical authors on his poetry. The designation fits Arthur Lewis admirably as well, and not only because of the influence of Ricardo and other classical authors on his economics.

Lexicographic orderings

C. Blackorby

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

interpersonal utility comparisons; lexicographic orderings; maximin; social choice

Article

Lexicographic orderings are orderings in which certain elements of the space being ordered have been selected for special treatment. I begin with an example. Suppose an agent has an ordering over commodities \( a \) and \( b \). Although he or she likes both \( a \) and \( b \), any bundle which has more of \( a \) is preferred to any bundle which has less of \( a \). Of course among bundles which have the same amount of \( a \), bundles with more \( b \) are preferred to those with less. Thus, there are no trade-offs between \( a \) and \( b \) and each indifference set is a single point. The name ‘lexicographic’ comes from the way words are ordered in a dictionary, alphabetically by the first letter and then the second and so on.

Lexicographic orderings were known chiefly as simple examples of orderings which could not be represented by a continuous real-valued function; see Debreu (1954) for the first discussion of this issue in economics. It is, however, in social choice theory and welfare economics where these orderings have come to prominence. To demonstrate their role a lexicographic maximin rule (leximin) follows. Let \( u = (u_1, \ldots, u_N) \) be an element of a Euclidean \( N \)-space where \( u_n \) is the utility of person \( n \). In each possible state of the world, say \( \bar{u}_1 = (\bar{u}_1, \ldots, \bar{u}_n) \), let \( r(\bar{u}) \) be the person who is the \( r \)th best off. For example, if \( N=3 \) and \( \bar{u} = (2, 7, 3) \) then \( 1(\bar{u}) = 2 \) as person 2 has the highest utility, \( 2(\bar{u}) = 3 \), and \( 3(\bar{u}) = 1 \); ties are broken arbitrarily. An ordering \( R \) is a leximin rule if and only if for all \( (u, \bar{u}), \bar{u} P \bar{u} \) if and only if there exists a \( k \), \( 1 \leq k \leq N \), such that \( \bar{u}_k(u) > \bar{u}_k(\bar{u}) \) and for all \( j > k \), \( \bar{u}_j(u) = \bar{u}_j(\bar{u}) \) where \( P \) is the strict preference relation, the asymmetric factor of \( R \). That is, if the worst-off \( N-k \) people have the same utility levels in \( \bar{u} \) and \( \bar{u} \) and the next worst-off person, \( k \), is better off in \( \bar{u} \) than in \( \bar{u} \), then \( \bar{u} \) is preferred to \( \bar{u} \). Continuing the numerical example above let \( \bar{u} = (2, 7, 2.5) \) so that \( 1(\bar{u}) = 2, 2(\bar{u}) = 3, \) and \( 3(\bar{u}) = 1 \). Then \( k = 2, \bar{u}_2(u) = 3 > \bar{u}_2(\bar{u}) \) and \( \bar{u}_3(u) = 2 = \bar{u}_3(\bar{u}) \) hence \( \bar{u} P \bar{u} \).

It is important to notice that if each person's utility function were subjected to the same increasing transformation the above ordering would not change. This is a case where utility is ordinally measurable.
but fully comparable as levels of utility can be compared across individuals. That the leximin rule satisfies all of the original axioms of Arrow (1951; 1963) except for the comparability of levels of utility was first worked out by D'Aspremont and Gevers (1977).

Other types of lexicographic orderings appear frequently in social choice theory; see Sen (1986, section 6).

liability for accidents

Steven Shavell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Legal liability for accidents determines the circumstances under which injurers must compensate victims for harm. The effects of liability on incentives to reduce risk, on risk-bearing and insurance (both direct coverage for victims and liability coverage for injurers), and on administrative expenses are considered. Liability is also compared with other methods of controlling harmful activities, notably, with regulation and corrective taxation.

Keywords

accident insurance; contributory negligence; corrective taxes; damages; due care; judgment-proof problem; liability for accidents; liability insurance; moral hazard; negligence rule; product liability; risk aversion; safety regulation; strict liability

Article

Legal liability for accidents governs the circumstances under which parties who cause harm to others must compensate them. There are two basic rules of liability. Under strict liability, an injurer must always pay a victim for harm due to an accident that he causes. Under the negligence rule, an injurer must pay for harm caused only when he is found negligent, that is, only when his level of care was less than a standard of care chosen by the courts, often referred to as due care. (There are various versions of these rules that depend on victims’ care, as will be discussed.) In fact, the negligence rule is the dominant form of liability; strict liability is reserved mainly for certain especially dangerous activities (such as the use of explosives). The amount that a liable injurer must pay a victim is known as damages. Our discussion of liability begins by examining how liability rules create incentives to reduce risk. The allocation of risk and insurance is next addressed, and, following that, the factor of administrative costs. Then a number of topics are reviewed. Comprehensive economic treatments of accident liability are presented in Landes and Posner (1987) and Shavell (1987); an early, insightful informal, economically
oriented treatment of liability is presented in Calabresi (1970). Empirical literature is surveyed in Kessler and Rubinfeld (2007) and is not considered here.

Incentives

In order to focus on liability and incentives to reduce risk, we assume in this section that parties are risk neutral. Further, we suppose that there are two classes of parties – injurers and victims – who do not have a contractual relationship. For example, injurers might be drivers and victims pedestrians, or injurers might be polluting firms and victims affected residents.

Unilateral accidents and the level of care

Here we suppose that injurers alone can reduce risk by choosing a level of care. Let $x$ be expenditures on care (or the money value of effort) and $p(x)$ be the probability of an accident that causes harm $h$, where $p$ is declining in $x$. Assume that the social objective is to minimize total expected costs, $x + p(x)h$, and let $x^*$ denote the optimal $x$.

Under strict liability, injurers pay damages equal to $h$ whenever an accident occurs, and they naturally bear the cost of care $x$. Thus, they minimize $x + p(x)h$, accordingly, they choose $x^*$.

Under the negligence rule, suppose that the due care level $\hat{x}$ is set equal to $x^*$, meaning that an injurer who causes harm will have to pay $h$ if $x < x^*$ but will not have to pay anything if $x \geq x^*$. Then the injurer will choose $x^*$: he will not choose $x > x^*$, for that will cost him more and he escapes liability by choosing merely $x^*$; he will not choose $x < x^*$, for then he will be liable (in which case the analysis of strict liability shows that he would not choose $x < x^*$).

Thus, under both forms of liability, injurers are led to take optimal care, as first shown in Brown (1973). Note that under the negligence rule courts need to be able to calculate optimal care $x^*$ and to observe actual care $x$, in addition to observing harm. Under strict liability courts need only to observe harm. It should also be noticed that, under the negligence rule with due care $\hat{x}$ equal to $x^*$, negligence is never found, because injurers are induced to be non-negligent. Findings of negligence may occur, however, under a variety of modifications of our assumptions. Courts might make errors in observing injurers’ care, so that an injurer whose true $x$ is at least $x^*$ might mistakenly be found negligent because his observed level of care is below $x^*$. Similarly, courts might err in calculating $x^*$ and thus might set due care $\hat{x}$ above $x^*$. If so, an injurer who chooses $x^*$ would be found negligent (even though care is accurately observed) because $\hat{x}$ exceeds $x^*$. As emphasized by Craswell and Calfee (1986), error in the negligence determination leads injurers to choose incorrect levels of care, and under some assumptions, to take excessive care in order to reduce the risk of being found negligent by mistake. Other explanations for findings of negligence are that individuals may not know $x^*$ and thus take too little care, the judgment-proof problem (see below), which may lead individuals to choose to be negligent, and the inability of individuals to control their behaviour perfectly at every moment or of firms to control their employees.

Bilateral accidents and levels of care

We now assume that victims also choose a level of care $y$, that the probability of an accident is $p(x,y)$ and is declining in both variables, that the social goal is to minimize $x + y + p(x,y)h$, and that the optimal levels of care $x^*$ and $y^*$ are positive.

Under strict liability, injurers’ incentives are optimal conditional on victims’ level of care, but victims have no incentive to take care because they are fully compensated for their losses. However, the usual strict liability rule that applies in bilateral situations is strict liability with a defense of *contributory negligence*, meaning that an injurer is liable for harm only if the victim’s level of care was not negligent, that is, his level of care was at least his due care level $\hat{y}$. If victims’ due care level is $y^*$, then it is a unique equilibrium for both injurers and victims to act optimally: victims choose $y^*$ in order to avoid having to bear their losses, and injurers choose $x^*$ since they will be liable because victims are non-negligent.

Under the negligence rule, optimal behaviour is also the unique equilibrium. Injurers choose $x^*$ to avoid being liable, and, since victims therefore bear their losses, they choose $y^*$. Two other variants of the negligence rule are negligence with the defence of contributory negligence (under which a negligent injurer is liable only if the victim is not negligent) and the comparative negligence rule (under which a negligent injurer is only partially liable if the victim is also negligent). These rules also induce optimal behaviour.

Thus, all of the negligence rules, and strict liability with the defence of contributory negligence, support optimal care, on the assumption due care levels are chosen optimally. Courts need to be able to calculate optimal care levels for at least one party under any of the rules, and in general this requires knowledge of the function $p(x,y)$. The main conclusions of this section were first proved by Brown (1973) (see also Diamond, 1974, for closely related results).

**Unilateral accidents, level of care, and level of activity**

Now let us reconsider unilateral accidents, allowing for injurers to choose their level of activity $z$, which is interpreted as the (continuously variable) number of times they engage in their activity (or, if injurers are firms, the scale of their output). Let $b(z)$ be the benefit from the activity, and assume the social object is to maximize $b(z) - z(x + p(x)h)$; here $x + p(x)h$ is assumed to be the cost of care and expected harm each time an injurer engages in his activity. Let $x^*$ and $z^*$ be optimal values. Note that, as before, $x^*$ minimizes $x + p(x)h$, and that $z^*$ satisfies $b'(z) = x^* + p(x^*)h$, the marginal benefit from the activity equals the marginal social cost, comprising the sum of the cost of optimal care and expected accident losses.

Under strict liability, injurers choose both the level of care and the level of activity optimally, as their objective is the social objective.

Under the negligence rule, injurers choose optimal care $x^*$ as before, but their activity is socially excessive. Because an injurer escapes liability by taking care of $x^*$, he chooses $z$ to maximize $b(z) - zx^*$, so that $z$ satisfies $b'(z) = x^*$. The injurer's cost of raising his activity level is only his cost of care $x^*$, which is less than the social cost, as that also includes $p(x^*)h$. The excessive level of activity under the negligence rule is more important the larger is the expected harm $p(x^*)h$ from the activity.
The failure of the negligence rule to control the level of activity arises because negligence is defined here (and for the most part in reality) in terms of care alone. A justification for this assumption is that courts might face informational difficulties were they to include the activity level in the definition of negligence. The problem with the activity level under the negligence rule is applicable to any aspect of behaviour that would be difficult to incorporate into the negligence standard (including, for example, research and development activity). The distinction between levels of care and levels of activity was developed in Shavell (1980).

Bilateral accidents, levels of care, and levels of activity

If we consider levels of care and of activity for both injurers and victims, then none of the liability rules that we have considered leads to full optimality (on the assumption that activity levels are unobservable). The reason that full optimality cannot be achieved is in essence that injurers must bear full accident losses to induce them to choose the right level of their activity, but this means that victims will not choose the optimal level of their activity.

Risk-bearing and insurance

We next examine the implications of risk aversion and the role of insurance in the liability system (see Shavell, 1982a). A number of general points may be made.

First, the socially optimal resolution of the accident problem now involves not only the reduction of losses from accidents but also the protection of risk-averse parties against risk. Risk bearing is relevant for two reasons: not only because potential victims may face the risk of accident losses, but also because potential injurers may face the risk of liability. The former risk can be mitigated through accident insurance, and the latter through liability insurance.

Second, the incentives associated with liability do not function in the direct way discussed in the previous section, but instead are mediated by the terms of insurance policies. To illustrate, consider strict liability in the unilateral accident model with care alone variable, and assume that insurance is sold at actuarially fair rates. If injurers are risk averse and liability insurers can observe their levels of care, injurers will purchase full liability insurance coverage and their premiums will depend on their level of care; their premiums will equal \( p(x)h \). Thus, injurers will want to minimize their costs of care plus premiums, or \( x + p(x)h \), so they will choose the optimal level of care \( x^* \). In this instance, liability insurance eliminates risk for injurers, and the situation reduces to the previously analysed risk-neutral case.

If, however, liability insurers cannot observe levels of care, ownership of full coverage could create severe moral hazard, so would not be purchased. Instead, as is known from the theory of insurance, the typical amount of coverage purchased will be partial, for that leaves injurers with an incentive to reduce risk. In this case, therefore, the liability rule results in some direct incentive to take care because injurers are left bearing some risk after their purchase of liability insurance, but their level of care tends to be less than first best.

This last situation, in which liability insurance dilutes incentives, leads to a third point, concerning the question whether the sale of liability insurance is socially desirable. (We note that, because of fears...
about incentives, the sale of liability insurance was delayed for decades in many countries and that it was not allowed in the Soviet Union; further, in the United States liability insurance is sometimes forbidden against certain types of liability, such as against punitive damages.) The answer to the question is that, even though it may dilute incentives, sale of liability insurance is socially desirable, at least in basic models of accidents and some variations of them. In the case just considered, for example, injurers are made better off by the presence of liability insurance, as they choose to purchase it, and victims are indifferent to its purchase by injurers because victims are fully compensated for any harm suffered. This argument must be modified in other cases, such as when the damages injurers pay are less than harm because injurers are judgment-proof.

Fourth, consider how the comparison between strict liability and the negligence rule is affected by risk bearing. The immediate effect of strict liability is to shift the risk of loss from victims to injurers, whereas the immediate effect of the negligence rule is to leave the risk on victims (as injurers tend to act non-negligently). However, the presence of insurance means that victims and injurers can substantially shield themselves from risk, attenuating the relevance of risk bearing for the comparison of strict liability and negligence.

Finally, the presence of insurance implies that the liability system cannot be justified primarily as a means of compensating risk-averse victims against loss. Rather, the justification for the liability system must lie in significant part in the incentives that it creates to reduce risk. To amplify, although both the liability system and the insurance system can compensate victims, the liability system is much more expensive than the insurance system (see the next section). Accordingly, were there no social need to create incentives to reduce risk, it would be best to dispense with the liability system and to rely on insurance to accomplish compensation.

**Administrative costs**

The administrative costs of the liability system are the legal and other costs (notably the time of litigants) involved in bringing suit and resolving it through settlement or trial. These costs are substantial; a number of estimates suggest that, on average, administrative costs of a dollar or more are incurred for every dollar that a victim receives through the liability system (Shavell, 2004, p. 281).

**Strict liability versus negligence**

The factor of administrative costs affects the comparison of liability rules. On one hand, we would expect the volume of cases – and thus administrative costs – to be higher under strict liability than under the negligence rule. On the other hand, given that there is a case, we would anticipate administrative costs to be higher under the negligence rule because due care will be at issue. Hence, it is not clear which liability rule is administratively cheaper.

**Social desirability of the liability system and private motives to sue**

The existence and the surprisingly high magnitude of administrative costs raise rather sharply the question whether the liability system is socially worthwhile. Moreover, the private motive to sue is not
liability for accidents: The New Palgrave Dictionary of Economics

in alignment with the social reasons for using the liability system. First, the private benefit of suit is the amount of money that would be obtained from it, whereas the social benefit is the deterrence that would be created. Second, the private cost of suit is the victim's cost, whereas the social cost includes also the injurer's and the state's cost. These differences give rise to the possibility of socially excessive or socially insufficient suit. To illustrate the former, suppose that care has no effect on the accident probability, so that it is socially undesirable for suit to be brought. Yet under strict liability a victim will bring suit as long as his cost is less than the harm suffered, so the volume of litigation activity could be high. To illustrate the possibility of socially inadequate suit, suppose that an expenditure on care of only one hundredth of harm will eliminate the possibility of otherwise certain harm, and suppose also that the magnitude of harm is less than the cost of suit. Then no suit will be brought. However, it would be desirable for victims to have an incentive to bring suit, for that would induce care to be taken, and, since no harm would then occur, no suit would ever occur. The private versus the social motive to make use of the legal system was first developed in Shavell (1982b, 1997); see also Polinsky and Rubinfeld (1988).

Topics

Damages

Under strict liability, damages must equal harm $h$ for incentives to be optimal. Under the negligence rule, however, damages higher than $h$ also would induce injurers to take optimal care of $x^*$. Higher damages will increase the incentive to be non-negligent; they will not lead injurers to take excessive care because injurers can escape liability merely by taking care of $x^*$. But when there is uncertainty in the negligence determination, damages higher than $h$ may lead to problems of excessive care. Damages exceeding $h$ are desirable if injurers sometimes escape liability, as when injurers may be hard to identify (the origin of pollution may be difficult to trace). If the probability of liability for harm is $q$, then, if damages are raised to $(1/q)h$, expected liability will be $h$. Thus, the more likely an injurer is to escape liability, the higher should be damages. On these points and others about punitive damages, see Cooter (1989) and Polinsky and Shavell (1998).

Causation

A fundamental principle of liability law is that a party cannot be held liable unless he was the cause of losses. For example, if cancer occurs in an area where a firm has polluted, the firm will be liable only for the cancer that it caused, not for cancer due to other carcinogens. This principle is necessary to achieve social efficiency under strict liability, because otherwise incentives would be distorted. Socially desirable production might be rendered unprofitable if the firm were held responsible for all cases of cancer. Under the negligence rule, restricting liability to accidents caused by an actor may be less important than under strict liability: if negligent actors were held liable for harms they did not cause, they would only have greater reason to act non-negligently. On causation and incentives, see Calabresi (1975), Kahan (1989), and Shavell (1987).

Judgment-proof problem

The possibility that injurers may not be able to pay in full for the harm they cause is known as the judgment-proof problem and is of substantial importance, for individuals and firms often cause harms significantly exceeding their assets. When injurers are unable to pay fully for the harm they may cause, their incentives to reduce risk are inadequate, and their incentives to engage in risky activities excessive. Policy responses to the judgment-proof problem include vicarious liability (imposed on a party who has some control over the judgment-proof party), minimum asset requirements for participation in harmful activities, safety regulation, and criminal liability. On the judgment-proof problem and responses to it, see Kornhauser (1982), Pitchford (1995), Shavell (1986; 2005), and Sykes (1984).

Product liability

When victims are customers of firms, the role of liability in providing incentives may be attenuated or even non-existent. If customers have perfect knowledge of product risks, then they will pay less for risky products, and incentives to reduce risk will be optimal without liability. If, however, customer knowledge of risk is imperfect, liability is potentially useful in reducing risk. In the latter case, a question of interest is whether court-determined liability or market-determined liability, namely, warranties, is likely to be better, on which see Priest (1981), Rubin (1993), and Spence (1977).

Liability versus other means of controlling risk

Liability is only one method of controlling harm-causing behaviour; safety regulation and corrective taxes are among the alternatives. Liability harnesses the information that victims have about the occurrence of harm, and thus may be advantageous when victims, rather than the state, naturally observe how harm comes about; whereas when harm-causing behaviour and its occurrence requires state effort to be ascertained, regulation and taxation may be advantageous. In order for liability to function well as an incentive device, injurers must have assets approximating the harm they might cause, whereas regulation and taxation (based on expected harm rather than actual harm) do not require injurers to have substantial assets. Liability, however, may enjoy an administrative cost advantage over regulation and taxation, in that administrative costs are incurred under the liability system only when harm comes about, whereas such costs generally are incurred more often under regulation and taxation. On the comparison of the liability system and other means of controlling risk, see Calabresi and Melamed (1972), Kolstad, Ulen and Johnson (1990), and Shavell (1993).

Liberalism is the theory and practice of reforms which has inspired two centuries of modern history. It grew out of the English Revolutions of the 17th century, spread to many countries in the wake of the American and French Revolutions of the 18th century, and dominated the better part of the 19th century. At that time, it also underwent changes. Some say it died, or gave way to socialism, or allowed itself to be perverted by socialist ideas; others regard the social reforms of the late 19th and 20th centuries as achievements of a new liberalism. More recently, interest in the original ideas of liberals has been revived. Thus, classical liberals, social liberals and neoliberals may be distinguished.

Classical liberalism is a simple, dramatic philosophy. Its central idea is liberty under the law. People must be allowed to follow their own interests and desires, constrained only by rules which prevent their encroachment on the liberty of others. Early liberals before and after John Locke (1690) liked to use the metaphor of a social contract to express this view. Society can be thought of as emerging from an agreement among its members to protect themselves against the selfish desires of others. Man's 'unsociable sociability' (Kant, 1784) makes rules necessary which bind all, but requires also the maximum feasible space for competition and conflict.

In fact, of course, early liberals were not concerned with building societies from scratch. They were concerned with forcing absolute rulers to yield to demands for liberty. The rule of law envisaged by liberals was a revolutionary force which heralded the enlightened phase of modernity. The notion, rule of law, is not without ambiguity. It is, in the first instance, largely formal. One thinks of...
rules of the game applying to all and regulating the social, economic and political process. In theory, such rules are intended not to prejudge the outcome of the game itself. Still, even their formal conditions, equality before the law and due process, involved fundamental changes which justify speaking of a movement of reform. Throughout the history of liberalism, however, the question of certain substantive rights of man has been an issue. The inviolability of the person and the rights of free expression have been liberal causes along with constitutional rules. Liberals have rarely found it easy to reason for such substantive rights to their own satisfaction. A certain tension between liberal thought and the notion of natural rights is unmistakable.

The modern debate of these issues began in Scotland and England. John Locke, David Hume (1740) and Adam Smith (1776) are but three of many names to consider. From Britain, the ideas spread to the United States and to continental Europe. Montesquieu and Kant borrowed some of their ideas from British liberals. The American Declaration of Independence and the Constitution, the Declaration of the Rights of Man three years after the French Revolution are only two practical illustrations of the effect of the new ideas. If one wants to, one can distinguish, with Friedrich von Hayek, between a British ‘evolutionary’ and a continental ‘constructivist’ concept of liberalism. Either or both however became the dominant reform movements of the early 19th century and determined the dynamics of Europe and North America between the 1780s and the 1840s or 1850s.

Liberalism had consequences for economic, social and political thought. Its economic application was the most obvious and remains the most familiar. If rules of the game are all that can be justified whereas otherwise interests should be allowed a free reign, the scene is set for the operation of the market. It is the forum where equal rights of access and participation but divergent and competing interests lead, through the operation of an ‘invisible hand’ (Adam Smith), to the greatest welfare for all. Liberalism and market capitalism are inseparable, much as later European theorists (notably in Germany and Italy) have tried to dissociate the two.

The social application of liberalism analogously leads to the emergence of the public, if by ‘public’ we understand the meeting place of divergent views from which a ‘public opinion’ emerges. On the Continent, a more emphatic language is often preferred; here, one likes to speak of the emergence of society from under the state. Either way, the basic idea involves the same departure from an all-embracing system of domination by traditional authorities to one in which public authority is confined to certain tasks of regulation, and thus bound to grant and defend the freedom of individuals to express their views.

This is the point at which classical liberalism was not only instrumental for the promotion of market capitalism and social participation, but also for the development of what is called today, democracy. Again, the term is anything but clear. It can be understood to mean a system of government which is based on the competition of divergent views – individual views or group views – for power, constrained by rules which limit the instruments used in the process, and stipulate the possibility for change. In this sense, a variety of constitutional forms of democracy respond to liberal views, including versions of representative government as well as forms of plebiscite. Liberalism is not anarchism, but anarchism is in some ways an extreme form of liberalism. The law has a key role in liberal thinking, but for a long time the prevalent interest of liberals was that of liberating people from the fetters of control imposed by the tangible force of the state (and the church) or the abstract force of tradition. Not surprisingly, some authors took this intention of liberation to its extreme. If they believed in the essential goodness of man, they advocated the abolition of all social restraint; at times, Jean-Jacques Rousseau seems to argue this
liberalism and economics: The New Palgrave Dictionary of Economics

way. If on the other hand they believed in the ambivalence of human nature, they were not afraid to
demand unlimited room for manoeuvre for ‘the singular one and his property’ (Max Stirner, 1845).
Perhaps this anarchist strain in early liberal thinking can be said to have been one of the reasons for the
counter-reaction of the 19th century. Marx was the first to point out the historical advance brought about
by ‘bourgeois’ equality before the law, including the contractual basis of economic action, but also the
price paid by many for the ‘anarchic’ quality of the resulting market. The market – it was increasingly
argued – was in fact not neutral, but favoured certain players to the systematic disadvantage of others.
Mass poverty, conditions of labour, the state of industrial cities were cited as examples. Nor was this
merely a view of anti-liberals. The great ambiguities in the thinking of John Stuart Mill tell the story.
There are two ways of describing the resulting history of thought and of social movements. One is to say
that as the 19th century progressed, and certainly in the early decades of the 20th century, liberalism was
replaced by socialism as a dominant force. People began to shrink back from the unconstrained market
and sought new kinds of intervention. Today, authors would add that the ‘structural change of the
public’ (J. Habermas, 1962) and the bureaucratization of democracy followed suit. Liberalism died a
‘strange death’; it ceased to be a source of reform and became a defence of class interest.
Another view ascribes the new reforms to liberals also, albeit to a different kind of liberalism. In his
Alfred Marshall Lectures of 1949, T.H. Marshall (1950) argued that the progress of citizenship rights
had to involve, from a certain point onwards, their extension from the legal and the political to the social
realm. Social citizenship rights turned out to be a necessary prerequisite for the exercise of equality
before the law and universal suffrage. Thus, the social, or welfare state was no more than a logical
extension of the process which began with the revolutions of the 18th century.
There is much to be said for this line of argument if one considers that the two men who above all
determined the climate of political thought and action from the 1930s to the 1970s, John Maynard
Keynes and William Beveridge, were both self-declared liberals. In effect if not in intention, they
advanced ideas which led to restrictions on the operation of markets. One will be remembered as the
author of economic policy as a deliberate effort by governments, the other has contributed much to the
creation of transfer systems which are operated by governments in the light of an assumed common
interest. In other words, these were liberals who pursued policies which led to strengthening rather than
limiting the power of public authorities. Theirs was a substantive, a social liberalism.
Liberal parties have found it difficult to follow the twists of theoretical liberalism. Before the First
World War, when socialist parties were still in their infancy and unable to determine policy in any major
country, they were often the spokesmen of the deprived and underprivileged. At least one strand of the
liberal tradition continued to be reformist. However, after the First World War, socialists or social
democrats came to form governments in many countries. Their gain was the liberals’ loss. Liberal
parties declined to the point of insignificance, unless they merely kept the name and changed their
policies out of recognition, either in the direction of social democracy (Canada) or in that of
conservatism (Australia). Indeed, as a practical political movement, liberalism came to present such a
confused picture that Hayek could argue that liberalism has become a mere intellectual, and not a
political force.
The experience of totalitarianism interrupted this process without stopping it altogether. To the dismay
but also to the surprise of many, basic human rights and the rules of the game of civil government
became an issue again in the 1930s and 1940s. This gave rise to an important literature in which the
underlying values of liberal thought were spelt out anew. Hayek's Road to Serfdom is one example, but
The most important one is probably Karl Popper's *Open Society and Its Enemies* (1952). Popper developed above all what might be called the epistemology of liberalism. We are living in a world of uncertainty. Since no one can know all answers, let alone what the right answers are, it is of cardinal importance to make sure that different answers can be given at any one time, and especially over time. The path of politics, like that of knowledge, must be one of trial and error. The principle can be applied to economy and society as well.

The liberal revolt against totalitarianism waned with the memory of totalitarianism itself. While the term ‘social market economy’ was coined for Germany in the 1950s, the quarter-century of the economic miracle was in fact a social-democratic quarter-century. In it, economic growth was combined almost everywhere with a growing role of government and with the extension of the social state. Entitlements came to matter as much as achievements. Consensus counted for more than competition or conflict. Despite variations, this was a very successful period in the countries of the First World. But by the 1970s, the side effects of success had become major problems in their own right. These were not only obvious problems like environmental and social ‘limits to growth’, but systematic ones arising from the role of the state. Both Keynes and Beveridge gave rise to new questions. Neither stagflation in the 1970s nor boom unemployment in the 1980s seemed amenable to government intervention. The social state had got out of hand; it became harder and harder to finance, and its bureaucracies robbed it of much of its plausibility. There were demands for a reversal of trends. Where such a reversal happened, it remained bitty, halting and inconsistent. However, the new climate gave rise also to elements of a new theory of liberalism. In one sense, this was, and is a return to the original project of asserting society against the state, the market against planning and regulation, the right of the individual against overpowering authorities and collectivities. American authors in particular restated the theory. Milton Friedman tried to show in a series of arguments that the role of government is usually contrary to the interests of people. Robert Nozick made a strong case for the ‘minimal state’ and against the arrogance of modern state power. James Buchanan (1975) and the ‘constitutional economists’ reconstructed the social contract and argued for severely limited rules and regulations, using the fiscal system as one of their main examples. This trend, more than the notion of supply-side economics (which in some ways is merely Keynes stood on his head) signifies the revival of liberalism. There are other facets of the many-faceted term. For many, the extension of civil rights to hitherto disadvantaged groups is a liberal programme. Others still concentrate on the separation of church and state and the reduction of church influence. Again others regard liberalism as an advocacy of cultural values, including pluralism and creativity. It is not difficult to see the connection of such preferences with the mainstream of liberal thought.

This mainstream has three elements. Liberalism is a theory and a movement of *reform* to advance *individual liberties* in the horizon of *uncertainty*. This means by the same token that the prevailing theme of liberalism cannot be the same at all times. In the face of absolutism, it is liberty under the law; in the face of market capitalism, it is the full realization of citizenship rights; in the face of the ‘cage of bondage’ (Max Weber, 1922) of modern bureaucratic government, it is the optimal, if not the minimal state. The struggle for the social contract has become virulent in the advanced free societies. The crisis of the social state, the new unemployment, issues of law and order all raise basic questions of what is Caesar's and what are therefore the proper limits of individual desires. It is no accident that constitutional questions have come to the fore in several countries. At such a time, liberalism is gaining new momentum. It will not solve all issues, but it will remain a source of dynamism and progress.

 Libertarians, in current American usage and in this essay, are those who prefer to organize the world through the decentralized mechanisms of private property, trade, and voluntary cooperation rather than through government. Their position is thus a modern variant of the liberalism of the 19th century. Libertarians are likely to be critical of eminent domain, government regulation of business, paternalistic
social policies, income redistribution, laws banning ‘victimless crimes’ such as drug use, gambling and prostitution, and much else. Since there are good arguments for government as well as good arguments against, only a minority of libertarians carry their position all the way to anarchism. Most accept some level of taxation to pay for the production of public goods such as national defence. Some accept government production or subsidy of things well short of pure public goods, such as schooling. The term ‘libertarian’ is also sometimes applied to left anarchists, usually outside of the United States; its original meaning seems to have been believers in free will. The current American usage is largely a response to the shift in the meaning of ‘liberal’ over the first half of the 20th century. Since believers in what used to be called liberalism could no longer use that term without confusion, many adopted ‘libertarian’ as a substitute.

One reason for libertarians to support a less than perfectly libertarian society is the belief that, in terms of individual liberty, it is the best we can do. A second is the belief that, while liberty is important, it is not the only thing that is important. Support by many libertarians for government funding of some public goods – scientific research and public health are examples – is based on the idea not that their production makes us freer but that it makes us better off in other ways.

In this article I sketch the general arguments for a libertarian position, discuss libertarian views on particular issues, and finally consider different forms of libertarianism and the internal disagreements that define them.

Why liberty is right

Libertarian conclusions may be supported either by showing that restraints on individual liberty are wrong or by showing that they lead to undesirable consequences. The former approach is often put in terms of individual rights. Each person has a right to control his own body, a right violated by laws against using drugs, by a military draft, and by many other government acts. Each person has a right to control his legitimately acquired property, a right violated by taxation, regulation, price controls,…..

Putting the argument in this form raises an obvious question: how to justify such claims. Libertarians offer a variety of answers, ranging from Objectivists, who believe that individual rights can be logically deduced from the nature of man, to intuitionists, who induce them by trying to generalize their moral intuitions (Rand, 1964; Den Uyl and Rasmussen, 1991; Rothbard, 1978; Lester, 2000; Nozick, 1974; Boaz, 1997; 1998).

It also raises questions about how rights are acquired and how far they extend. Almost nobody argues that my right to control my body includes the right to punch you in the nose. Whether it includes the right to make noise on my property that keeps you awake or burn coal in my fireplace whose smoke makes you cough is less clear.

Robert Bork, in the article (Bork, 1971) explaining why he was not a libertarian, argued that my disutility from knowing that you are doing something I disapprove of is just as real an externality as my disutility from breathing your smoke, hence that there is no rights-based case for individual freedom as libertarians understand it. If we treat everything I do that affects others without their consent as a trespass liable to be enjoined, we are left with no self-regarding actions and no liberty – the exception swallows the rule. A response from the standpoint of moral philosophy depends on some way of deriving rights that distinguishes between those sources of disutility to me that do and those that do not violate my rights – hitting me over the head versus living your life in a way I disapprove of.
The economic response starts by observing that the enforcement cost of a rule giving me control over my own body is low, since I already control my body. The enforcement cost of giving you control over my body is substantial. Hence the latter alternative is an inefficient definition of property rights, at least unless my use of my body clearly imposes substantial and measurable costs on you that cannot be dealt with by voluntary transactions along Coasean lines. Although your disutility from knowing that I am reading pornography may be just as real as your disutility from breathing my smoke, it is considerably harder to demonstrate to a court, so a liability rule awarding you damages for the disutility you suffer from my reading pornography is likely to result in inefficient outcomes and substantial litigation costs. Alternatively, a property rule giving you rather than me a property right in my behaviour – requiring me, before doing anything, to get permission from everyone who objects – imposes transaction costs due to the hold-out problem sufficient to guarantee that nobody ever does anything, which is unlikely to be the efficient outcome. Following out this line of argument provides a defence of libertarian conclusions on consequentialist grounds.

‘Liberty’ and ‘rights’ are rhetorically powerful words, so it is not surprising that libertarians are not the only ones who claim them. Competing uses can be clarified by distinguishing between negative rights (‘the area within which a man can act unobstructed by others’, Berlin, 1969, p. 122) and positive rights. A negative right is a right to be left alone. A positive right is the right to some outcome. The right not to be killed is a negative right, the right to live – implying the right to be provided with what you need to live, such as food – a positive right. Other positive rights sometimes claimed include the right to decent housing, adequate food, medical care and equal treatment.

One problem with positive rights is that they contradict negative rights, including some that many find persuasive. If I have the right to decent housing and medical care, someone else must have the obligation to produce them, which is inconsistent with his right to control his own body. If I have the right to equal treatment, the right not to have an employer or homeowner decide whether to deal with me on the basis of my race or religion, someone else does not have the right of freedom of association, since he is required to deal with me even if he prefers not to. If I have the right not to be hated or despised for my sexual preferences, that means that I have a claim over the inside of your head, that being where your emotions are to be found. Thus the assertion of positive rights can be seen, and by libertarians often is seen, as the claim that some people are to some degree the slaves of others, required to serve them without having consented to do so – the violation of a deeply held negative right.

A second problem with positive rights is that they are more prone to internal inconsistency than negative rights. There is no conflict between my not killing or enslaving you and your not killing or enslaving me. But there is a conflict between my having adequate food, housing and medical care and your having them, if one or another of those goods happens to be in short supply.

Why liberty is useful

Large parts of the consequentialist argument for individual freedom go back to Adam Smith and should be familiar to every economist. Private property, exchange, prices provide a decentralized coordination mechanism that makes it possible for individuals with different objectives, knowledge and abilities to cooperate while pursuing their separate ends. In the limiting case of perfect competition, the result is provably efficient in the usual economic sense – cannot be improved by even a perfectly intelligent central planner with unlimited control over the actions of the planned. (For both the classical and
modern versions of the First Efficiency Theorem, see Arrow, 1983, and references therein. For a non-technical sketch of the classical version, see D. Friedman, 1997, ch. 16.)
The fact that this argument is correct, non-obvious, and included in the professional training of any economist is part of the reason why libertarianism is more popular with economists than with most other academics and why even non-libertarian economists tend to be sympathetic to market approaches. To put it differently, one important reason for the rejection of libertarian conclusions by non-economists is the failure to understand price theory – how markets solve the coordination problem.

The case against

Yet not all economists, not even all good economists, are libertarians. The economic counter-argument starts with the facts that real markets are imperfectly competitive and real individuals are limited by, at least, imperfect information, transaction costs, and limited calculating ability. Once we drop the assumptions of the ideal model we are faced with the possibility of market failure, situations where individual rationality fails to lead to group rationality and hence where it is possible for restrictions on the actions of each to produce a better outcome for all. Familiar examples include the underproduction of public goods, the overproduction of negative externalities, and potentially beneficial transactions blocked by adverse selection.

These are real problems, but not always insoluble ones. A market failure results in an outcome inferior, for all concerned, to some alternative outcome. A sufficiently ingenious entrepreneur may be able to create that alternative and collect a share of the net benefit as his reward; a market failure is also a profit opportunity. Radio broadcasts are a pure public good produced privately. So are the services that Google provides to its users. Other forms of market failure may be dealt with by the development of systems of private norms (Ellickson, 1991; Posner, 2000). Where market failure exists we can expect private arrangements to produce imperfect outcomes, but less imperfect than casual consideration might suggest. (For an interesting example of a real world solution to a theoretically intractable market failure, see Cheung, 1973.)

A second objection to the argument for laissez-faire is that efficiency as defined in economics in the sense of Marshall or Hicks–Kaldor (D. Friedman, 1997, ch. 15) is inadequate as a normative criterion, so that a less efficient outcome may be preferable to a more efficient one. What is maximized by the market is value defined by willingness to pay, measured in dollars not utiles, so a transfer from rich to poor might decrease value measured in dollars but increase total utility.

This utilitarian argument for redistribution can be seen as a special case of the argument from market failure. Declining marginal utility is not merely a conjecture of philosophers; it is observed, in the form of risk aversion, in individual choices under uncertainty. In a perfect market, individuals would buy insurance against the risk of being born poor up to the point where the marginal utility costs of any resulting disincentives or transactions costs just balanced the marginal utility gain of transferring income from states of the world where they were rich to ones where they were poor. Thus the outcome of a perfect market would mirror the welfare programme that would be proposed by a utilitarian. It is merely our inconvenient inability to negotiate and sign insurance contracts prior to being born that prevents the market from solving the problem. The argument for utilitarianism in Harsanyi, 1955 – that it is what individuals would choose if they were designing a society behind a veil of ignorance with an equal
probability of living any of its lives – makes it possible to view redistribution of income either as a way of increasing total utility or as a correction for market failure.

Other objections to market outcomes come from egalitarians who see equality as good in itself and from those who put substantial weight on values unrelated to individual humans achieving their objectives. If what really matters is the preservation of endangered species, whether or not of any value to human beings, there is no guarantee that the market to achieve it. The same is true if what really matters is behaving according to God's will, producing great art and literature, or doing justice whatever the consequences.

A libertarian response

It follows that one can imagine outcomes that improve, in one sense or another, on the outcome of pure laissez-faire. It does not follow that one can construct institutions that predictably produce such outcomes.

Consider the case of market failure. It exists because actions taken by A sometimes have effects on B. If A is free to ignore those effects he may make the pair on net worse off by taking actions that increase his welfare by less than they decrease B's or failing to take actions that would increase B's welfare by more than they decrease A's. A well-designed legal structure can sometimes make it in A's interest to take account of those effects, whether through property rules, liability rules, or bargaining between the parties. But sometimes, for reasons explored by Coase (1960) and others (D. Friedman, 2000, pp. 39–45), no legal structure can be constructed that makes it in the interest of all parties to make the efficient choices.

All this is true in private markets. But it is true far more often in the political markets that control the political institutions that are proposed as a solution to market failure in private markets.

Consider the naive model of democracy – politicians doing good because if they do not they will lose the next election. In order for it to work, individual voters have to acquire the information needed to know what politicians are doing and whether it is good. No politician campaigns on the slogan ‘I'm the bad guy’. No farm bill is labelled ‘An act to make farmers richer and city folk poorer’.

If I correctly identify the better candidate, vote for him, and – improbably – my vote proves decisive, the benefit is shared with everyone in the polity. The cost is borne by me alone. Time and energy spent acquiring the information necessary for informed voting produce something very close to a pure public good. Public goods are underproduced; one with a public of many millions is likely to be very badly underproduced. The implication is rational ignorance, voters failing to acquire the information they need to judge politicians because its value to them is less than its cost. That eliminates the simple argument for why politicians will find it in their political interest to act as we would wish them to.

A similar problem arises with a more sophisticated model in which political outcomes are driven by interest group pressure. The more an interest group stands to gain by passing or blocking a piece of legislation, the more it will offer politicians in order to support or oppose it. If that were the only relevant factor, the market for legislation would produce something close to an efficient outcome. If a bill produced net benefits, its supporters would spend more supporting it than its opponents spent to block it, and the bill would be likely to pass.

It is not the only relevant factor. An interest group lobbying for legislation is producing a public good for its members and faces an internal public good problem in doing so, since members that refuse to
contribute will still benefit if the bill passes. Some interest groups are much better able than others to solve their internal public good problem. A concentrated interest group such as the auto industry – a handful of firms and one union – can raise a substantial fraction of the benefit it expects from an auto tariff in order to lobby for it. A dispersed interest group such as consumers of automobiles and producers of export goods, the people that bear most of the burden of such a tariff, can raise a negligible fraction of the cost to lobby against. Hence we would expect the political market to consistently redistribute from dispersed interest groups to concentrated ones, even when the benefit to the latter is much smaller than the cost to the former – as demonstrated by the continued existence of tariffs nearly two centuries after Ricardo demonstrated that they are, under most circumstances, injurious to the nation that imposes them.

In a private market, a producer receives a price that measures the value to consumers of what he produces, pays a cost that measures the cost to the suppliers of his inputs of producing them, and pockets the difference. It is only when special circumstances arise – externalities that cannot be dealt with by the market, information asymmetry, and the like – that his actions impose net costs or benefits on others. In the political market, in contrast, almost all decisions are made by people who bear few of the costs and receive few of the benefits those decisions produce. A legislator who passes an auto tariff imposes net costs of many billions of dollars on those affected, but all that comes out of his pocket is the extra cost of the car he buys. A judge whose precedent establishes a seriously inefficient legal rule might reduce national income by, say, a tenth of a percentage point – a staggering amount of damage for a single human being to do. But not only will he not pay any of the cost, he will never even know he made a mistake.

Consider, for example, *Davis v. Wyeth Laboratories, Inc.*, 399 F.2d 121 (9th Cir. (Idaho) Jan 22, 1968), where the court found Wyeth liable for the failure to adequately warn of the risk of polio vaccination. Their argument hinged on whether, if warned, Davis might reasonably have chosen not to be vaccinated. The court wrote: ‘Thus appellant's risk of contracting the disease without immunization was about as great (or small) as his risk of contracting it from the vaccine. Under these circumstances we cannot agree with appellee that the choice to take the vaccine was clear.’ They reached this conclusion by comparing the 0.9 in a million chance of getting polio from the vaccination with the 0.9 in a million annual rate of adult polio from natural causes. Since vaccination provided protection for many years, possibly a lifetime, the proper comparison was to the risk over many years, not one. The court made a mathematical error of more than an order of magnitude, set a precedent which substantially discouraged the development of new vaccines, caused many, perhaps thousands, of unnecessary deaths, and suffered no penalty for doing so.

Market failure is a real problem. It is a problem in ordinary private markets and a much more severe problem in political markets. That is an argument for shifting decisions, so far as possible, from political to private markets – an argument for, not against, the libertarian position.

A possible response is that decisions should be shifted to public markets only where private markets fail. But some degree of market failure can be alleged for almost any activity. Under legal rules permitting government intervention to correct any alleged market failure, intervention can be expected whenever it is politically profitable.

Libertarians vary in how far they are willing to push the arguments that I have just sketched. Consider the case of national defence, a public good with a very large public. The failure to produce it privately at an adequate level is likely to lead to a drastic reduction in liberty. That is an argument sufficiently strong to convince many, although not all, libertarians to include it in the proper functions of government.
So far I have been dealing with arguments based on market failure, but similar points can be made with regard to other criticisms of market outcomes. It is true that the market takes account of values only to the extent that individuals do; if nobody cares about the survival of the oldest tree in the world or some threatened species of birds, there is no reason to expect the market to preserve it. But the same is true of the political system. It too is driven by the desires of individuals. It just does a much clumsier job of satisfying them.

Indeed, there are some reasons to expect the market to do a better job of serving ‘non-economic’ values than the political system. Many are things, not that nobody cares about, but only that most people don’t, and the market is generally better at providing for small minorities than the political system. A religion followed by a per cent or two of the population has no difficulty getting the market to produce copies of its scriptures. If it is sufficiently unpopular with the majority, it may have problems getting the government to permit them to be printed. A minority in power might be able to do a better job of diverting resources to serve its values, whether religious or environmental, through the political system than through the market. But shifting decisions to the political system for that reason could be a risky gamble.

Another common criticism, but a mistaken one, is that the market ignores the interest of future generations. Future as well as present demand counts. It is worth planting hardwoods today for harvest a century hence as long as the return is at least as great as from alternative investments. Markets allocate resources over time, as Hotelling (1931) showed, in an economically efficient fashion. If it can be predicted that petroleum will be very valuable a century hence, it is profitable to leave it unpumped now so as to sell it then.

This argument depends on secure property rights. It breaks down if oil saved or a tree planted today is likely to be expropriated tomorrow, making holding it for future use a poor gamble. The alternative to decisions by the market is decisions by political mechanisms. Property rights in the political marketplace are much less secure than those in the private marketplace. A president who accepts costs today for benefits 10 or 20 years in the future can be reasonably confident that neither he nor his party will receive credit for those benefits. A dictator, unlike an entrepreneur, rarely has the opportunity to collect the benefit from investments expected to pay off in the future by transferring his long-term assets to a successor in exchange for immediate payment. Hence we would expect political institutions to be much more inclined to sacrifice the future to the present than market institutions, a conclusion supported by the evidence of environmental policy in the Soviet Union and Social Security in the United States.

What about income redistribution? Here again, the question is not whether there is an outcome that some would prefer to that produced by the market but whether there are institutions that predictably create such an outcome. The equal distribution of votes gives the poor some advantage on the political marketplace, but it may easily be outweighed by the very unequal distribution of other politically relevant resources. Modern governments are observed to redistribute from rich to poor via welfare, from poor to rich by subsidies for art, music, and – the big one – higher education, paid for mostly by state and local taxes and consumed mostly by people from the upper part of the income distribution. (The median family income of US college freshmen in 2001 was $67,200, compared with a median family income for all households of $42,228 – US Census Bureau, 2003, Tables 284 and 683. See Gwartney and Stroup, 1986, for a discussion of theory and evidence of the consequences of redistributional policies.) Similarly, farm policy provides a subsidy mostly to wealthy farmers and pays for it mainly by a regressive tax in the form of higher food prices.
A second problem with redistribution is rent seeking. In a polity that redistributes, it is in the interest of nearly everyone to spend resources trying to shift the redistribution in his favour, opposing redistribution from him and promoting redistribution to him (Tullock, 1967; D. Friedman, 1973, ch. 38; Krueger, 1974). The resulting deadweight cost might easily outweigh any utility gain from redistribution.

Issues

Libertarians differ in how far they are willing to carry their libertarianism. In the following discussion I present libertarian positions and the arguments for them while recognizing that in many cases the libertarian position is not supported by all who consider themselves libertarians.

The easy cases

Most of the arguments against price control, wage control, rent control, usury laws, and similar restrictions on the terms of market exchange are familiar to any economist. Many libertarians also argue that such restrictions violate individual rights. If I own my body, it is up to me to decide on what terms I will sell my labour to you. If I own my house, it is up to me to decide what terms I am willing to offer to potential tenants and up to them to decide what terms they are willing to accept. Thus many libertarians would reject not only rent and wage control but also legal restrictions on private discrimination in home sales, employment, and the like. (Nozick, 1974, ch. 7, provides an extended discussion and defence of a libertarian view of self-ownership.)

Libertarians taking that position may defend it either in terms of individual rights or by arguing that minorities are worse off in a world where such decisions are controlled by government than in one where they are controlled by private contract. State intervention in the US South during the first half of the 20th century provides an obvious example. A prejudiced majority can do a great deal more harm to the minority it is prejudiced against where decisions are made by the government than where they are made privately.

Free trade is another easy case. If building cars in Detroit costs more than growing grain, putting it on ships, sending them out into the Pacific, and having them come back with Hondas on them, we are better off growing our cars instead of building them. A tariff forces us to use the more expensive technology instead of the less expensive; it protects American auto workers from the competition of American farmers, making Americans on the whole worse off. While economists can construct special circumstances in which a trade restriction might benefit the nation that imposed it, such as infant industries that require temporary protection, the restrictions we observe are not those suggested by such arguments: In the U.S., steel and auto are not infant industries. We observe instead the restrictions predicted by the public choice analysis offered earlier, policies that benefit concentrated interest groups at the expense of dispersed interest groups. (For an explanation of why tariff protection is particularly likely for declining industries such as steel, see D. Friedman, 1997, p. 294.)

Many libertarians find paternalism another easy case, since it contradicts the idea that each individual owns his own body and is free to make choices regarding it. As a practical matter, paternalistic regulations substitute for each individual's decisions about his own welfare the decisions of someone else. The regulator may have expert information the individual lacks, but he lacks both the individual's
specialized knowledge about his own circumstances and the individual's incentive to act in that individual's interest. Thus professional licensing, justified as a paternalistic protection of the consumer, is in practice used by professions to reduce competition and so benefit themselves at the expense of their customers. (The classic discussion is M. Friedman, 1962, ch. 9). Similar arguments apply to laws against victimless crimes – the War on Drugs, laws against prostitution and gambling. Individuals might make the wrong decisions for themselves; others should be free to warn them against doing so. But the final decision ought to be made by each individual for himself.

A familiar example of the dangers of such regulation in the United States is the Food and Drug Administration (FDA). Letting a dangerous drug onto the market ends the regulator's career. Keeping a drug off the market for a few more years can do enormous damage – arguably an excess mortality on the order of a hundred thousand lives in the case of beta-blockers (Gieringer, 1985. For a webbed discussion, see FDAReserve.org.) But damage that appears only in the mortality statistics is very nearly irrelevant, politically speaking. And the connection between over-regulation, higher prices and fewer new drugs is still less visible. (See Peltzman, 1973, for a classic examination of the effect of regulation on quality and rate of introduction of new drugs.)

**Antitrust**

There are legitimate arguments, widely supported by economists, in favour of government intervention against monopolies. Even libertarians are troubled by hypotheticals in which one firm owns the only well in the desert and insists on thirsty travellers giving all they own and indenturing their labour for decades into the future in exchange for a drink. Government regulation of monopoly, however, has its own problems. The regulator needs information he is unlikely to have – cost curves and demand curves – in order to force the firm to follow welfare-maximizing rather than profit-maximizing strategies (D. Friedman, 1997, pp. 238–43). And it is far from clear why a real-world regulator, driven by political rather than altruistic incentives, would attempt to regulate in the public interest rather than letting himself be captured by the regulated industry, a concentrated interest well positioned to reward politicians with money and regulators with future jobs (Stigler, 1971). An industry that is imperfectly competitive may be imperfectly efficient, but the situation is not improved by giving firms the opportunity to use government regulation, as the US railroad industry used the Interstate Commerce Commission (ICC), to exclude competitors and restrict competition (Kolko, 1977).

Such considerations persuade many libertarians that antitrust, both as a legal doctrine and as a basis for regulation, does more harm than good – that we would be better off putting up with any ills private monopoly may produce, since the cure is likely to be worse than the disease (M. Friedman, 1962, pp. 128–9). Others argue that the state need not prevent monopoly but ought not to support it, and can avoid doing so by refusing to enforce contracts in restraint of trade.

**Immigration**

The economic arguments for free movement of goods apply to capital and labour as well, implying that immigration produces net benefits for the country that permits it, just as free trade produces net benefits for the country that practises it. Freer immigration also produces what many would consider a desirable
redistribution, since its major beneficiaries, the immigrants, are much poorer than those who might be made worse off by their move: workers in the country the immigrants go to, capitalists and landowners in the countries they come from.

This assumes a context of voluntary transactions. Some immigrants may come in order to profit by involuntary transactions, private or political – to commit robbery or collect welfare. And new immigrants, once they become citizens and voters, might use the political mechanism to advantage themselves at the cost of the rest of us. Such arguments help explain why not all libertarians support free immigration – despite empirical evidence that, at least under current circumstances, immigrants pay more in taxes than they collect in benefits (Simon, 1989; 1995).

The flip side to the ‘immigrant as welfare recipient’ argument is that, while the existence of a welfare state makes the desirability of free immigration less clear, free immigration makes it more difficult to maintain a welfare state. Free movement of people imposes limits on the ability of governments to exploit those they rule, similar to the limits that market competition imposes on the ability of firms to take advantage of their customers (Tiebout, 1956). For libertarians, that is an additional advantage to freer immigration.

Schooling

The usual argument for government provision or subsidy of schooling is that a democracy requires educated voters and an economy educated workers, hence that money spent educating my children benefits you and your children, hence that leaving education to the free market will result in too little. The first part of that argument might be true, although it is hard to find evidence to support it. The second is simply bad economics. To the extent that education makes a worker more productive, the additional productivity is reflected in his wages; investing in human capital is no more a public good than investing in physical capital. In both cases the investor may receive less than the full value of his investment due to the distorting effect of taxation – some of my additional productivity goes, not to me, but to the Internal Revenue Service. But subsidizing the investment merely shifts the inefficiency to whoever pays the taxes that fund the subsidy.

There may be indirect externalities to subsidized education – a cure for cancer, say. But not all such externalities are positive. By educating my children I make them better able to use the political system to advantage themselves at the expense of your children. By sending my son to Harvard I give him an opportunity to feel superior to your son, who went to Podunk U. That is a benefit to me and my son, a cost to you and yours, and a negative externality produced by my expenditure on education. As Robert Frank (1986) has persuasively argued, one of the things humans care about and economists ought to take account of is relative status.

This example illustrates a common problem with arguments based on externalities. Those making them usually count only externalities that lead to the conclusion they want – positive if they want to subsidize something, negative if they want to ban it. If an activity produces both positive and negative externalities, as many do, and if we are unable to measure them accurately enough to determine the sign of their sum, we do not know whether we should be encouraging the activity or discouraging – in which case it might be wiser to do neither (D. Friedman, 1971).

Another argument for government involvement in schooling is that, since parents act in their own
interest rather than that of their children, they may fail to pay the cost of schooling even when it produces a benefit larger than its cost. But shifting the decision to the political system means shifting it, not to children, but to other adults. Adults routinely make large sacrifices on behalf of their children, much more rarely on behalf of other people's children. So while a parent is not a perfect proxy for his children, he may be the best proxy available – a much better one than either the legislature or the teachers’ unions.

Other government activities can be supported, and opposed, with similar arguments. Subsidies for basic research can be defended as producing a public good, rejected on the grounds that enough of the benefits can be privatized to make subsidy unnecessary (Kealey, 1997), that government involvement diverts too many smart people into whatever field is currently in fashion, and that it subverts the scientific enterprise by converting the search for truth into a search for grants.

The relevance of public good theory is less clear for police and courts, government activities traditionally accepted by believers in a minimal government. Law enforcers can choose to pursue criminals who commit crimes against those who have paid for their services and not those who have not; England survived with private thieftakers but without police in the modern sense until well into the 19th century. (Davies, 2002; D. Friedman, 1995. Both argue that there is no clear evidence that failure of the traditional system was the reason why it was eventually replaced.) Courts can refuse to settle disputes among those unwilling to pay for the service, and some – both private arbitrators and government courts – do. Many libertarians accept the conventional arguments for state provision of police and courts, paid for by taxation; others do not (D. Friedman 1973, part 3).

There are a few issues where libertarians disagree among themselves about which side is more libertarian. Intellectual property is one example. Some argue that a book or an invention, as the pure creation of a human mind, deserves strong protection. Others regard all intellectual property as coercive, a restriction on how individuals are permitted to use their own material property. Limited liability for corporations is another such. Many libertarians reject it on the grounds that individuals ought to be liable for their actions. Others see it as a legitimate consequence of freedom of association and contract and observe that, while it is possible for a corporation to impose costs it does not have the resources to compensate for, the same is true for an individual.

Foreign policy provides a particularly divisive example. Opponents of the United States in recent decades have been strikingly unfree societies – Hitler's Germany, Stalin's Russia, Mao's China, Ho Chi Minh's Vietnam – making a policy of overthrowing, or at least containing, them attractive to many libertarians. But such a policy is conducted by a government whose competence and motives libertarians find suspect – and badly done interventionism may well be worse than no interventionism (D. Friedman, 1989, ch. 45). Hence many libertarians favour the non-interventionist policy famously advocated by George Washington – peace and friendship with all, entangling alliances with none.

Libertarian: yes/no or more/less

Some libertarians propose a bright line definition of who is a libertarian, often along the lines of ‘one who believes in never initiating force against another’. One problem with this is that libertarians do not have an entirely satisfactory account of what determines who owns what – in particular, of how unproduced resources, such as land, become property. Without a clear answer to that question, it is
sometimes hard to distinguish the initiation of force from the use of force to defend what you justly own. A second problem is that the bright line definition, taken literally, eliminates almost everyone, including almost all libertarians. Consider a scenario popularized by the late R.W. Bradford, editor of *Liberty Magazine*. You have carelessly fallen out of a 50th storey window. By good luck, you catch hold of the flagpole of the apartment immediately below you and start trying to climb in the window. The owner of the apartment objects that you are violating his property rights – not only by climbing in his window, but by using his flag pole without his permission. Do you let go and fall to your death? Such arguments suggest that ‘libertarian’ is more usefully defined as a continuum – more libertarian or less rather than libertarian or not.

An issue which has attracted a good deal of attention within the libertarian movement is whether there ought to be any government at all. One faction, sometimes labeled ‘minarchist’, supports a government that provides, at least, for courts, police, and national defence. The other – anarchists or anarcho-capitalists – argues that, with suitable institutions, voluntary cooperation in a free market can adequately provide all government services worth providing (D. Friedman, 1989, part 3; Rothbard, 1978). The latter position can be defended either on the (rights-based) grounds that all other alternatives involve violations of rights or on the (consequentialist) grounds that, just as the free market does a better job than government of building cars and growing food, it could also do a better job of producing laws and defending rights. While the latter claim seems obviously false to many when they first encounter it, it has proved sufficiently persuasive to be adopted by a significant minority of those seriously involved with libertarian ideas and libertarian argument. (Liberty Magazine Editors, 1999.)

**Varieties of libertarianism**

Does ‘individuals have the right not to be coerced’ mean that one should never initiate coercion or that one should act to minimize coercion? If rights are best protected by a tax-supported system of police and courts, should one support such taxes as a way of minimizing rights violations or oppose them as a violation of rights? (Nozick, 1974, pp. 28–35, discusses the distinction between rights as side constraints and a ‘utilitarianism of rights’ and offers arguments for the former.) One answer makes anarchism something close to a moral imperative, the other decides the anarchist/minarchist issue in terms of how well either alternative works.

It is useful for land to be treated as private property. But how does a claimant get ownership? Locke (1689, ch. 5, section 27) famously argued that he did it by mixing his labour with the land – clearing trees, plowing, removing boulders. But that argument included the proviso that there be as much land and as good available for other claimants, since otherwise the first claimants deprive others of the opportunity to claim land themselves. The value of the land is in part site value and in part value due to human effort; how does the owner get a just claim to the former?

Many libertarians avoid these questions by simply accepting existing titles to land. Others argue that such claims are legitimate only if based on a chain of voluntary transfer back to a legitimate appropriation, whether by Lockean mixing of labour with land or some other mechanism. A few, ‘geolibertarians’ or, more confusingly, ‘left libertarians’, reject unqualified private ownership of land entirely, arguing for the land tax of Henry George or something similar (Brody, 1983; D. Friedman, 1983; Valentyne and Steiner (2000a; 2000b); George, 1879.)
For a final variant on libertarianism, consider someone who accepts both the utilitarian argument for redistribution from rich to poor and libertarian arguments against government intervention in the market. He might favour a laissez-faire society combined with some very simple system of redistribution – say a flat tax used to finance a modest demogrant. (The best-known proposal along these lines is the negative income tax; M. Friedman, 1962, pp. 191–5. A more recent version is Murray, 2006.) Making the redistribution simple reduces the opportunity for individuals to spend resources trying to shift it in their favour. Putting all redistribution in one form eliminates arguments for other government interventions defended – often implausibly – as helping the poor. While many, perhaps most, libertarians would be reluctant to consider this a fully libertarian position, it provides a possible compromise for those who accept large parts of the consequentialist argument for libertarian policies while remaining unconvinced by libertarian arguments about rights.

Lieben, Richard (1842–1919)

Jürg Niehans

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Auspitz, R.; consumer's rent; gold standard; Lieben, R.; mathematical economics; reciprocal demand curves; Walras, L.

Article

Lieben was born on 6 October 1842, in Vienna; he died there on 11 November 1919. After studying mathematics and engineering sciences, he became a partner in the Jewish family bank and a respected member of the Viennese business community. In 1892 he advocated the adoption of a gold standard. He married late and had no children. He seems to have been of scholarly and artistic tastes, more contemplative than active.

Together with his cousin and brother-in-law Rudolf Auspitz, Lieben wrote the ‘Researches on the Theory of Price’ (1889), the only Austrian contribution to mathematical economics and one of the outstanding contributions in the last two decades of the 19th century. (This book is discussed in the dictionary entry on Auspitz, Rudolf.)

As a correspondent to the Economic Journal, Lieben provided a lucid summary of their views on consumer's rent (1894). After his collaborator's death he concluded the controversy with Walras by a complex three-dimensional analysis of reciprocal demand curves (1908), gracefully acknowledging their original misunderstanding. Appropriate corrections were made in the French translation of the ‘Researches’ (1914). While it is impossible to separate Auspitz's and Lieben's contributions, these papers suggest that Lieben was more than a junior partner.

Selected works

1890. (With R. Auspitz.) Reply. (To article by L. Walras in same publication.) *Revue d'économie politique* 4.

Life tables present the age incidence of mortality in a population. The population may be all those people in a country or other area, or some category within a country; it may be all persons counted at a particular moment or period of time, say 1980 (period table); or it may be those born at a particular time and followed through life (cohort table).

The abridged life table officially calculated for the United States deaths and population of 1983 (National Center for Health Statistics, 1983) is shown as Table 1. It is based on population estimated to mid-year ($P_x$ for age $x$ to $x+4$ at last birthday) and extrapolated from the 1980 census, and corresponding deaths to residents occurring during the year 1980 ($D_x$). Unregistered deaths are few in developed countries, but population censuses tend to under count, and give a life table of too high mortality unless a correction is made. In most less developed countries registration of deaths is incomplete, and model (e.g. Coale and Demeny, 1983 or UN, 1982) tables fill the gap.

Having the age-specific death rates, $M_x = D_x / P_x$, the important step is calculating the probability that a person living at the beginning of the age interval will survive to the end. If the death rate within the interval can be assumed constant then the exact probability is $l_x + 1 / l_x = e^{-5M_x}$. In fact, for ages from about 10 onwards the death rate rises within as well as between intervals, and this is partly taken into account by the alternative more precise expression

$$\frac{l_x + 5}{l_x} = \frac{1 - 5M_x / 2}{1 + 5M_x / 2}.$$ 

Greville (1943) gives a more general expression. More generally yet, if $p(x+t)$ is the continuous age distribution within the interval $x$ to $x+5$, and $\mu(x+t)$ the continuous death rate, then we have the equation

$$5M_x = \frac{\int_0^5 p(x + t) \mu(x + t) \, dt}{\int_0^5 p(x + t) \, dt}.$$
The life table: The New Palgrave Dictionary of Economics

from which it is required to extract the quantity

\[ l_{x+5} / l_x = \exp \left[ - \int_0^5 \mu(x + t) \, dt \right]. \]

A solution (Keyfitz, 1985, p. 39) is obtained by expanding the \( p \)'s and the \( \mu \)'s by Taylor's theorem.

Having obtained the probability of surviving from one point of age to the next, the life table is completed by cumulating these probabilities from age 0; with an arbitrary starting point ('radix') of 1 or 100000 the \( l_x \) column is obtained by successive multiplication

\[ l_{x+5} = l_x \left( \frac{l_{x+5}}{l_x} \right), \text{ etc.} \]

The \( l_x \) column has three interpretations: (1) The probability of a person just born surviving to age \( x \). (2) The number of survivors in a hypothetic cohort (say starting with 100,000 births) by the time age \( x \) is reached. (3) The number of persons aged \( x \) in the stationary population.

For this last interpretation one integrates over one- or five-year age intervals, and so obtains

\[ L_x = \int_0^5 l(x + t) \, dt, \]

the number of individuals in a stationary population (say one in which there are exactly 100,000 births per year) at age \( x \) to \( x+4 \) at last birthday.

What makes possible the simultaneous representation of these three quite different entities is a central assumption of the life table: that the actual number of deaths to occur will be the probability multiplied by the initial number exposed. In short, the life table is a deterministic model: if there are a million people, each with a probability of 0.01 of dying during the following year, there will be exactly 10,000 deaths. It also assumes that every individual of a given age and sex has the same probability of dying.

The estimators above do not make explicit allowance for withdrawals, nor for the individual times at death. With small populations, for instance those used in follow-up studies after a diagnosis of cancer, or after a particular treatment, more refined methods are needed. One such, called the product-limit method and using maximum likelihood, is due to Kaplan and Meier (1958). This and ways of dealing with withdrawals and censoring are taken up in Elandt-Johnson and Johnson (1980, ch. 6).

From the probability of surviving the life expectancy is calculated as

\[ e_x^L = \int_0^5 x l(x + t) \, dt. \]

In the deterministic model this traces a (usually synthetic) cohort consisting of \( l_x \) individuals, who will live \( 5L_x \) person-years over the next five years; \( 5L_x + 5 \) over the five years after that, etc. These future years may be thought of as divided among the \( l_x \) persons, giving each of them an average of

\[ e_x^0 = \frac{\sum L_x + n}{l_x}. \]
An original purpose of the life table was to calculate annuities and life insurance, and much of the modern notation has been developed by actuaries. If money carried no interest then the value of an annuity starting at age 65, say, would be \( \int_{65}^{\infty} l(t) \, dt \), and if this was to be paid for by yearly payments from age 20, the annual premium would be \( \int_{20}^{\infty} l(t) \, dt \div \int_{65}^{\infty} l(t) \, dt \). If money carries interest we need to discount this (say back to birth), and the premium will be less, being calculated as

\[
\int_{65}^{\infty} e^{-it} l(t) \, dt \div \int_{20}^{\infty} e^{-it} l(t) \, dt,
\]

where \( i \) is the rate of interest compounded momentarily (Jordan, 1967).

The expectation of life at age 0 is a common measure of mortality, for comparing countries and other population aggregates: in the United States the life expectancy was 75 years in 1983, compared with 66 years for Mexico. Mexico's crude rate (1000x\( D/P \)) is 6 per thousand against the US 9, a comparison that does not reflect true mortality because Mexico's population is much younger.

The third meaning of the life table can be generalized to represent the age distribution of a population that is increasing at a steady rate \( r \); in this generalization the number of persons aged \( x \) to \( x+4 \) at last birthday is proportional to

\[
\int_{0}^{5} e^{-(x+4)l} \, dt.
\]

The life table idea is readily extended to more than two states of exit. One can work out the chance of dying from the several possible causes of death – cancer, heart disease, etc.; this is still a decrement table, but now with several causes of decrement.

While the notation and the concepts of the life tables were worked out for mortality, it is applied to many processes other than living and dying. A woman has a certain probability month by month of becoming pregnant; the probabilities can be cumulated to give the probability of still not being pregnant by the \( x \)th month, from which the expected months to pregnancy can be calculated for women who are fertile. An aircraft engine has a certain probability of breaking down in the first month, the second month, etc.; a life table shows the expected number of months of service, and by an extension the number of engines that will have to be kept in reserve for replacements up to a given level of security.

Biological ecologists calculate life tables for many species of animals and insects. Probability of divorce in the first year, the second year, etc. after marriage can be worked out in the same two-state model, except that now first marriage and divorce rather than living and dead are the states in question. A table can be made for survival within the school system, in which the states are attending school and dropping out.

In increment–decrement tables persons can re-enter some of the states. For instance they can enter the labour force, then leave it, then enter again. The same applies to marriage, or to migration among regions of a country. For this a multi-dimensional analogue of the life table is available, and has been extensively used (Rogers, 1975, 1984; Schoen, 1975). The relevant formulas are matrix analogues of the ordinary life table formulas given above.

A main use of life tables is for population projection. If the population age \( x \) to \( x+4 \) at the jumping-off point is \( 5P_x \), then 5 years later it will be \( 5P_x L_{x+5}/5L_x \) if the life table is appropriate and random variation and migration can be disregarded. (For the birth component and other aspects of projection, see Brass, 1974.)

In pursuing these and other purposes, one often deals with populations for which mortality data are deficient or altogether lacking. A common procedure in the past was to substitute a suitable member of a series (for example England and Wales at an appropriate date). Today it is more convenient to use one of the sets of model tables calculated for the purpose, based not on one country, but on all the countries for
which reliable data are available (UN, 1982; Coale and Demeny, 1983).

Life tables are calculated on the (unrealistic) assumption that the population is homogeneous in respect of all unmeasured variables. Because the observed population is constantly being selected towards persons of greater robustness, the true expectation for a person initially of average robustness is less (by something of the order of one year) than that shown by published tables (Vaupel and Yashin, 1985).

The central idea of limit pricing is that an incumbent monopolist or collusive group will or can forestall entry by charging some price below that which maximizes static own profit. But a strategic price response is only one possible incumbent response to entry. A full understanding of the determinants of equilibrium market structure in inherently oligopolistic industries must take the full range of possible responses into account.

Keywords

advertising; commitment; entry; excess capacity; limit pricing; potential competition; predatory pricing

Article

Modern economists generally trace models of limit pricing to Modigliani (1958). The idea of limit pricing is closely related to, and often not distinguished from, the much older idea that potential competition will induce a profit-maximizing incumbent monopolist or dominant group to set a price that would allow it (or, in some formulations, an entrant) only a normal rate of return (Giddings, 1887; Gunton, 1888; Liefmann, 1915; Marshall, 1890, p. 270; 1919, pp. 397–8, 524; Kaldor, 1935). With this second idea, it is the presence of potential entrants that constrains the options of incumbents, not the other way around.

Modigliani's (1958) more-than-a-book-review of Bain (1956) and Sylos-Labini (1957) offered a formal model based on what Modigliani called the Sylos postulate (1958, p. 217) ‘that potential entrants behave as though they expected existing firms to adopt the policy … of maintaining output’ in the face of entry. Given such beliefs, if incumbents produce a sufficiently large output that the best post-entry price a profit-maximizing entrant could expect would be below its average cost, entry would not occur.

Gaskins (1971) generalizes the static limit price model to a dynamic context, with a model in which incumbent pricing determines the rate of expansion of a fringe of price-taking suppliers. This might also
be regarded as a dynamic generalization of the familiar Forchheimer–Auspitz–Lieben model of a dominant firm in a market with a price-taking fringe.

Friedman (1979) points out that, under conditions of complete and perfect information, profit-maximizing incumbents would not, in general, maintain post-entry output at pre-entry levels, and entrants would not expect them to do so. Much the same point had been made, less formally, by Bain (1949, p. 452). Without commitment, a low price fails as an entry-limiting device if entrants believe that in the post-entry market incumbents will act in their own self-interest.

One line of research that seeks to finesse the unsatisfactory nature of the Modigliani–Sylos postulate can be traced to Spence (1977) and Dixit (1979). They offer models in which an incumbent's pre-entry investment (in capacity) alters the incumbent's post-entry incentives, and by so doing gives credibility to post-entry conduct that renders entry unprofitable. See Allen et al. (2000) for careful discussion. The vast literature on strategic entry deterrence (Salop and Scheffman, 1983; Fudenberg and Tirole, 1984) springs from this root.

An alternative approach is taken by Kreps and Wilson (1982) and Milgrom and Roberts (1982). They give up the assumption of complete information and model entry-limiting behaviour based on an incumbent firm's reputation or entrants' uncertainty about an incumbent's costs. The modelling techniques employed here have been generalized to analyse predation and the conduct of regulation/competition policy under conditions of uncertainty.

The development of internally consistent theoretical models in which entry-limiting behaviour might occur as an equilibrium phenomenon was a major step in laying the game-theoretic foundation for modern industrial economics. The assembling of empirical evidence on the occurrence of limit pricing and other strategic reactions to entry has similarly followed the general trend of empirical research in industrial economics, studying particular markets for specific instances of entry-deterring behaviour. There are case studies of limit-pricing behaviour (Blackstone, 1972). But empirical studies of entry suggest that theoretical models of entry and entry deterrence abstract from essential aspects of the phenomena (Simon, 2005, p. 1230).

Some real-world entry, no doubt, is like the entry of limit price and other entry-deterrence models – entry at large-scale into production of a standardized product hitherto offered by a small number of firms themselves aware of their oligopolistic interdependence. Archer Daniel Midland's well-known 1991 entry into lysine production is a case in point. Much more often, however, entry seems like the act of beginning small-scale production at a point on a Hotelling line, when location in characteristic space is largely fixed after entry and neither the entrant nor incumbents have a terribly good idea of the distribution of consumers in the region near the entrant's location.

Geroski (1995, p. 433) concludes in his careful survey that ‘price is not frequently used by incumbents to deter entry, but that marketing activities are’, and (1995, p. 434, fn. 7) ‘work that has tried to test for the presence of limit pricing … in general … has produced somewhat ambiguous results…. Studies of the strategic use of excess capacity to block entry have also generally produced weak and fairly unpersuasive evidence on its importance.’

Empirical work suggests that the incumbent response to entry will vary with entrant and incumbent characteristics. The response to entry will sometimes be by lowering price, sometimes by other rival strategies, and sometimes by accommodating entry.

Scott Morton (1997) finds that longer-established entrants into turn-of-the-19th-century shipping cartels
were less likely to evoke a hostile response, as were entrants with substantial financial resources. Podolny and Scott Morton (1999) suggest that a predatory response was less likely if social factors were present that would allow incumbents and entrants to judge each others’ ‘types’. Thomas (1999) finds that incumbent US breakfast cereal manufacturers are more likely to respond with advertising to entry into a product group by other incumbents, and more likely to lower price in response to entry by a new firm. Yamawaki (2002) finds a price response to Japanese entry by German manufacturers of luxury cars for the US market, but no such response by British manufacturers. In a study of entry into the US magazine industry, Simon (2005) finds that multi-market and single-market incumbents respond differently to entry. Multi-market incumbents are more likely to cut price in response to entry by a new firm, single-market incumbents more likely to cut price in response to entry by an established publisher. He also finds that a hostile response to entry is more likely the more concentrated the target market. Conlin and Kadiyali (2006) find some evidence of the use of excess capacity as an entry-deterring device in the Texas hotel market, and also that the maintenance of excess capacity is more likely by larger firms and by firms in more concentrated markets.

It thus appears that, while a strategic price response is one possible incumbent response to entry, it is only one. A full understanding of the determinants of equilibrium market structure in inherently oligopolistic industries must take the full range of possible responses into account.

Lindahl equilibrium

John Roberts
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Lindahl equilibrium embodies a market solution to the problem of providing public goods. Each individual faces personalized prices at which he or she may buy total amounts of the public goods. In equilibrium, these prices are such that everyone demands the same levels of the public goods and thus agrees on the amounts that should be provided. Since individuals buy the total production of public goods, the price to producers is the sum of the prices paid by individuals, and equilibrium involves the supply at these prices equalling the common demand, with costs being shared in proportion to (marginal) benefits.

R.; misrepresentation of preferences; missing markets; Nash equilibrium; optimality; property rights; public goods; pure public goods; revealed preferences; tax incidence; Walras equilibrium

Article

Lindahl equilibrium attempts to solve the problem of determining the levels of public goods to be provided and their financing by adapting the price system in a way that maintains its central feature of an efficient allocation being the outcome of voluntary market activities within the context of private property rights. Instead of some political choice mechanism and coercive taxation, under the Lindahl approach each individual faces personalized prices at which he or she may buy total amounts of the public goods. In equilibrium, these prices are such that everyone demands the same levels of the public goods and thus agrees on the amounts of public goods that should be provided. Since each individual buys and consumes the total production of public goods, the price to producers is the sum of the prices paid by individuals, and equilibrium involves the supply at these prices equalling the common demand.
Thus, Lindahl equilibrium brings unanimity about the level of public goods provision, with costs being shared in proportion to (marginal) benefits.

The basic idea of a market solution to the problem of providing public goods is due to Erik Lindahl (1919). In its modern formulation, Lindahl equilibrium has come to play a benchmark role in the study of economies with public goods, externalities, and government expenditure which parallels that played by Walrasian competitive equilibrium in the analysis of questions where these factors are absent. For example, tax incidence can be measured relative to the Lindahl equilibrium. On the other hand, the Lindahl concept does not share the competitive equilibrium's centrality of position as a predictor of the actual outcomes of economic activity.

This latter point involves some irony, because Lindahl's original exposition of the idea treats it as having both normative and descriptive/predictive value.

Lindahl considered a legislature in which two parties represent the two homogeneous classes that constitute the electorate. (He also indicates how to extend the analysis to more classes and their representatives.) The issue is how much government activity should be carried out and how the costs of this activity should be shared between the two groups.

Lindahl identified two functions, say \( f_A(s) \) and \( f_B(s) \), which give, respectively, the expenditure on public activity that group A would want if it had to pay a fraction \( s \) of the corresponding costs and the level that B would want if it had to pay the complementary fraction \( 1 - s \). The value \( x = f_A(s) \) is just the solution to the problem of maximizing the utility of after-tax income and public expenditure for group A, given that it will pay \( 100s\% \) of the costs, while \( f_B \) solves the corresponding problem for B. Ignoring income effects, Lindahl obtained \( s = v_A(f_A(s)) \), where \( v_A \) is A's utility for public expenditure, and, correspondingly, \( 1 - s = v_B(f_B(s)) \). Note that \( f_A \) is decreasing and \( f_B \) is increasing. Thus, assuming \( f_A(0) > f_B(0) \) or \( f_A(1) < f_B(1) \), so that a group bearing all the costs wants less expenditure than does the group paying nothing, there is a unique value \( s^* \) strictly between zero and one at which the two groups agree on the desired level of expenditure, that is, \( x^* = f_A(s^*) = f_B(s^*) \).

Much of Lindahl's analysis is in terms of bargaining between the two groups over \( x \) and \( s \) under the assumption that, at any partition of the costs, the smaller of the two proposed quantities will be implemented. (This reflects the connection to voluntary exchange, where no one is forced to transact.) He recognized that such bargaining would not automatically lead to \( s^*, x^* \). However, he claimed that if both groups were equally adept at defending their interests, this outcome would result.

Foley (1970) provided the basic general equilibrium treatment of Lindahl's idea in the context of an Arrow–Debreu private ownership economy with both private and pure public goods (no rivalry in consumption and no possibility of exclusion) where there are zero endowments of public goods, these goods are never used as inputs, and production takes place under constant returns to scale. See Milleron (1972), Roberts (1973), and Kaneko (1977) for extensions and Roberts (1974) for a survey.

Foley's model focuses on prices for the public goods rather than cost shares. Individual demand functions for public goods, as depending on the prices of both private and public goods, are defined (exactly as for private goods) as the choices of quantities to consume that maximize utility subject to the budget constraint defined by the prices and the agent's endowment. Thus, the quantity demanded of any public good at a particular price vector differs with individual preferences and endowments. However,
the nature of pure public goods requires that all agents’ consumption of any of these goods be equal. Thus, if prices are to lead different individuals all to demand the same quantities of public goods, it is clear that the prices charged to consumers must be personalized, differing across individuals to reflect differences in preferences and incomes. The price received by a producer of public goods is then the sum of the price paid by individuals, because each unit of each public good is allocated to and paid for by every individual. Meanwhile, private goods markets involve standard competitive pricing. With this, Lindahl equilibrium is a vector \( p \) of private goods prices, a vector \( q_i \) of public goods prices for each consumer \( i \), an allocation of private goods \( x_i \) to each \( i \) and a vector of public goods \( y \) such that: \((x_i, y)\) is the most preferred consumption bundle for consumer \( i \) from those affordable at prices \((p, q_i)\), given \( i \)’s wealth as determined by \( p \) and \( i \)’s initial endowment of private goods \( \omega_i \); and also such that the net input–output vector \( (\Sigma i x_i - \omega_i, y) \) is profit maximizing at the producer prices \((p, \Sigma j q_j)\). Note that both consumers and producers are following standard, competitive, price-taking behaviour just as in the Walrasian equilibrium.

Further appreciation of the connection between Lindahl and Walrasian equilibria can be gained using Arrow’s insight (1970) that externalities (and the public goods problem in particular) can be viewed as a phenomenon of missing markets. Given a public goods economy with \( I \) consumers, \( M \) private goods and \( N \) public goods such as studied by Foley, consider an associated economy with \( I \) consumers, \((M + K)\) private goods, and no public goods, where \( K = IN \). In this economy, each public good \( n \) in the original economy is replaced by a collection of \( I \) private goods, each of which is of interest to and consumable by only one consumer and which together are joint products in production. A net input–output vector in this economy of the form

\[
(z, y), \quad z \in R^M, \quad y = (y_1, \ldots, y_{IN}) = (y_1, y_2, \ldots, y_N, y_1, y_2, \ldots, y_N, \ldots, y_1, y_2, \ldots, y_N) \in R^K_{+}
\]

is producible if and only if \((z, y_1, \ldots, y_N)\) is in the production set of the original public goods economy. A Walras equilibrium in this economy is a price vector \((p, q_1, \ldots, q_{IN}) \in R^{MK}_+\) and consumption vectors \((x_b, y_1^b, \ldots, y_{IN}^b) \in R^{M+K}_+\), \( i = 1, \ldots, I \), where \((x_b, y_1^b, \ldots, y_{IN}^b)\) is the most preferred bundle for \( i \) from among those costing no more than \( p \omega_i \) and where \((\Sigma j x_j - \omega_b, \Sigma j y_j^1, \ldots, \Sigma j y_j^{IN})\) is profit maximizing at prices \((p, q_1^1, \ldots, q_{IN}^1)\). Clearly, these conditions imply \( y_j^q = 0 \), for \( i \neq j \) so that no consumer receives positive amounts of another’s personalized goods, and \( y_j^q = y_j^q \) for all \( i, j, \) and \( n \), so that each individual consumes the same quantities of these personalized goods. Thus, Walras equilibria of the artificial economy exactly correspond to the Lindahl equilibria of the original economy, with a parallel correspondence between the feasible allocations in the two economies and between the Pareto optima.

This construction, which was used by Foley to prove existence of Lindahl equilibrium, illuminates the claim that the Lindahl equilibrium involves voluntary exchange in the context of maintaining private companies.

property rights. It also makes clear that Lindahl equilibria are Pareto optimal and that any optimum can be supported as an equilibrium with a reallocation of resources. (In fact, Silvestre, 1984, has characterized Lindahl allocations in terms of optimality plus a condition that no agent wants to reduce his or her contribution to paying for public goods if the level of provision would be proportionately reduced.) The Lindahl equilibrium's role as a benchmark is largely attributable to its having these properties, plus the fact that the Lindahl equilibrium allocations belong to the core if blocking is defined by a group being able to produce a more preferred consumption bundle for each of its members, even if non-members contribute nothing to public goods production (Foley, 1970). However, this construction also suggests some of the problems with the Lindahl equilibrium which prevent it from having great appeal as a positive prediction.

In particular, the usual complaint against a price-based solution to the public goods problem is that there would be no reason for an individual to take the Lindahl prices as given: misrepresentation of preferences should be profitable. Of course, as long as there are only a finite number of participants in a market, the behaviour of each typically has some influence on price formation, and so the assumption of price-taking in Walrasian, private goods equilibrium is questionable too.

Progress on this incentives question requires being more specific about the mechanism used to determine the allocation as a function of the initially dispersed information about the economic environment. In this context, Hurwicz (1972) formalized the idea that there must be incentive problems even with only private goods by showing that if a mechanism always yields Pareto optima and, if participation is voluntary, so that its outcomes must be unanimously preferred to the no-trade point, then it cannot be a dominant strategy always to report one's preferences (demand) correctly. The exactly parallel result for public goods was achieved by Ledyard and Roberts (see Roberts, 1976). Thus neither Walrasian nor Lindahl equilibria can be the outcome of a mechanism which is incentive compatible in this dominant-strategy sense.

Of course, the standard case in which the Walrasian equilibrium seems appealing is a ‘large numbers’ one where each individual’s influence is small. This intuition has been formalized in a number of ways: revealing one’s true demand for private goods generically is asymptotically a dominant strategy as the number of participants in the economy becomes large; only competitive allocations are in the core of large economies; Nash equilibria of various models in which individuals recognize their influence on prices converge to the competitive solution as the economy grows. However, with public goods the situation is much different: increasing the size of the economy makes price-taking less attractive. This too has been shown in various ways. Roberts (1976) showed that increasing numbers can worsen the incentives for correct revelation of preferences for public goods and that as the numbers grow, the departure of the outcome from efficiency can also increase. Muench (1972) showed that the core and Lindahl equilibria do not coincide in large economies, and Champsaur, Roberts and Rosenthal (1975) demonstrated that the core of a public goods economy may actually expand when the number of consumers increases. In terms of the artificial economy, the essential intuition is that the market for each of the personalized goods is monopsonized, and the joint-product interaction constrains the bargaining power of the producer which otherwise might permit an efficient outcome to the bilateral monopoly situation. Thus, it seems that in the large numbers situations that have been the traditional concern of economics, the price-taking assumption renders the Lindahl solution of little predictive or descriptive value.
These essentially negative results are in some contrast with the results on incentives for correct
revelation in iterative planning procedures for determining public goods. This literature was begun by
Malinvaud (1971a; 1971b) and Drèze and de la Vallée Poussin (1971) and is surveyed in Roberts (1986).
In this context, the notion of incentive-compatible behaviour is Nash equilibrium: each agent selects his/
er her responses to the central planning authority's proposals so as to maximize his/her payoff, given the
strategies being used by the other agents to determine their responses. Such behaviour typically involves
misrepresentation of preferences. However, various authors (Roberts, 1979, Champsaur and Laroque,
1982, and Truchon, 1984, for example), have shown that this misrepresentation need not prevent
convergence to a Pareto optimum and, in particular, to the Lindahl allocation.
However, as argued in Roberts (1986), these results are of limited interest because they rely on the
implausible assumption that each agent is perfectly informed about the other's preferences. (A similar
criticism can be laid against the static mechanisms for obtaining Walrasian or Lindahl allocations as
Nash equilibria; Hurwicz, 1979.) Moreover, once the (self-selection or truthful reporting) constraints
associated with preferences being private information are recognized, it is not clear that any mechanism
can achieve Lindahl allocations (see Laffont and Maskin, 1979; d'Aspremont and Gerard-Varet, 1979).
This gives a further reason for doubting the empirical relevance of Lindahl equilibrium.

Lindahl, Erik Robert (1891–1960)

Otto Steiger

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Erik Lindahl's writings between 1919 and 1959 covered four major areas. In public finance his pioneering contribution is today known as the ‘Wicksell–Lindahl paradigm of just taxation’. In dynamic analysis he was first to develop the methods of intertemporal equilibrium and temporary equilibrium. In macroeconomics Lindahl anticipated many of the insights of Keynes's *General Theory*, and in his discussion of the concepts of income and capital he laid the foundations of the theory of national accounting. His contributions in the four fields have been acknowledged internationally step by step only since the 1950s – in the third area since the 1970s.

Article
Lindahl was born on 21 November 1891 in Stockholm and died on 6 January 1960 in Uppsala, Sweden. He is now reckoned one of the great economists who were at work between the two world wars, and earned his reputation above all as a leading member within a group of Swedish economists during the 1930s consisting, besides himself, of Gunnar Myrdal, Bertil Ohlin, Dag Hammarskjöld, Alf Johansson, Erik Lundberg and Ingvar Svennislsson – a body which Ohlin (1937) had baptised the ‘Stockholm School’.

The son of a prison governor, Lindahl grew up in Jönköping, the capital of a province in southern Sweden. After passing the studentexamen at a Stockholm Secondary School in spring 1910, he enrolled the following autumn as a student at the University of Lund, where economics soon became the favourite subject in his studies of humanities and law, which he passed with the degrees of the filosofie kandidatexamen (BA) in 1912 and the juris kandidatexamen (LLB) in 1914. Although Knut Wicksell was professor of economics and fiscal law in Lund at that time (1901–16), Lindahl did not have any personal contact with him during this period. However, Emil Sommarin, the successor to Wicksell’s chair (1916–39) and at the time of Lindahl’s student years docent (reader) in economics and a great admirer of Wicksell, succeeded in encouraging Lindahl to study the former’s works to such an extent that the latter became in effect the first pupil of Wicksell. As Lindahl's dissertation of 1919, Die Gerechtigkeit der Besteuerung, was largely based on Wicksell's theory of public finance (1896), Sommarin let Wicksell read and comment on it, and, at the public defence of the thesis at Lund University on 13 December 1919, Wicksell officiated as the official ‘challenger’ appointed by the faculty of law (Lindahl, 1951, pp. 26–7).

With his doctoral thesis Lindahl had earned the title docent in public finance at Lund University (1920) and later also in economics and fiscal law at Uppsala University (1924), but not yet the position of a professor. In 1926 he became responsible for the planning of the voluminous investigations on Wages, Cost of Living and National Income in Sweden 1860–1930 (see Lindahl, 1937a; and Benny Carlson, 1982, pp. 11–20) carried on in the following decade at the Institute for Social Sciences in Stockholm University and financed by the Rockefeller Foundation. In his attempts to obtain a chair in economics Lindahl failed twice: in 1924 he lost the competition for a professorship at the University of Copenhagen to Bertil Ohlin, later his colleague in the Stockholm School, and in 1930 he was ranked as number two only for a chair in political economy and sociology at Gothenburg University, this time defeated by Gustaf Åkerman, like Lindahl an early pupil of Wicksell.

Only two years later, however, in 1932, Lindahl obtained the chair in political economy at the Gothenburg School of Business Economics without application, and from this time onwards Swedish universities competed to call him to their departments of economics. In 1939, the year of publication of his most famous work, Studies in the Theory of Money and Capital, he succeeded Sommarin at Lund University, and in 1942 he became professor at the University of Uppsala, where he retired in 1958. Internationally, Lindahl's outstanding position as economist was honoured by his election as President of the International Economic Association in 1956.

Lindahl's growing reputation from the early 1930s onwards also led to numerous calls for economic expertise by Sweden's governments and official institutions. When Sweden left the gold standard in 1931 he became an adviser to Riksbanken, the Swedish central bank. When as a result of the Great Depression the final report of the Swedish Unemployment Committee had to be given a theoretical foundation of its proposal for public works as remedy against unemployment (see Hammarskjöld, 1935, p. ix and ch. 1; Otto Steiger, 1971, p. 40; and Bent Hansen, 1981, pp. 266–7) and when, therefore, the
character of Sweden's budget system had to be superseded in 1937 by a system deliberately designed to operate in a countercyclical manner (see Lindahl, 1935; cf. 1939a, app.), his expertise was sought by the Minister of Finance. Lindahl also became an economic adviser to the League of Nations (1936–9) and on two occasions to the United Nations (1949–50 and 1952–4).

Lindahl's work can be said to cover four major areas: (a) public finance; (b) methods of dynamic analysis; (c) monetary and macroeconomic theory; and (d) concepts of income and capital. Although Lindahl did not neglect empirical research, especially in public finance and national accounting, his contributions concentrated mainly on pure economic theory (see the detailed bibliography by Gertrud Lindahl and Olof Wallmén, 1960).

### Public finance

Lindahl started his scientific career with a treatise on ‘just taxation’, his doctoral dissertation of 1919, which built on Wicksell (1896) and which, together with two re-examinations in 1928 and 1959, made it a pioneering contribution to the economic theory of the public household, today known as the ‘Wicksell–Lindahl paradigm of just taxation’ (Heinz Grossekettler, 2006, p. 557; for more detail see Peter Bohm, 1987, and John Roberts, 1987). It can be characterized as a culmination of the neoclassical reformulation of the classical version of the benefit approach to the simultaneous determination of public revenue and expenditure – a reformulation which applied a new interpretation of the benefit rule as a condition of equilibrium instead of as a standard of justice as in the classical version.

Lindahl formulated this condition in a partial equilibrium framework, where ‘financial equilibrium’, that is, the equilibrium of public finance, is determined by equalization of the ratio of prices paid by each taxpayer for public and for private goods to his marginal benefits derived from public and from private goods, the equilibrating financial process brought about by the political mechanism in a parliamentary democracy (cf. Roberts, 1987). Lindahl was convinced that his model could explain voting behaviour and the influence of pressure groups on decisions of the government concerning public expenditures and taxes (Bohm, 1987, p. 201). However, this ‘voluntary exchange approach’ (Richard A. Musgrave, 1959, pp. 73–8) for a long time failed to meet with much understanding. The importance of Lindahl's pathbreaking contribution was first acknowledged in the 1950s via the works on the pure theory of public expenditure of Paul A. Samuelson (1954) and Musgrave (1959) as well as by the English translation of important parts of his dissertation of 1919 in 1958 in the volume *Classics in Public Finance*, edited by Musgrave and Alan T. Peacock. In the 1970s and the 1980s, however, Lindahl's model came under attack. It was criticized for relying on the ‘implausible assumption that each agent is perfectly informed about the other's preferences’ (Roberts, 1987, p. 200), and also for lacking empirical relevance in face of today's, unlike in Lindahl's time, ‘considerable amount of taxes raised for income distribution purposes’ (Bohm, 1987, p. 201).

### Methods of dynamic analysis

Lindahl's contributions to dynamic method were formulated as part of the theoretical core of his macroeconomic ideas, culminating in 1939 in his *Studies in the Theory of Money and Capital*. As has
been shown by Björn Hansson (1982; cf. 1987; 1991, pp. 168–202; and Jan Petersson 1987). Lindahl's dynamic theory was developed by mutual influence within the Stockholm School, with himself and Myrdal as the key figures and mainly independent not only from influences from other contemporary economists but also – contrary to William P. Yohe (1959) – from Wicksell.

Already in his first macroeconomic treatise, the first edition of Penningspolitikens mål ([The aims of monetary policy], 1924, ch. 3), Lindahl stressed the time factor as a problem for economic analysis and used the notion of ‘subjective calculations of the future’ and also the term ex post (p. 33). A first coherent dynamic method was formulated in his treatise on capital theory (1929a; cf. 1939a, pt. III), where Lindahl developed the famous notion of intertemporal equilibrium, that is, the analysis of the sequential character of an economy by a sequence of periods with equilibrium in each period as a consequence of the assumption of perfect foresight. This approach has been praised by Gérard Debreu (1959, p. 35) as being ‘the first mathematical study of an economy whose activity extends over a finite number of elementary time-intervals’. However, as has been pointed out later (Murray Milgate, 1982, pp. 133–5), Friedrich A. Hayek had been moving on similar lines one year earlier. But this does not disturb the claim of Lindahl's originality, because a comparison of the 1929 and 1930 editions of his Penningspolitikens medel [The means of monetary policy] clearly shows that Lindahl became aware of Hayek's approach first after having worked out his own concept – Hayek's 1928 paper is referred to only in the second (1930, p. 11), not in the first edition (1929c, p. 10).

As has been shown by Hansson (1982, ch. 4, pp 59–67; 1987, pp. 504–5), Lindahl's formulation of intertemporal equilibrium, however, does not really represent a sequential process, since all prices and quantities are determined simultaneously at the beginning of the process for all periods. Lindahl became aware of this weakness when, under the influence of Myrdal's explicit introduction of expectations in equilibrium theory (1927, ch. 1), in the last section of his treatise on capital theory (1929a, pp. 80–1; cf. 1939a, pt. III, pp. 348–50) he substituted imperfect for perfect foresight. In Penningspolitikens medel (1930, pp. 18–24, 31–2; cf. 1939a, pt. II, pp. 158–9) Lindahl abandoned therefore, for the case of imperfect foresight, the method of intertemporal equilibrium for the notion of temporary equilibrium, that is, the analysis of the sequence of an economy as a series of very short periods of temporary equilibria with changes allowed only at the transition points of the periods. This notion looks closely akin to John R. Hicks's dynamic analysis in Value and Capital (1939, ch. 9) which in fact had been influenced decisively by Lindahl via personal contacts in 1934 and 1935, as later acknowledged by Hicks (cf. 1973, p. 8; 1985, pp. 66, 69; 1991, pp. 372–6; and Claes-Henric Siven, 2002, pp. 142–5).

More important in a historical perspective, however, is the striking fact that general equilibrium theorists, from the late 1960s onwards, began to give up their mathematically more elaborated intertemporal equilibrium models of Arrow–Debreu type and to develop different notions of temporary equilibrium for very much the same reason as Lindahl in 1929 and 1930: recognition of the fact that intertemporal equilibrium does not reflect the sequential character of an economy in an essential way and the impossibility of handling imperfect foresight, that is, problems involving uncertainty and money. However, under the influence of the criticism of his approach by Lundberg in 1930 and Myrdal in 1932 and 1933, Lindahl realized that even with the notion of temporary equilibrium there was no real causation between the periods when he applied this dynamic method to the analysis of the saving–investment mechanism during a Wicksellian cumulative process, since the equilibrium approach in the construction of temporary equilibrium cannot handle unforeseen events during a period. Therefore, he
abandoned this notion and formulated instead the method of *sequence analysis*. This was done in the first part, Section 1, of his *Studies* (1939b, pp. 21–69), but a fully developed sequence analysis had already been presented in two unpublished papers of 1934a (published in Steiger, 1971, pp. 204–11) and 1935 (cf. Hansson, 1982, ch. 9). Furthermore, in Section 2 of the first part of his book Lindahl was the first economist who, in an extensive algebraic discussion of the relations between fundamental economic concepts (1939b, pp. 74–136), made the methodologically important distinction between ‘micro-economic’ and ‘macro-economic terms’ (p. 74) by which he tried to base the relations between macro values on some kind of microeconomic behaviour (pp. 111, 125; cf. Svennilsson, 1938, ch. 1; Siven, 1991, pp. 155–6; and Jens Christopher Andvig, 1991, p. 414). As shown by Hal R. Varian (1987, p. 461), this innovation has been wrongly attributed to Ragnar Frisch who, in an article of 1933 (pp. 172–3), had used the related terms ‘micro-dynamic’ and ‘macro-dynamic analysis’ in which he, however, ‘was uninterested in the problems of microeconomic roots’ of macroeconomics (Andvig, 1991, p. 415).

Incorporating the method of *ex ante* and *ex post* (cf. Steiger, 1987a) developed by Myrdal (1932; 1933) in his disequilibrium analysis and adopted by Ohlin (1934, ch. 1), where the former had criticized Lindahl's method of temporary equilibrium, and taking care of the sequence analysis of consecutive periods formulated by Hammarskjöld (1933a; 1933b, chs 1–5) and Svennilsson (1938, ch. 1), Lindahl's dynamic method in 1939b consisted of two parts: (a) a single-period analysis where *ex ante* plans determine *ex post* results; and (b) a continuation analysis where these *ex post* events lead to revised *ex ante* plans of a subsequent period. While Lindahl allowed for disequilibrium as long as he analysed a single period only, his analysis for several periods demanded equilibrium within each period. Because of this assumption Lindahl's sequence analysis – although it can be regarded as the first dynamic method with a meaningful sequential character, that is, not relying on the mutual interdependence of all events – did not imply the solution to the dynamic problem of establishing a convincing explanation of the causal connection between successive periods. In the end, while acknowledging Myrdal's plea for disequilibrium analysis, Lindahl hesitated to rely on the ‘cumbersome *ex ante* and *ex post* terminology’ (1939b, p. 68; cf. 1939c, pp. 264–5) because of its ‘analytical complexity’ (Siven, 2006b, p. 694; cf. 1985, p. 590; and Hansen, 1981, p. 274).

It was left to Lundberg's sequence analysis of 1937 (ch. 9) to overcome this limitation by allowing for disequilibrium within the different periods with the help of the assumption of constant expectation functions (cf. Hansson, 1982, ch. 10). Lindahl accepted Lundberg's method in his *Studies* (1939b, pp. 57–9), but was not keen on the time-related model sequences based on difference equations which were incorporated in the latter's construction. On the contrary, this dynamic method was rejected by Lindahl because of its mechanical character resulting from the assumption that expectations need not enter explicitly. However, it was exactly this approach which came to dominate dynamic theory until the late 1960s when general equilibrium theorists reintroduced the notion of temporary equilibrium and developed dynamic models which look very similar to Lindahl's sequence analysis (for example, Frank H. Hahn, 1980).

**Monetary and macroeconomic theory**

While Lindahl's contributions to dynamic analysis were formulated independently of Wicksell, his work
on monetary and macroeconomic theory was clearly derived from the latter (1898; 1906). This influence can be traced back as far as Lindahl's first treatise on monetary matters, *Penningpolitikens mål* (1924; 1929b), where he systematized and extended the concepts used in the Swedish controversy between Wicksell and David Davidson before and after the First World War on the aim of monetary policy being to preserve the real value of contracts, that is, Wicksell's desideratum of a constant price level versus Davidson's proposal of price level variations in inverse proportion to changes in productivity (cf. Hammarskjöld, 1944; Carl G. Uhr, 1960, pp. 270–305; Klas Fregert, 1993; and Siven, 2002, 124–9).

While Lindahl's analysis is worked out along Wicksellian lines, he ends up with Davidson's and not Wicksell's solution by showing that the latter's proposition of a 'normal' rate of interest, that is, the particular level of the money rate which is equal to the ‘natural’ rate, determined by the marginal productivity of capital, does not hold for a constant price level in the face of productivity variations. A more systematic treatment of Wicksell's concept of the normal rate was given in *Penningpolitikens medel* (1930, pp. 121–30; cf. 1939a, pt. II, pp. 245–57), where Lindahl was the first to show that this notion implies three different conditions for equilibrium: ‘(1) it corresponds to the natural or … the real rate of interest; (2) it establishes equilibrium between the demand for and supply of saving [that is, investment and savings]; and (3) it is neutral in relation to the price level – whereas a rate of interest above or below “normal” will influence the price level in a downward or upward direction’ (1939a, pt. II, p. 246; cf. 1930, p. 122). It was this formulation which inspired Myrdal's famous reconstruction of Wicksell's normal rate (1932; 1933; 1939) in which the three conditions were characterized as monetary equilibrium (cf. Steiger, 1987c, p. 507; Siven, 2006a, pp. 11–12; 2006b, pp. 672–4).

However, in the central part of *Penningpolitikens medel*, the analysis of the relation between the rate of interest and the price level, Lindahl (1930, pp. 131–4; cf. 1939a, pt. II, pp. 257–60; and 1939c, pp. 260–8) did not employ the notion of the normal rate, because his explicit consideration of expectations showed him the impossibility of a unique equilibrium rate irrespective of the rate of change of the level of prices – a reasoning very similar to John Maynard Keynes's emphasis in the *General Theory* (1936, pp. 242–4) that there are different normal rates for different levels of employment. Instead, Lindahl explained changes in the general price level with the help of another concept introduced by Wicksell (1906, p. 159): the approach of aggregate demand and supply. In Lindahl's formulation of this approach changes in the price level were determined by changes in the relation between the total demand for and the total supply of consumption goods, the total demand for consumption goods being defined as ‘the portion of the total nominal income which is not saved’, \( E (1 - s) \) where \( E \) denotes total nominal income and \( s \) the ratio of saving to income, and the total supply defined as \( PQ \), where \( P \) denotes the price level and \( Q \) the quantity of consumer goods of a certain period (1930, pp. 12–13; cf. 1939a, pt. I, pp. 142–3). In general, he never analysed imbalances in macroeconomic variables ‘caused by “wrong” relative prices’ (Siven, 2002, p. 141). Using Wicksell's suggestion of a perfect credit system, this approach left no room for the quantity of money either, and it was indeed, in Lindahl's analysis of the issue of money by the central bank, directed against the quantity theory of money, although he did not deprive it of all significance for the theory of money (cf. 1929d, p. 18; 1955, pp. 32–4). In fact, as has been first emphasized by Hansen (1979, p. 123) and later confirmed by Axel Leijonhufvud (1991, p. 464) and Lars Werin (1991, p. 178) as well as Mauro Boianovsky and Hans-Michael Trautwein (2006, pp. 881–2, 888–95), Lindahl in his later writings (cf. 1957, pp. 13–15, 19–21) was ‘a true monetarist’ and the first one to formulate the ‘accelerationist’ hypothesis in inflation theory offered a decade later by Edmund S. Phelps.
Lindahl, Erik Robert (1891–1960) : The New Palgrave Dictionary of Economics (1967) and Milton Friedman (1968). This hypothesis lies also at the heart of Lindahl's critical reformulation of *The General Theory*, in which he criticized Keynes's method of comparative statics in the equilibration of savings and investment by changes in income and employment, because it presupposes ‘correct anticipations’ (Lindahl, 1953, p. 27; cf. already 1934a, pp. 209–10; 1939c, pp. 264–5). Instead, Keynes should have relied on the dynamic analysis of changes of monetary and real variables where, like in his own analysis, expectations are allowed to adapt to the changes, but where expectational errors may nevertheless have effects that alter the equilibrium rates of interest and (un)employment (cf. Boianovosky and Trautwein, 2006, p. 897). It is most interesting to note that Keynes (1934), in a correspondence with Lindahl (1934b) on the latter's paper of 1934a, rejected Lindahl's method because its ‘dealing with time leads to undue complications and will be very difficult either to apply or to generalise about’.

Although Lindahl did not attempt to explicitly explain changes in output and employment, his aggregate analysis resulted in achievements which paved the way for Myrdal's (1932; 1933; 1939) and Ohlin's (1933; 1934, chs 1–3) monetary approaches, and which are still important for modern macroeconomics: (a) the use of the savings ratio \( s \) in the expression \( E(1 – s) \) which related saving to expected income and which can be regarded as an alternative formulation of Keynes's (1936) propensity to consume, led to a definite distinction between saving and investment, with Lindahl (1929c, pp. 11–12, written in 1927–28; cf. Hansen, 1981, p. 261) being the first economist to see the independence of the latter from the former variable; (b) their distinction allowed him to divide aggregate income into saving and consumption demand and aggregate output into investment and consumer goods; (c) the ‘paradox of savings’ could be solved according to which a reduction in savings results in increased savings; (d) the assumption of unused resources was introduced (1930, pp. 42–51; cf. 1939a, 176–9 and 185–6), and unemployment was explained by deflation caused by a fall of aggregate demand where even the possibility of a stable unemployment equilibrium was visualized (1929c, pp. 43–4; 1930, p. 44); however, deleted in 1939a, pt. II; cf. Hansen, 1981, pp. 261–3). Compared with Keynes's principle of effective demand determining the equilibrium level of (un)employment there are, however, certain limitations in Lindahl's aggregate demand/supply approach: (a) unemployment equilibrium was considered only as an ‘exceptional case’, with – like in the other Stockholm School analyses on the relation between unemployment and wages (esp. Alf Johansson, 1934, ch. 5) – ‘rigid money wages as a necessary condition for’ and no ‘complete macro model of unemployment’ (Hansen, 1981, pp. 268–9; cf. Siven, 2002, p. 141); (b) the rate of interest was treated in its orthodox role as equilibrator of savings and investment in the long run; (c) saving and investment were not equilibrated by changes in aggregate income but by variations in its *distribution* (cf. the discussion initiated by Karl-Gustav Landgren, 1960, ch. 6:3; and followed up by Steiger, 1971, pp. 173–9; 1978, pp. 424–5; 1991, 129–30; Hansen, 1981, pp. 261–3; Don Patinkin, 1982, pp. 44–6; and Johan Myrman, 1991, pp. 272–6). In the analysis of this adjustment process, however, Lindahl was able to anticipate the whole neo-Keynesian or Kaldor–Pasinetti theory of distributive shares (cf. Guglielmo Chiodi and Kumaraswamy Velupillai, 1983; Velupillai, 1988).

On the other side, the equilibrating role of changes in total income with respect to saving and investment is implicit in Lindahl's sequence analysis of 1934 (1934a, pp. 208–11), where he showed how a difference between investment and saving *ex ante* leads to their *ex post* equality, and it was clearly visualized in his discussion of loan-financed public works as a means against unemployment (1932, pp.

136–7; 1935, pp. 1–5; cf. 1939a, app., pp. 356–67). As has been pointed out by Hansen (1955, p. 41), Lindahl in *Penningpolitikens medel* (1930, pp. 63–8; however, deleted in 1939a, pt. II) was the first economist to consider the possibility of a systematic use of variations in the relation between public expenditures and public incomes, that is, the budget balance, as a means to stabilize economic fluctuations because, as he recognized, a surplus in the balance can be defined as equivalent to state saving and a deficit as state investment (1930, p. 65). With this analysis he paved the way for Ohlin's (1934, ch. 5) and Myrdal's (1934, pts III–IV) more detailed analysis of loan-financed public works as remedies against unemployment. Unlike Keynesian economists, however, Lindahl in this discussion did not neglect the effects of such a fiscal policy for the national debt which he analysed in detail in 1944 (cf. 1946). There he formulated rules governing state borrowing which are very similar to those developed at the same time by Evsey D. Domar (1944), that is, that the problem of public debts is first and foremost a problem of the growth of national income.

Another innovation in Lindahl's monetary and macroeconomic theory was his discussion of how to organize the central banking system in a monetary union of independent nations (cf. 1930, pp. 170–9; however, deleted in 1939a, pt. II). As recently recognized by Gunnar Heinsohn and Steiger (2003, p. 13; cf. Steiger, 2007, pp. 43–5), Lindahl was the first economist to develop the model of a decentralized, two-stage central banking system for a common currency consisting of a main central bank and the national central banks, where the latter would receive the banknotes in the same way from the former like the domestic commercial banks of their national central bank. With this model he hoped to open the possibility for the main central bank to equilibrate differences in real rates of interest due to different rates of inflation between the union's members by allowing for differences in nominal rates of interest. With this proposal, Lindahl anticipated the central Achilles’ heel of the Eurosystem, the central banking system of the European Monetary Union (EMU), where its Council can decide only on a unique nominal rate of interest (cf. Dieter Spethmann and Steiger, 2005, pp. 55–8). Furthermore, in spite of its name, the European Central Bank is not designed for issuing money and, therefore, not the central monetary authority of the EMU that could push through such a differentiation of credit. In his model, Lindahl (1930, p. 171) also demonstrated the necessity of a central fiscal authority in a monetary union to support the main central bank – another problem that has not been solved in the EMU (cf. Heinsohn and Steiger, 2003, pp. 13, 39).

**Concepts of income and capital**

While Lindahl's contributions to macroeconomic theory have been discussed extensively in the literature on the Stockholm School, his work on the macroeconomic concepts of income and capital have not received much attention (cf. Yohe, 1962).

The discussion of the notions of capital and income in Lindahl's theoretical framework stemmed from two different roots: (a) the approach to capital theory conceiving capital goods as stored services of land and labour, originally formulated by Eugen von Böhm-Bawerk (1889) and developed by Wicksell (1893; 1901) and Gustaf Åkerman (1923–4); and (b) the approach to the concept of income regarding income as a flow of benefits from the stock of capital and introduced into economic theory by Irving Fisher (1906). Both approaches had in common that *time* was included in a decisive manner and in

In his piece on capital theory where he had introduced the method of intertemporal equilibrium (1929a; 1939a, pt. III), Lindahl avoided the theoretical difficulties of working with the concept of total capital in a world of heterogeneous capital goods by developing a completely disaggregated stationary equilibrium system—a ‘Walrasian model with capital à la Wicksell’ and with ‘a striking similarity’ to John von Neumann’s model of equilibrium growth of 1937 (Hansen, 1970, pp. 199, 207–8). Although Lindahl did not make use of the concept of total capital in his equilibrium system, it can be shown that its total capital value can be determined on the basis of the term ‘income’ employed in his model—an insight which Lindahl formulated unequivocally in Penningpolitikens medel (1930, pp. 13–15; cf. 1939a, pt. II, pp. 143–6) and in more detail in his contributions on the concept of income (1933; 1937b, pp. 76–111).

Starting from Irving Fisher’s basic premise that income consists of the services obtained from capital goods during a certain period, whereas capital is a stock existing at a given point of time, Lindahl (1933, pp. 400–1) looked upon income as interest accruing on the value of capital goods, and considered capital value as future income discounted. With this concept of income, implying that income is equal to the sum of consumption and saving, he solved the inconsistencies in Fisher’s analysis of capital and income where saving, a flow term expressing the increase in capital value, had been excluded from income and incorporated into capital, a stock term. Consequently, Lindahl’s discussion also made clear that changes in capital value, contrary to what had been the premises of Böhm-Bawerk, Wicksell and Åkerman, are not determined by changes in the use of capital but in the use of income, that is, the part which is not consumed: saving.

However, as Lindahl realized, this thesis holds true only under the assumption of perfect foresight. Following Myrdal’s analysis of expectations of 1927, he showed that as soon as uncertainty about future events is introduced changes in anticipation of owners of capital assets lead to changes in capital value by gains and losses which cannot be regarded as positive or negative income, because like the stock of capital they refer not to a certain period but to a point of time (1929a, p. 75; 1939a, pt. III, p. 341; cf. Myrdal, 1927, p. 44, and the further discussion in Lindahl, 1939b, pp. 101–10). This insight led Lindahl to abandon the most practical concept of income—income as earnings—because it included gains and losses. Although Lindahl’s concept of income—like his abstract classification of capital goods (Hansen, 1970, p. 200)—has been criticized for not being capable of empirical application and measurement, his contributions—together with Myrdal’s approach of 1927—have been acknowledged as ‘the fundamental theoretical work concerning the notion of income’ (Nicholas Kaldor, 1955, p. 162). This work should also become fundamental to Lindahl’s research on national accounting (1937b; 1939b, pp. 74–136; 1954) which made him ‘the father of Social Accounting theory’ (Hicks, 1973, p. 8; cf. Carlson, 1982, 33–6).

During his lifetime—and until the late 1980s—Lindahl never earned a reputation comparable to that of his colleagues in the early Stockholm School, Gunnar Myrdal and Bertil Ohlin, and it has been argued by one of his younger colleagues (Lundberg, 1982, p. 275) that his contributions to economics were not distinguished by ‘ingenious ideas’ like those of Myrdal and Ohlin. As has been shown in this survey of Lindahl’s work, however, the numerous original ideas in each of the four fields covered by his writings argue for quite different judgement. This holds especially true for Lindahl’s monetary and macroeconomic theory, as has been demonstrated since the late 1980s by Boianovsky and Trautwein (2006), Leijonhufvud (1991), Siven (1991; 2002; 2006a; 2006b), Steiger (1987a; 1987b; 1987c; 2006a;
The author wishes to thank Claes-Henric Siven (Stockholms Universitet) and Hans-Michael Trautwein (Universität Oldenburg) for valuable suggestions

linear models

Edwin Burmeister

Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Von Neumann's linear economic model was first published in German in 1938 and translated into English in 1945. Since then there have been numerous economic and mathematical refinements, most of which are summarized in Burmeister and Dobell (1970) and/or Morishima (1969). The original von Neumann formulation did not admit either primary factors or final consumption. However, in the generalized von Neumann model described below, one primary factor, labour, is allowed, as well as a vector of final consumption goods. A further generalization allowing a vector of different primary factors is possible. Accordingly, linear models of Leontief–Sraffa (1960) type become a special case.

Assume there exist \( m \) alternative production activities for producing \( n \) different commodities, where \( m \times n \). Activity \( j \) operating at a unit intensity level requires a labour input \( a_0j \) and a vector of commodity inputs \( (a_1j, a_2j, \ldots, a_nj) \) to produce a vector of commodity outputs \( (b_1j, b_2j, \ldots, b_nj) \). Production takes one time period, so inputs at time \( t \) result in outputs at time \( t+1 \). Constant returns to scale is implied by linearity, and inputs \( \lambda a_0j \) and \( (\lambda a_1j, \lambda a_2j, \ldots, \lambda a_nj) \) yield outputs \( (\lambda b_1j, \lambda b_2j, \ldots, \lambda b_nj) \) for all \( \lambda \geq 0 \).

The vector of labour requirements for the \( m \) alternative production activities is written as \( A_0 = (a_{01}, a_{02}, \ldots, a_{0m}) \). The input matrix is

\[
[ A_0 ] = \begin{bmatrix}
a_{01} & \cdots & a_{0m} \\
a_{11} & \cdots & a_{1m} \\
\vdots & \ddots & \vdots \\
a_{n1} & \cdots & a_{nm}
\end{bmatrix}
\]

the output matrix is
and the intensity levels at which each of the $m$ production activities is operated is given by the column vector

$$g = \begin{bmatrix} b_{11} & \cdots & b_{1m} \\ \vdots & & \vdots \\ b_{n1} & \cdots & b_{nm} \end{bmatrix}$$

Although in general some of the $a_{ij}$'s, $a_{0j}$'s and $b_{ij}$'s may be zero, here we assume that they are all positive; we thereby avoid some technical difficulties and gain expositional simplicity. Assume that labour grows at the rate $g \geq 0$,

$$L(t + 1) = (1 + g)L(t),$$  \hfill (1)

and is fully employed with

$$L(t) = A_0(t)x(t).$$  \hfill (2)

For all $t$ production must satisfy the resource constraint

$$Ax \leq Bx - C$$  \hfill (3)

where $C$ denotes the column vector of commodities consumed.
The economy is capable of producing positive final consumption and balanced growth at the rate $g$ provided the inequalities

\[(1 + g)A x \leq Bx - C, \quad C \geq 0, \quad C \neq 0 \]
\[x \geq 0, \quad x \neq 0 \]

are satisfied.

Prices for a unit of labour services and the $n$ commodities are given by $p_0 = w$ and the row vector $p = (p_1, p_2, \ldots, p_n)$, respectively, where

\[\sum_{i=0}^{n} p_i = 1\]

is one convenient normalization. The steady-state (or balanced growth) rate of interest (or profit rate) is denoted by $r$.

The economy can achieve a steady-state equilibrium at a given value of $r \geq 0$ if the von Neumann price system has a solution satisfying the inequalities

\[wA_0 + (1 + r) pA \geq pB, \quad w \geq 0, \quad w \neq 0 \]
\[p \geq 0, \quad p \neq 0 \]

are satisfied.

The quantity system (4) is dual to the price system (5) when $r=g$.

The von Neumann solution to (5) involves three economically essential inequalities:
(i) If the cost of operating an activity exceeds the revenue from that activity, then that activity is not used in a steady-state equilibrium solution, that is that activity is operated at a zero intensity level. Formally,

\[ x_j = 0 \text{ if } w_{i0} + (1 + r) \sum_{i=1}^{n} p_{i} a_{ij} > \sum_{i=1}^{n} p_{i} b_{ij}, \quad j = 1, \ldots, m. \quad (6) \]

(ii) If a commodity has a positive price, then its supply and demand are equal:

\[ (1 + g) \sum_{i=1}^{m} a_{ij} x_j = \sum_{j=1}^{m} b_{ij} x_j - C_i \text{ if } p_i > 0, \quad i = 1, \ldots, n. \quad (7) \]

(iii) The price of a commodity is zero if it is in excess supply:

\[ p_i = 0 \text{ if } (1 + g) \sum_{i=1}^{m} a_{ij} x_j < \sum_{j=1}^{m} b_{ij} x_j - C_i, \quad i = 1, \ldots, n. \quad (8) \]

The above generalized von Neumann model is not a general equilibrium model because there is one missing equation. Some behavioural equation involving the rate of interest and consumption is required to form a general equilibrium model. Nevertheless, this incomplete specification can be used to confirm and generalize many well known results.

For example, in steady-state equilibrium equations (5), (6), (7) and (8) imply that

\[ (1 + g) Ax + pC = pBx = \text{value of output} = wA_0 + p(1 + r) Ax. \quad (9) \]

Using (2), the per capita value of commodity inputs or capital is given by
\[
\nu = \frac{\nu \mathbf{A} \mathbf{x}}{\mathbf{A}_0 \mathbf{x}}; \\
(10)
\]

Similarly the per capita value of consumption is

\[
\nu \mathbf{c} = \frac{\nu \mathbf{c}}{\mathbf{A}_0 \mathbf{x}}. \\
(11)
\]

Substituting (10) and (11) into (9) and rearranging yields

\[
\nu \mathbf{c} = \mathbf{w} + (r - g) \nu. \\
(12)
\]

The Golden Rule result that the value of per capita consumption is equal to the wage rate at the Golden Rule point where \( r = g \) is an immediate consequence of (12). Other such results are easily derived; thus allowing for the possibility of joint production does not invalidate many economic results.

Two familiar classes of models are special cases of this generalized von Neumann model. First, Leontief–Sraffa models result simply by setting \( m = n \) and \( B = I \), which implies that the technology is free of joint production. Then if \( p > 0 \) from (7)

\[
\mathbf{c} = [I - (1 + g) \mathbf{A}] \mathbf{x} \\
(13)
\]

where now the column vector \( \mathbf{x} \) is interpreted as the output vector for commodities \( 1, \ldots, n \). Provided (4) has a solution, (13) may be solved for

\[
\mathbf{x} = [I - (1 + g) \mathbf{A}]^{-1} \mathbf{c}, \\
(14)
\]
and premultiplying (14) by the vector $A_0$ gives the consumption possibility frontier

$$A_0 x = L = [I - (1 + g) A]^{-1} C.$$  
(15)

Similarly, steady-state equilibrium prices for the Leontief–Sraffa model are given by

$$p = w A_0 [I - (1 + r) A]^{-1}.$$  
(16)

Second, most neo-Austrian models of the type studied by Hicks (1973a) are a special case of this generalized von Neumann model. The latter fact is most easily demonstrated by considering the simple numerical example due to Burmeister (1974). A neo-Austrian process is a time sequence of input–output vectors

$$\{(a_t, b_t)\}_{t=0}^T$$  
(17)

where $a_t$ is the input of a commodity and $b_t$ is the output (of the same commodity) in period $t$. Consider a process

$$\{(a_t, b_t)\}_{t=0}^2 = \{(a_0, 0), (a_1, b_1), (a_2, 1)\}.$$  
(18)

The neo-Austrian model (18) is equivalent to a von Neumann specification with

We see, therefore, that the generalized von Neumann model is extraordinarily useful for unifying several apparently different ways of describing the production technology. However, when we do not restrict our attention to steady-state equilibria, the dynamic evolution of the model becomes extremely complex. The inequalities (4) and (5) must be satisfied for each $t$, as well as some additional equation to determine the interest rate $r$. Known results on the dynamics of models with heterogeneous capital goods – see, for examples the discussion and references cited in Chapters 5 and 6 of Burmeister (1980) – warn us that the task of completely characterizing the dynamic properties of von Neumann models will not be easy. The fact that the von Neumann formulation admits joint production makes the task even harder.

linear programming

George B. Dantzig
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

An article by George Dantzig, the ‘father of linear programming’. The problem of minimizing or maximizing a function of several variables subject to constraints when all the functions are linear is called a ‘linear program’. Linear programs can be used to approximate the broad class of convex functions commonly encountered in economic planning. Thousands of linear programs are efficiently solved with the simplex method, an algorithm. Solving a model with alternative activities requires software not only for solving on computers large systems of equations but also for selecting the best combination from an astronomical number of possible combinations of activities.

Keywords

bimatrix games; convex program; Dantzig, G.; decomposition principle; Dantzig, G. B.; Kantorovich, L. V.; Koopmans, T. C.; Kuhn–Tucker conditions; Lagrange multipliers; Leontief input–output model; linear programming; mathematical programs; mini-max theorem; mixed strategies; simplex method for solving linear programs; von Neumann, J.

Article

A list of applications of linear programming, since it was first proposed in 1947 by G. Dantzig, could fill a small volume. Both J. von Neumann and L. Kantorovich made important contributions prior to 1947. Its first use by G. Dantzig and M. Wood was for logistical planning and deployment of military forces. A. Charnes and W. Cooper in the early 1950s pioneered its use in the petroleum industry. S. Vajda and E.M.L. Beale were early pioneers in the field in Great Britain. In socialist countries, it is used to determine the plan for optimal growth of the economy. Thousands of linear programs are efficiently solved each day all over the world using the simplex method, an algorithm, also first proposed in 1947. Many problems which once could only be solved on high-speed mainframe computers can now be solved on personal computers.

The problem of minimizing or maximizing a function $f_0$ of several variables $X = (X_1, X_2, \ldots, X_n)$ subject to constraints $f_i(X) \leq 0$, $i = 1, \ldots, n$ is called a mathematical program. When all the functions $f_i$ are linear, it is called a linear program; otherwise a non-linear program. If all $f_i$ are convex functions, it is called a convex program. At first glance, linear inequality systems appear to be a very restricted class. However, as pointed out by T. C. Koopmans as early as 1948, linear programs can be used to approximate the broad class of convex functions commonly encountered in economic planning.
Linear programs may be viewed as a generalization of the Leontief Input–Output Model, one important difference being that alternative production processes (activities) are allowed to compete; another being the representation of capacity as an input that becomes available at a later point in time as an output (possibly depreciated). Solving a model with alternative activities requires not only software for efficiently solving on computers large systems of equations as in the Leontief case, but also software for selecting the best combination from an astronomical number of possible combinations of activities. (See the entry simplex method for solving linear programs.)

Formulating a linear program

Finding an optimal product mix (for example blend of gasoline, or metals, or mix of nuts, or animal feeds) is a typical application. For example, a manufacturer wishes to purchase at minimum total cost a number of solder alloys $A, B, C, D$ which are available in the marketplace in order to melt them down to make a blend of 30 per cent lead, 30 per cent zinc, and 40 per cent tin. Their respective costs per pound are shown in Table 1.

<table>
<thead>
<tr>
<th>Alloy</th>
<th>Composition</th>
<th>A</th>
<th>B</th>
<th>C</th>
<th>D</th>
<th>Desired blend</th>
</tr>
</thead>
<tbody>
<tr>
<td>% Lead</td>
<td>10</td>
<td>10</td>
<td>40</td>
<td>60</td>
<td>30</td>
<td>30%</td>
</tr>
<tr>
<td>% Zinc</td>
<td>10</td>
<td>30</td>
<td>50</td>
<td>30</td>
<td>30</td>
<td>30%</td>
</tr>
<tr>
<td>% Tin</td>
<td>80</td>
<td>60</td>
<td>10</td>
<td>10</td>
<td>40</td>
<td>40%</td>
</tr>
<tr>
<td>Cost/lb</td>
<td>4.1</td>
<td>4.3</td>
<td>5.8</td>
<td>6.0</td>
<td>Minimize cost per pound</td>
<td></td>
</tr>
</tbody>
</table>

Suppose 100 pounds of blend is desired and $X_A, X_B, X_C, X_D$ are the unknown number of pounds of $A, B, C, D$ to be purchased. The problem to be solved is clearly: find $Z$ and $(X_A, X_B, X_C, X_D) \geq 0$, such that:

\[
\begin{align*}
0.1X_A + 0.1X_B + 0.4X_C + 0.6X_D &= 30 \\
0.1X_A + 0.3X_B + 0.5X_C + 0.3X_D &= 30 \\
0.8X_A + 0.6X_B + 0.1X_C + 0.1X_D &= 40 \\
4.1X_A + 4.3X_B + 5.8X_C + 6.0X_D &= Z_{\text{min}}
\end{align*}
\]

This example can be solved in a few seconds on a personal computer. The standard form of a linear program is: find min $z$, $x = (x_1, ..., x_n) \geq 0$:

\[Ax = b, \quad cx = z_{\text{min}}\]

where $A$ is a $m$ by $n$ matrix, $b$ a column vector of $m$ components and $c$ a row vector of $n$ components. The matrix $A$ of coefficients is referred to as the technology matrix.
One way to formulate a linear program is to begin by (a) listing various constraints such as resources availability, demand for various goods by consumers, known bounds on productive capacity; (b) listing variables to be determined representing the levels of activities whose net inputs and outputs must satisfy the constraints, and finally (c) tabulating the coefficients of the various inequalities and equations.

Since linear programming models can be very large systems with thousands of inequalities and variables, it is necessary to use a special software, called *matrix generators*, to facilitate the model building process. Such systems have millions of coefficients, fortunately most of them are zero. Matrices with very few nonzero elements are called *sparse*. The World Bank uses software called GAMS to generate moderate-size sparse matrices $A$ by rows. Another type of software called OMNI has been developed by Haverly Systems and has been used to generate very large sparse matrices by columns. When a model is formulated by columns, it is called *Activity Analysis*: the column of coefficients of a variable is the same as a recipe in a cook book – these are the input and output flows required to carry out one unit of an activity (or process). The variables, usually non-negative, are the unknown levels of activity to be determined. For example the activity of ‘putting one unit (pound) of solder alloy $A$ in the blend’ has an input of $4.10$ and outputs to the blend of $0.10\cdot $ lb of lead, $0.10\cdot $ lb of zinc, $0.80\cdot $ lb of tin.

In economic applications, *output* coefficients are typically stated with + signs and *input* coefficients with – signs. Under this convention, the signs of the coefficients of the $Z$ equation in the blending example should be reversed and, net revenues, $(-Z)$ maximized. In practice, instead of equations in non-negative variables, there can be a mix of equations and inequalities. Simple algebraic steps allow one to pass from one form of the system to another.

**Primal and dual statements of the linear program**

John von Neumann in 1947 was the first to point out that associated with a linear program is another called its *Dual*, formed by transposing the matrix $A$ and interchanging the role of the RHS $b$ and the ‘cost’ vector $c$. The original problem is called the *Primal*. Von Neumann expressed both of these LP in inequality form:

$$\begin{align*}
\text{Primal: min } \ z &= cX: AX \geq b, \ X \geq 0, \ (P) \\
\text{Dual: min } \ z &= Y^T b: Y^T A \leq c, \ Y \geq 0, \ (D)
\end{align*}$$

where $Y^T$ is the transpose of column vector $Y$.

If we denote the $j$th column of $A$ by $A^{(\ast,\ j)}$, the $n$ inequalities $Y^T A \leq c$ may be rewritten as $Y^T A^{(\ast,\ j)} \leq c_j$ for $j = 1, \ldots, n$.

(P) expresses the physical constraints of the system under study. The variables $Y$ of the dual (D) can be interpreted as *prices*. Mathematicians call them *Lagrange multipliers*. The dual conditions, $Y^T A^{(\ast,\ j)} - c_j \leq 0$ for $j = 1, \ldots, n$, may appear strange and just the opposite from what one would expect. They state that levels $X_j$ of all activities $j$ that show profit in the economy will rise to the point that all ‘price out’ nonprofitable. It turns out that when the value $z = Y^T b$ in (D) is maximized, all activities $j$ that are operated at positive levels will just break even, i.e., just ‘clear their books’ and that all activities $j$ operating at a strict loss will be operating at zero levels.

The famous duality theorem of von Neumann states that, when there exist ‘feasible’ solutions $AX \geq b, \ X \geq 0$ to (P) and $Y^T A \leq c, \ Y \geq 0$ to (D),

$$\begin{align*}
\text{Max } z &= \text{Min } z
\end{align*}$$
It is easy to prove that any feasible solutions to (P) and (D) not necessarily optimum satisfy

\[ z = y' \cdot b \leq cX = z, \]

so that if it happens that \( y^* \cdot b = cX^* \), for some feasible \( X = X^* \), \( y = y^* \) then by the duality theorem we know that such a pair \((X^*, y^*)\) are optimal solutions to (P) and (D).

This makes it possible to combine the primal and dual problems into the single problem of finding a feasible solution to the following: find \((X, \bar{X}, \gamma, \bar{\gamma}, \theta) \succeq 0; \)

\[
\begin{bmatrix}
0 & A & -b \\
-A' & 0 & \epsilon' \\
b' & -\epsilon & 0
\end{bmatrix}
\begin{bmatrix}
\gamma \\
X \\
1
\end{bmatrix}
=
\begin{bmatrix}
\bar{\gamma} \\
\bar{X} \\
\theta
\end{bmatrix}
\tag{P,D}
\]

where we have introduced two slack vectors \( \bar{\gamma} \succeq 0 \) and \( \bar{X} \succeq 0 \) which turn the inequality relations (P) and (D) into equality relations \( AX - \bar{\gamma} = b \) and \( Y^*A + \bar{X}' = \epsilon \). The last relation is the single equation \( Y^*b - cX = \theta \) where \( \theta \succeq 0 \) is a scalar.

It we multiply (P•D) by the vector \((\gamma', \bar{X}', 1)\) on the left and perform all the matrix multiplications, everything on the left side cancels out because of the skew symmetry of the matrix and we are left with

\[ 0 = [Y'X'] [\bar{\gamma}\bar{X} \theta]' = \sum_i Y_i \bar{\gamma}_i + \sum_j X_j \bar{X}_j + \theta. \]

Because all terms are non-negative, it follows that

\[ X_j \bar{X}_j = 0, \ Y_i \bar{\gamma}_i = 0, \ \theta = 0 \text{ for all } i \text{ and } j. \]
These are called *complementary slackness* or *Kuhn–Tucker* conditions for optimality.

**Zero-sum matrix games**

These games can be formulated as a special class of linear programs. The ‘row’ player chooses row $i$ of a matrix while his opponent, the ‘column’ player, simultaneously chooses column $j$. Column player wins an amount $a_{ij}$ if $\gamma^* j \geq 0$ otherwise he pays the other player $-a_{ij}$. The payoff matrix is $A = [a_{ij}]$. It is called a *zero-sum* game because the sum of the payments each player receives adds up to zero. Von Neumann analysed this game in 1928 and introduced the notion of a *mixed strategy* $(\gamma_1, \gamma_2, ..., \gamma_m)$, $(x_1, x_2, ..., x_n)$ which are the probabilities of the players choosing any particular row and column. He showed that there exist optimal mixed strategies, $\gamma = \gamma^*$ for the row player and $x = x^*$ for the column player, such that if a player’s mixed strategy is discovered by his opponent, it will have no effect on his expected payoff and hence no effect on the expected payoff of his opponent which is the negative of his.

The column player, if he plays conservatively and assumes his mixed strategy will become known to his opponent, will choose his probabilities $x_j \geq 0$ so as to maximize $L$ where Max $L$ and $x \geq 0$ are chosen so that

$$\sum_j a_{ij} x_j \geq L, \ x_j \geq 0, \ i = 1, ..., m; \sum_j x_j = 1.$$

(C)

Likewise the row player's-optimal mixed strategy, if he plays conservatively, will choose his probabilities $\gamma_i \geq 0$ so as to minimize $K$ where Min $K$ and $\gamma \geq 0$ are chosen so that

$$\sum_i \gamma_i a_{ij} \leq K, \ \gamma_i \geq 0, \ j = 1, ..., n; \sum_i \gamma_i = 1.$$

(R)

It is not difficult to prove that (C) and (R) are feasible linear programs and each is the dual of the other. Let $(\gamma_1^*, ..., \gamma_m^*)$ and $(x_1^*, ..., x_m^*)$ be optimal solutions to (R) and (C). Applying the duality theorem, we obtain von Neumann's famous *mini-max theorem* for zero-sum bimatrix games:

$$\max L = \min K = \sum_i \sum_j \gamma_i^* a_{ij} x_j^*.$$
the expected payoff to the column player.

Decomposition principle

Linear programming can be used in an iterative mode to aid a Central Authority to allocate scarce resources to factories in an optimal way without having to have detailed knowledge about each factory. Specifically the Central Authority proposes prices on the scarce commodities that induce the factories to submit a summary plan for approval of their requirement for scarce resources. The Central Authority blends these proposed plans with earlier ones submitted and uses them to generate new proposed prices. The entire cycle is then iterated. This method, first proposed by Dantzig and Wolfe in 1960, is known as the D–W or Primal Decomposition Principle.

The dual form of the Decomposition Principle is known as Benders Decomposition and was proposed by Benders in 1962. We illustrate it here in the context of a two-period planning problem.

\[
\begin{align*}
\text{Find} \quad \min \ Z & = c_1X_1 + c_2X_2 \quad \text{subject to:} \quad b_1 = A_1X_1, \ (X_1, X_2) \geq 0, b_2 = -B_1X_1 + A_2X_2 \\
\end{align*}
\]

where \( A_1, B_1, A_2 \) are matrices, \( b_1, b_2, c_1, c_2 \) vectors and \( X_t \geq 0 \) are the vectors of activity levels to be determined in periods \( t = 1 \) and \( 2 \).

The first period planners determine a feasible plan \( \{p\} \) that satisfies \( b = A_1X_1^p, X_1^p \geq 0 \) (augmented by certain necessary conditions, called ‘cuts’), which they submit to the second period planners in the form of a vector \( B_1X_1^p \) which is used by them to solve the second period sub problem:

\[
A_2X_2 = b_2 + B_1X_1^p, X_2 \geq 0 \Rightarrow Z_2(\min).
\]

The second period planners respond with a vector of optimality prices \( n_2^k \) corresponding to the second period if the sub-problem is feasible, or with infeasibility prices \( \sigma_2^l \) (obtained at the end of phase 1 of the simplex method) if it is infeasible.

The first period planners then iteratively resolve, their problem augmented by \( k' + l' \) additional necessary conditions (cuts) shown below:

\[
\begin{align*}
\text{Find} \quad c_1X_1 + \theta = Z(\min) A_1X_1 = b_1, X_1 \geq 0, \text{optimality cuts:} \quad - (n_2^kB_1)X_1 + \theta \geq n_2^k b_2, \quad k = 1, ..., k' \quad \text{infeasibility cuts:} \quad - (\sigma_2^lB_1)X_1 \geq \sigma_2^l b \quad l = 1, ..., l'
\end{align*}
\]

where \( \theta = (c_2X_2) \) is treated as an unknown variable. The iterative process stops if \( \theta = Z_2 \), or \( Z_2 - \theta = \Delta > 0 \) is small enough.

Note that the additional conditions imposed on Period 1 are expressed in terms of Period-1 variables and \( \theta \) only. These serve as surrogates for future contents.
periods (in this example for only one future period). The decomposition principle allows one to solve a multi-time-period problem one period at time and pass the ending conditions of one period on to initiate the next and to pass back price vectors to earlier periods that are translated into policy constraints called cuts. Applying this same approach to a multi-stage production line, one obtains an iterative process that can be viewed as an intelligent control system with learning.

linkages

Antonio Ciccone
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economic activities in different industries are linked to each other through aggregate income (horizontal linkages) and input–output relationships (vertical linkages). Could such linkages give rise to vicious circles of underdevelopment or virtuous circles of development when there are increasing returns to scale at the firm level?

Keywords

cost linkages; demand linkages; horizontal and vertical linkages; increasing returns to scale; industrialization; input chains; linkages; multiple equilibria; pre-industrial production methods; underdevelopment traps

Article

1 Introduction

Economic activities in different industries are linked to each other through aggregate income (horizontal linkages) and input–output relationships (vertical linkages). Could such linkages give rise to vicious circles of underdevelopment or virtuous circles of development when there are increasing returns to scale at the firm level? A standard account of a vicious circle goes as follows. Small-scale production methods in industry $A$ lead to low output and income. This translates into low demand for industry $B$, which therefore also ends up using small-scale production methods and generating low output and income. The result is low demand for industry $A$, which justifies the small-scale production methods used in this industry. Low aggregate output and income are seen as the result of a vicious circle because the same economic environment is thought to be compatible with a high-income equilibrium where all industries use technologies that achieve high productivity at large scale. This high-income equilibrium is sustained by a virtuous circle. Large-scale production methods in industry $A$ are profitable because of
high income in industry $B$, and vice versa.

We will show that vicious or virtuous circles based on demand linkages are subject to a simple fallacy if increasing-returns-to-scale technologies differ from pre-industrial technologies only in that they are more productive at large scale. Still, vertical demand linkages will give rise to vicious or virtuous circles if increasing-returns-to-scale technologies use intermediate inputs more intensively than the technologies they replace. And horizontal demand linkages will do so if firms adopting increasing-returns-to-scale technologies must pay a compensating wage differential. Moreover, when there are both vertical demand and cost linkages, underdevelopment traps can be consistent with economic principles even if increasing-returns-to-scale technologies differ from pre-industrial technologies only in that they are more productive at large scale. We first discuss the role of horizontal demand linkages, then that of vertical demand linkages, and finally turn to vertical cost linkages.

Horizontal demand linkages. Imagine an economy populated by households and by firms in different industries. Suppose that each industry sells only to households. Assume also that the amount households spend on each industry is independent of prices (industry demand functions are unit elastic). In this case, demand linkages among industries are said to be horizontal. This simply means that economic activity in one industry affects spending on other industries only through the aggregate income of households. Could horizontal demand linkages lead to economies being trapped into a situation of low income due to a vicious circle of low income and output? Rosenstein-Rodan (1943) and Nurkse (1953) thought so. They imagined a situation where low aggregate income was an obstacle to the adoption of technologies that achieve high productivity at large scale. But large-scale production methods would be profitable if all industries adopted them, because incomes generated in one industry would create demand for other industries.

The elements necessary for underdevelopment traps to be consistent with economic principles have always been subject to debate. Increasing returns to scale appeared to be crucial. But Fleming (1955) made clear that this was not enough. He imagined a situation where, because of low aggregate income, industry $A$ cannot make a profit from adopting the increasing-returns-to-scale technology and that the same is true for industry $B$. Is it possible that the increasing-returns-to-scale technology becomes profitable if both $A$ and $B$ adopt it? Consider forcing $A$ to adopt. In this case, the loss made in industry $A$ will lower aggregate income. As a result, industry $B$ will now face even lower demand and therefore make an even greater loss if it adopts the increasing-returns-to-scale technology. This means that aggregate income will fall further if we also force industry $B$ to adopt the increasing-returns-to-scale technology. Hence, if the adoption of increasing-returns-to-scale technologies is unprofitable for any single industry, adoption in all industries will not be profitable either. Increasing returns alone can therefore not explain why industrialization does not take place although it would ultimately be profitable. All accounts of underdevelopment traps did in fact feature (several) additional elements. In particular, Rosenstein-Rodan maintained that firms using large-scale production methods had to pay a compensating wage differential (partly because of the higher costs of living in urban areas, where industrial firms were located). Section 2 follows Murphy, Shleifer and Vishny (1989) in showing that underdevelopment traps may emerge when firms adopting the increasing-returns-to-scale technologies must pay a compensating wage premium.

Vertical demand linkages. Suppose now that industries sell goods to households and each other (to be used as intermediate inputs). Economic activity in one industry can then affect demand in another industry even if aggregate income remains unchanged. As a result, there are said to be vertical linkages.
For example, consider the situation where industry B buys from A (industry A is upstream of B). In this case there is a vertical demand linkage as demand for the upstream industry A will depend on the economic activity in downstream industry B. There could also be a vertical cost linkage because the cost of production in downstream industry B is partly determined by the cost of goods produced in upstream industry A.

While the effects of horizontal demand linkages on economic development have always been subject to some controversy, there appears to be a consensus among early contributors that vertical demand linkages can lead to underdevelopment traps when technologies are subject to increasing returns to scale (Fleming, 1955; Scitovsky, 1954; Hirschman, 1958). It is simple to show however that this is not the case if increasing-returns-to-scale technologies differ from pre-industrial technologies only in that they are more productive at large scale. To see this, note that with vertical demand linkages the adoption of increasing-returns-to-scale technologies affects aggregate income directly and indirectly: directly through the profits made in the adopting industry, and indirectly through the profits made in supplying (upstream) industries. It would therefore seem that increasing-returns-to-scale technologies could be unprofitable in the adopting industry but still increase aggregate income. But this cannot happen when the increasing-returns-to-scale and the pre-industrial technologies use upstream inputs with the same intensity. In this case, the increase in the value of upstream goods demanded by a firm adopting increasing-returns-to-scale technologies is always a fraction of the (absolute value of the) loss that it makes. Moreover, as profits cannot exceed revenues, the increase in profits in supplying industries is necessarily smaller than the increase in the value of goods they sell. It therefore follows that the increase in profits in supplying industries (the positive indirect effect) can never compensate for the loss made in the industry adopting the increasing-returns-to-scale technology.

The empirical evidence indicates that the intermediate-input intensity of production increases with a country's level of industrialization. Increasing-returns-to-scale technologies may therefore be using intermediate inputs more intensively than the production methods they replace. Section 3 draws on Ciccone's (2002) model of input chains to show that vertical linkages can in this case explain why countries may be trapped into a vicious circle of underdevelopment, and why escaping this trap may be associated with large gains in aggregate income and productivity.

The interplay of vertical cost and demand linkages. The greater demand for intermediate inputs brought about by industrialization (vertical demand linkages) may partly be caused by falling intermediate input prices (vertical cost linkages). Falling intermediate input prices, on the other hand, are possible because of the higher productivity of large-scale production methods. Vertical cost and demand linkages therefore feed on each other (Young, 1928; Okuno-Fujiwara, 1988; Rodriguez-Clare, 1996). For example, Rodriguez-Clare considers a small open economy framework where the entry of new intermediate input varieties lowers the cost of intermediate inputs relative to labour, which leads final-good producers to substitute towards intermediate inputs. When this substitution effect is strong enough, it translates into greater revenues and profits for intermediate-input producers, which may validate intermediate-input producers’ decision to start up new varieties in the first place. Rodriguez-Clare shows that this interplay of vertical demand and cost linkages may lead to two equilibria: a low-income equilibrium where final-good producers use labour-intensive production methods because of the limited range of intermediate inputs available, and a high-income equilibrium where a large variety of intermediate inputs leads final-good producers to use intermediate-input intensive production methods. Okuno-Fujiwara (1988) considers a situation where vertical demand and cost linkages interact because
greater demand for intermediate inputs leads to lower prices due to competition among a larger number of Cournot oligopolists. The final section of this entry uses the model with input chains to show that the interplay between vertical demand and cost linkages can result in underdevelopment traps even if increasing-returns-to-scale technologies differ from pre-industrial technologies only in that they are more productive at large scale.

2 A model of horizontal demand linkages

We will now examine the role of horizontal demand linkages for economic development using the model of Murphy, Shleifer, and Vishny (1989) (for a historical and methodological perspective on the horizontal-linkages literature, see Krugman, 1993; 1994). The first step is to describe the model set-up – the household sector, the production sector, and market structure. The second step is to characterize equilibrium prices and equilibrium allocations.

Households. There are \( L \) households, each of whom supplies one unit of labour inelastically (labour is the only production factor in this model and serves as the numeraire). Households spend an equal share of their incomes on each of the \( N \) goods produced in the economy.

Production. Each of the \( N \) goods demanded by households can be produced using two different production methods: a pre-industrial method requiring one unit of labour for each unit of output produced, and an industrial or increasing-returns-to-scale method, which is more efficient at the margin but subject to a fixed labour requirement \( f \). Formally, the increasing-returns-to-scale production method requires

\[
l_i = f + \epsilon q_i
\]  

(1)

units of labour to produce \( q_i \) units of good \( i \), where \( f > 0 \) and \( 1 > \epsilon > 0 \).

Industry wage premium. Working in the industrial sector generates a disutility \( \nu \geq 0 \) for households. Hence, relative to pre-industrial firms, industrial firms will have to pay a wage premium \( \nu \geq 0 \) as a compensating wage differential.

Market structure. Many firms are assumed to know the pre-industrial method to produce good \( i \). As a result, the pre-industrial sector (also called competitive fringe) will be characterized by perfect competition. By contrast, only a single firm is taken to have the ability to produce each good in the industrial sector. These firms set prices optimally, taking the prices of all other firms as given. The labour market is taken to be perfectly competitive.

What keeps this model simple to analyse is that the equilibrium price of each good is unity whether the good is produced by the pre-industrial or the industrial sector. To see this, note that perfect competition and constant returns to scale in the pre-industrial sector imply that the price of goods produced in this sector must be equal to unity. A higher price would mean strictly positive profits and therefore further entry of pre-industrial producers, while a lower price would mean that no pre-industrial producer could break even. Now consider goods produced in the industrial sector. Clearly, the industrial producer will
not set a price above unity, as she would lose the entire market to pre-industrial producers in this case. Moreover, industrial producers do not have an incentive to set a price below unity either, as households spend the same fraction of income on their good irrespectively of the price. Hence, industrial producers find it optimal to use a limit pricing strategy, setting prices exactly equal to the marginal cost of pre-industrial producers. As a result, the price of each of the $N$ goods is equal to unity independently of the production method.

**Pre-industrial equilibrium.** Under what conditions will there be an equilibrium where all goods are produced with the pre-industrial method? In such an equilibrium, firms just break even, and aggregate income $Y$ in the economy is therefore equal to aggregate labour income $L$. Because households spread income equally among all $N$ goods, the quantity of good $i$ demanded and supplied is $q_i = L / N$. The remaining question is whether firms in the industrial sector have an incentive to adopt the increasing-returns-to-scale method. The potential profit of such firms is $\pi_i = q_i^m - (f + ccq_i^m)(1 + \psi)$, where $q_i^m$ is the demand faced by the industrial producer of good $i$. As industrial and pre-industrial producers set the same price, the first industrial producer faces exactly the same demand as the pre-industrial producers she replaces, $q_i^m = L / N$. Her profits are therefore

$$\pi_i = L / N - (f + cL / N)(1 + \psi).$$

(2)

If $\pi_i < 0$, an industrial producer has no incentive to adopt the increasing-returns-to-scale method, and it will be an equilibrium for all goods to be produced with the pre-industrial method. Hence, (2) implies that there is an equilibrium where all goods are produced with the pre-industrial method if

$$L(1 - \psi(1 + \psi)) < f(1 + \psi),$$

(3)

where $F \equiv fN$.

**Industrial equilibrium.** What about equilibria where all goods are produced using the industrial method? We already know that prices of all goods will be equal to unity in this equilibrium also. Moreover, households will keep spending the same share of income on all goods. Hence, all industries will employ the same amount of labour, $L / N$, in equilibrium. (1) therefore implies that the value of production in each industry is $(L / N - f) / \psi$. Summing across the $N$ industries in the economy yields a value for gross domestic product, and hence aggregate household income, of $Y = (L - F) / \psi$ (recall that $F \equiv fN$).

Do firms make the profit necessary to sustain the industrial production method when all production takes place in the industrial sector? Profits of firms in the industrial sector are $\pi_i = q_i^m - (f + ccq_i^m)(1 + \psi) \geq 0$, where $q_i^m$ is the demand faced by the industrial producer of good $i$. 

Efficient allocation. When is the adoption of increasing-returns-to-scale technologies efficient? The aggregate value of production is $Y = (L - F) / c$ when industrial production methods are used and $Y = L$ with pre-industrial methods. The amount of goods necessary to pay the compensating wage differential when all workers are employed in the industrial sector is $\nu L$. Hence aggregate welfare will be higher with industrial production methods if and only if $(L - F) / c - \nu L \geq L$, or

$$L(1 - c(1 + \nu)) \geq F.$$  

(4)

Note that (4) and (5) coincide. Hence, an industrial equilibrium exists if and only if it is efficient.

Multiple equilibria and underdevelopment traps. Only one of the two inequalities in (3) and (4) can hold if there is no industry wage premium ($\nu = 0$). Hence, the equilibrium is unique in this case and, as a result, there cannot be development traps. Moreover, because an industrial equilibrium exists if and only if it is efficient, economies in a pre-industrial equilibrium actually do the best they can given the economic environment.

But when there is an industry wage premium ($\nu > 0$) there may be multiple equilibria as the inequalities in (3) and (4) can both be satisfied. When this is the case, economies may be stuck in a pre-industrial equilibrium, although the same economic environment would be compatible with an (efficient) industrial equilibrium. To understand why, suppose the economy is in a pre-industrial equilibrium when we force an industry to adopt the increasing-returns-to-scale technology. If (3) holds, then the adopting firm will make a loss. Still, its contribution to aggregate income is strictly positive. To see this, note that demand for this industry is $L/N$, and that this is also the amount of labour required to produce the amount of goods demanded using the pre-industrial production methods. Production with the increasing-returns-to-scale technology requires $cL / N + f$ units of labour, which is strictly smaller than $L/N$ if (4) holds.

Hence, the adoption of the increasing-returns-to-scale technology saves labour in the adopting industry, and therefore increases aggregate output and income. This increases demand faced by other industries and therefore raises the profitability of further adoption of the increasing-returns-to-scale technology. Eventually, industrialization raises aggregate income enough for increasing-returns-to-scale industries to break even. Hence, the industrial equilibrium can be seen as the result of a virtuous circle. The adoption of increasing-returns-to-scale technologies raises aggregate income and therefore the profitability of adopting increasing-returns-to-scale technologies. At the same time, the economic environment also
allows for a development trap where low aggregate income is both the cause and the consequence of the failure to adopt increasing-returns-to-scale technologies.

3 Vertical demand linkages in an input chain model

The economic activity of different industries is linked to each other because the output of some industries is used as input in other industries. Can such vertical linkages give rise to vicious circles of underdevelopment or virtuous circles of development when there are increasing returns at the firm level? We will show that – just as for horizontal linkages – this cannot happen if increasing-returns-to-scale technologies differ from pre-industrial technologies only in that they are more productive at large scale. Chenery, Robinson and Syrquin's (1986) comparative study of industrialization shows, however, that the industrialization of countries has typically been accompanied by an increase in the intermediate-input intensity of production. This suggests that industrial technologies may use intermediate inputs more intensively than the technologies they replace. We will therefore start by analysing a model of development where increasing-returns-to-scale technologies use intermediate inputs more intensively than pre-industrial technologies.

It will be useful to analyze the consequences of vertical linkages for industrialization in a framework that is as close as possible to the model of horizontal linkages of Murphy, Shleifer and Vishny. In particular, the aggregate amount of labour supplied by households continues to be \( L \) and households spend an equal share of their incomes on each of the \( N \) goods produced in the economy. On the production side, we continue to assume that each good can be produced using two different production methods, namely, a pre-industrial method and an industrial (increasing-returns-to-scale) method. The pre-industrial method requires one unit of labour for each unit of output. The increasing-returns-to-scale method will turn out to be cheaper at the margin but subject to a fixed labour requirement \( f \). Many firms know the pre-industrial method, but for each good there is only a single firm with the ability to produce in the industrial sector.

Input chains and industrial production. The key difference with the horizontal linkages model is that now the increasing-returns-to-scale method is taken to be more intermediate-input intensive than the pre-industrial method. One way to model the intermediate-input structure of the economy is to think of goods being produced in \( S \) different locations along a river. Each location produces \( H \) different goods (the total number of goods is \( N = HS \)). Goods at location 1 are produced using labour only. Goods at any location \( s > 1 \), on the other hand, are produced using all goods at location \( s - 1 \). This implies that all goods at locations \( s < S \) may face intermediate-input demand from downstream industries in addition to consumption-goods demand from households (the exception are the \( H \) goods furthest downstream, at location \( S \), which face consumption-goods demand only). In particular, we assume that, after having incurred the overhead labour cost, one unit of any good \( j \) located at \( s > 1 \) can be produced with \( c \) units of an intermediate-input composite \( z_{j,s} \) that combines all \( H \) goods produced at location \( s - 1 \),

\[
z_{j,s} = \prod_{i=1}^{H} (HQ_{i,s-1})^{1/H},
\]

(6)
where \( q_{i,s-1} \) is the input of good \( i \) at location \( s-1 \). This formulation implies that industrial firms spend the same amount on all upstream inputs. As a result, the marginal cost of the intermediate-input composite necessary for industrial production at location \( s > 1 \) is simply a geometrically weighted average of prices \( \bar{p}_{i,s-1} \) of the \( H \) upstream goods,

\[
MC_s = \prod_{i=1}^{H} \frac{1}{\bar{p}_{i,s-1}}.
\]  

(7)

Industrial production for goods at location \( s = 1 \) requires \( f \) units of overhead labour and \( c \) units of labour for each unit of output. (The assumption that the industrial overhead requires labour only while production at the margin requires intermediate inputs only simplifies the analysis considerably. Ciccone (2002) analyses the case where production of the overhead and at the margin use both labour and intermediate inputs.)

Just as in the horizontal linkages model, industrial firms find it optimal to use a limit pricing strategy for consumption goods vis-à-vis the competitive fringe. Their intermediate-input pricing strategy is potentially more complicated but also simplifies to a limit pricing strategy vis-à-vis the competitive fringe when \( H \) is sufficiently large.

**Pre-industrial equilibrium.** When will there be an equilibrium where all goods are produced with the pre-industrial method? It turns out that if \( H \) is sufficiently large the condition is

\[
L(1 - c) < F,
\]

(8)

which coincides with the condition for a pre-industrial equilibrium in the Murphy, Shleifer, and Vishny model of horizontal linkages. To see this, suppose that all goods are produced with the pre-industrial technology and their price is unity. When (8) holds, any single firm adopting the increasing-returns-to-scale method to produce consumption goods will make a loss. Moreover, when \( H \) is sufficiently large, (7) also implies that single industrial firms are unable to generate intermediate-input demand for their good even if they lower their price to the marginal cost of production. To see this, suppose that one industrial firm at location \( s-1 \) is considering selling its good at marginal cost to firms at location \( s \) in order to generate intermediate-input demand. In this case, one of the \( H \) inputs of potential industrial firms at \( s \) would become available at price \( c \) and (7) implies that the marginal cost of production would
therefore fall from \( \xi \) to \( \xi \left( 1 + \frac{1}{H} \right) \) (recall that the remaining \( H - 1 \) inputs are available at price of unity). Goods at \( S \) face demand \( L / N \), which comes exclusively from households as there are no upstream industries. Hence, profits of the potential industrial firm at \( S \) producing at marginal cost \( \xi \left( 1 + \frac{1}{H} \right) / H \) would be \( (1 - \xi \left( 1 + \frac{1}{H} \right) / H) L / N - f \), which is strictly negative if (8) holds and \( H \) is large enough.

Potential industrial firms at location \( S \) would therefore find it unprofitable to start production even after the price cut, which implies that potential industrial firms at location \( S - 1 \) must break even on consumption-goods demand only. Applying the same argument sequentially to potential industrial firms in locations \( S - 2, S - 3, ..., 1 \) yields that pre-industrial production of all goods is an equilibrium when (7) holds and \( H \) is sufficiently large.

**Industrial equilibrium.** To determine the conditions for the existence of an industrial equilibrium, it is necessary to determine aggregate income when all goods at location \( \sigma \) and upstream of location \( \sigma \) are produced with the increasing-returns-to-scale technology. This turns out to be straightforward. If aggregate income is \( Y \), the quantity of each good demanded by households is \( Y / N \). The intermediate-input structure implies that industrial production of \( Y / N \) units of each of the \( H \) goods at location \( \sigma \) requires \( cY / N \) units of each of the \( H \) goods at location \( \sigma - 1 \). Hence, as \( Y / N \) units of good \( \sigma - 1 \) are demanded by households, production of each good at \( \sigma - 1 \) must be \( Y / N + cY / N \). Production of this quantity of goods at \( \sigma - 1 \) requires \( c(\gamma / N + cY / N) \) units of each good at \( \sigma - 2 \). Adding the \( Y / N \) units of goods at \( \sigma - 2 \) demanded by households, yields that production at \( \sigma - 2 \) must be \( Y / N + cY / N + c^2 Y / N \). Continuing all the way upstream yields that the total production of each of the \( H \) goods at location 1 must be

\[
q_1 = \frac{Y / N + cY / N + c^2 Y / N + ... + c^{\sigma - 1} Y / N}{1 - \xi} = \frac{1 - c^\sigma}{1 - \xi} Y / N. \tag{9}
\]

To turn to the labour market, \( f \) units of labour must be used as overhead in the production of each good produced with the industrial technology. Moreover, \( Y / N \) units of labour are required for the production of each good produced with the pre-industrial technology. Hence, the amount of labour available for production at the margin of the \( H \) goods at \( s = 1 \) is \( L - \sigma H f - (N - \sigma H) Y / N \). Labour market clearing requires \( cHq_1 = L - \sigma H f - (N - \sigma H) Y / N \). Substituting (9) yields aggregate income in an economy where the \( \sigma \) industries furthest upstream have industrialized:

\[
Y(\sigma) = \frac{L - F(\sigma H / N)}{c\theta(\sigma)(\sigma H / N) + (1 - (\sigma H / N))} = \frac{L - F(\sigma H / N)}{1 - (\sigma H / N)(1 - c\theta(\sigma))}, \tag{10}
\]
where

\[ \theta[\sigma] = \frac{1 - \frac{\sigma}{1 - \sigma}}{\sigma}. \]

\( \theta[\sigma] \) has a simple interpretation. It is the amount of labour required to produce one additional unit of goods located at \( \sigma \) if all industries upstream of (including) \( \sigma \) have adopted the industrial technology. Note that the amount of labour required to produce one additional unit of goods at location \( \sigma \) falls the longer the industrial input chain (\( \theta[\sigma] \) is strictly decreasing in \( \sigma \)).

The intermediate-input structure implies that the demand for goods is greater the further upstream they are located. Hence, profits from adopting the increasing-returns-to-scale technology fall the further downstream industries are located. An equilibrium where all industrial firms make a profit will therefore exist if goods produced furthest downstream (at location \( S \)) can be produced using the increasing-returns-to-scale technology without a loss. Because firms furthest downstream sell to households only, their sales are equal to aggregate income divided by the number of goods, \( Y[S] / N \) (recall that all firms set prices optimally at unity). As a result, their profits are positive if and only if

\[
(1 - \epsilon) L \geq (\epsilon \theta[S] + (1 - \epsilon)) F.
\]

Multiple equilibria and underdevelopment traps. Comparison of (8) and (11) yields that, with input chains (\( S > 1 \)), it is possible for the pre-industrial equilibrium and the industrial equilibrium to exist side by side. (When \( S = 1 \) then \( \theta = 1 \) and the model is that of Murphy, Shleifer, and Vishny without an industry wage premium.) This is because the adoption of increasing-returns-to-scale technologies now has a direct and indirect effect on income. The direct effect is given by the profit or loss in the adopting industry. The indirect effect is equal to the profits generated upstream of the adopting industry. When the indirect profits generated by the increased intermediate-input demand more than offset direct losses of industrial technologies, then industrialization increases aggregate income. As a result, further industrialization becomes more profitable. When (7) and (10) hold simultaneously, this effect is strong enough to ensure that all industrial firms make a profit once all goods are produced with increasing-returns-to-scale technologies.

The pre-industrial and industrial equilibrium can exist side by side even if aggregate income is much greater in the industrial equilibrium. Note that aggregate income in the industrial equilibrium is \( Y[S] = (L - F) / (\epsilon \theta[S]) \), see (10). As intermediate-input chains become longer, \( \theta[S] \) in (10) tends to zero, and aggregate income in the industrial equilibrium increases. Aggregate income in the pre-industrial equilibrium, on the other hand, is independent of \( S \) as production does not rely on intermediate inputs.
inputs. Moreover, the range of parameter values for which the industrial equilibrium exists increases. Hence, long input chains imply that equilibrium multiplicity is more likely and also that the aggregate income difference between industrial and pre-industrial equilibria may be very large.

**Vertical linkages and equilibrium uniqueness.** To see that the equilibrium is unique when increasing-returns-to-scale technologies use intermediate inputs as intensively as pre-industrial technologies, note that costs of production plus profit must add up to the value of firms’ sales, \( \text{COST} + \pi = q \). Suppose that intermediate inputs are a share \( \alpha \) of costs of production for both the pre-industrial and the industrial production method. In this case, the demand for goods produced at \( s - 1 \) is equal to \( \alpha \text{COST}_s = \alpha (q_s - \pi_s) \). Now suppose that all goods upstream of \( \sigma \) are produced with the increasing-returns-to-scale technology. Is it possible that aggregate income increases with the adoption of the increasing-returns-to-scale technology at \( \sigma \) even if the adopting firm makes a loss? A switch to industrial production at \( \sigma \) does not affect the value of goods produced at this location (\( q_\sigma \) is unchanged). Hence, the adoption of the increasing-returns-to-scale technology at \( \sigma \) increases demand for each good produced at \( s - 1 \) by \( -\alpha \pi_\sigma / H \). Loss-making industrialization at \( \sigma \) therefore leads to greater demand at \( s - 1 \). But the profits generated by this input demand can never be greater than the initial loss \( \pi_\sigma \). To see this, notice that total profits at location \( s - 1 \) increase by \( -(1 - \epsilon)\alpha \pi_\sigma \). Total profits at \( s - 2 \) increase by \( -(1 - \epsilon)\alpha^2 \epsilon \pi_\sigma \), where \( -(1 - \epsilon)\alpha^2 \epsilon \pi_\sigma / H \) is the increase in demand for each good produced at \( s - 2 \). The general formula is that total profits at location \( s - i \) increase by \( -(1 - \epsilon)\alpha^i \epsilon^{i-1} \pi_\sigma \). Summing profits across all locations yields \( -(1 - \epsilon)\pi_\sigma \alpha \left[ 1 + \alpha \epsilon + (\alpha \epsilon)^2 + \ldots + (\alpha \epsilon)^{\sigma - 1} \right] \), which is smaller than \( -(1 - \epsilon)\pi_\sigma \alpha \left[ 1 + \alpha \epsilon + (\alpha \epsilon)^2 + \ldots \right] = -\pi_\sigma (\alpha - \alpha \epsilon) / (1 - \alpha \epsilon) \). Hence, \( \alpha \leq 1 \) implies that the sum of profits generated upstream of \( s \) by loss-making industrialization at \( s \) is always smaller than the initial loss \( (\pi_\sigma) \). Loss-making industrialization necessarily lowers aggregate income. The aggregate demand externality necessary for multiple equilibria is therefore absent when increasing-returns-to-scale technologies are no more intermediate-input intensive than pre-industrial technologies.

### 4 Vertical demand and cost linkages with input chains

So far firms adopting increasing returns to scale technologies did not have an incentive to cut prices. This eliminated virtuous circles of development where lower intermediate-input prices (vertical cost linkages) and greater intermediate-input demand (vertical demand linkages) feed on each other. A simple way to capture the interplay between vertical demand and cost linkages is to suppose that firms in the competitive fringe can produce one unit of goods at location \( s > 1 \) with \( 1 + \epsilon > 1 \) units of the intermediate-input composite in (6) or one unit of labour. That is, firms have access to two modes of production, a labour-intensive mode and an intermediate-input intensive mode. The exception continues to be goods at location 1, for which there is a labour-intensive mode of production only. Industrial firms at locations \( s > 1 \) also have access to a labour-intensive and an intermediate-input intensive mode of production, but are more efficient than pre-industrial firms at the margin. Once they have incurred the overhead labour requirement \( f \), industrial firms can produce one unit of output with \( \epsilon (1 + \epsilon) < 1 \) of the intermediate-input composite in (6) or \( \epsilon < 1 \) units of labour. Industrial firms producing goods at location 1 have access to the labour-intensive mode of production only. The assumption that the overhead is

produced using labour only continues to simplify the analysis considerably. A new by-product of this assumption is that industrial firms now actually use intermediate inputs less intensively than pre-industrial firms at the same factor prices – the opposite of what we assumed in the previous section.

**Pre-industrial equilibrium with labour-intensive production.** Can there be an equilibrium where all goods are produced with the pre-industrial technology using labour only? The marginal cost of production with the pre-industrial technology in the labour-intensive mode is unity. Hence, the price of all goods would be equal to unity. To see that these prices make it optimal to use the labour-intensive mode of production, note that they imply that the marginal cost of intermediate-input composites in (7) is unity. The marginal cost of production using the intermediate-input intensive mode compared with the labour-intensive mode is therefore $1 + \varepsilon > 1$ (in the pre-industrial as well as the industrial sector). Hence, all firms will find it optimal to use the labour-intensive mode of production.

In a pre-industrial equilibrium, the adoption of the increasing-returns-to-scale technology by a single firm must lead to losses. If industrial firms can count on consumption-goods demand only, this will be the case if $L(1 - \varepsilon) < F$. But an industrial firm may be able to generate additional demand by getting industries just downstream to switch to an intermediate-input intensive mode of production. While this can happen in principle, it will not happen if $H$ is sufficiently large. To see this, consider the case where a single industrial firm supplies its good to downstream industries at marginal cost. In this case, (7) yields that the marginal cost of the intermediate input-intensive mode of production relative to the labour-intensive mode becomes $1/H(1 + \varepsilon)$, which will be greater than unity when $H$ is sufficiently large (recall that $1 + \varepsilon > 1$). Hence, a single industrial firm cannot generate downstream intermediate-input demand even if it reduces its price to marginal cost. For $H$ sufficiently large, a pre-industrial labour-intensive equilibrium will therefore exist if $L(1 - \varepsilon) < F$.

**Industrial equilibrium with intermediate-input intensive production.** When is there an industrial equilibrium where all firms use the intermediate-input intensive mode of production? To simplify the analysis, suppose that industrial firms can price discriminate between households and industrial users of their goods. As before, industrial firms will find it optimal to follow a limit pricing strategy when it comes to sales to households. Industrial firms will therefore price consumption goods at unity. When it comes to intermediate-input sales to downstream industries, industrial firms must also take into account that users will switch to the labour-intensive mode of production if the cost of the intermediate-input composite is greater than $1/(1 + \varepsilon)$. Hence, each industrial firm will find it optimal to set a limit price of $1/(1 + \varepsilon)$ for intermediate inputs if other industrial intermediate-input suppliers do the same.

Aggregate income in the industrial equilibrium where all firms use the intermediate-input intensive mode of production can be determined following the argument that led to (10). The only difference is that an additional unit of all goods at location $s > 1$ now translates into a demand of $\varepsilon(1 + \varepsilon)$ units of each good at location $s - 1$. Aggregate income when all goods are produced with the industrial technology in the intermediate-input intensive mode is therefore $\gamma(S) = (L - F) / \hat{\theta}(S)$ where

$$
\hat{\theta}(S) = \frac{1 - (\varepsilon(1 + \varepsilon))S}{(1 - \varepsilon(1 + \varepsilon))S}.
$$

(12)
An industrial equilibrium exists if the firm furthest downstream can break even given the demand for consumption goods, \( \eta_{5} = (1 - \zeta(1 + \varepsilon)) \left( \gamma_{5} / N \right) - f \geq 0 \) or, to make use of the expression for aggregate income just above,

\[
(1 - \zeta(1 + \varepsilon))L \geq \left( c\theta_{5}^{\ast} + (1 - \zeta(1 + \varepsilon)) \right)F.
\]

**Multiple equilibria with vertical demand and cost linkages.** There will be multiple equilibria if both \( L(1 - \zeta) < F \) and \( (1 - \zeta(1 + \varepsilon))L \geq \left( c\theta_{5}^{\ast} + (1 - \zeta(1 + \varepsilon)) \right)F \). This implies that the pre-industrial equilibrium with labour-intensive production and the industrial equilibrium with intermediate-input intensive production may exist side by side if and only if there are input chains \( \theta_{5}^{\ast} < 1 \). The virtuous circle sustaining industrial equilibria now consists of an interplay between vertical demand and cost linkages. The increase in the intermediate-input intensity of production necessary for increasing-returns-to-scale technologies to be profitable (vertical demand linkages) comes about because the adoption of increasing-returns-to-scale technologies translates into falling intermediate-input prices (vertical cost linkages). Note that, for this virtuous circle to be operative, the elasticity of substitution between intermediate inputs and labour in industrial production must be greater than unity (our model assumed that this elasticity is infinity for simplicity). In a pre-industrial equilibrium, on the other hand, pre-industrial technologies are both the cause and the consequence of labour-intensive modes of production.

**5 Conclusion**

Neither horizontal nor vertical demand linkages across industries lead to underdevelopment traps if increasing-returns-to-scale technologies differ from pre-industrial technologies only in that they are more productive at large scale. Nevertheless, theories of underdevelopment based on vicious circles of low demand and low productivity are consistent with economic principles. For example, in the case of vertical demand linkages, there can be development traps if increasing-returns-to-scale technologies use intermediate inputs more intensively than the technologies they replace. More generally, multiple equilibria in our models exist under assumptions that do not appear to be in contradiction by empirical evidence. The exception is that all our model economies were taken to be closed to international trade, but we could have assumed instead that only some goods are non-tradable or that all goods are tradable at some cost (for example, Okuno-Fujiwara, 1988; Rodriguez-Clare, 1996; Krugman and Venables, 1995). Still, it remains to be seen what part of international income differences can be attributed to development traps (for steps in this direction, see Fafchamps and Helms, 1996; Graham and Temple, 2006).

Article  

Lintner was born in Lone Elm, Kansas. He received the Ph.D. at Harvard University in 1946, becoming a member of the faculty a year earlier. He remained a member of the Harvard faculty throughout his career and was designated the George Gund Professor of Economics and Business Administration in 1964, with a joint appointment in the Business School and the Faculty of Arts and Sciences in Economics.  

The contributions by John Lintner that are most frequently cited in the economic literature involve asset pricing, dividend policy, mergers, and capital formation under inflation. Along with others, Lintner was one of the independent creators of the modern theory of asset pricing. This model is usually referred to as the capital asset pricing model (CAPM) which holds that the equilibrium rates of return on all risky assets are a function of their covariance with the returns on the market portfolio. In addition to his major contribution to the creation of the modern theory of financial markets, Lintner wrote the seminal articles on dividend policy which provided the foundations for further research and remain the basic references on the subject.  

Mergers represented the third area of important contributions. An early study focused on the impact of taxes on mergers (Butters, Lintner and Cary, 1951). One important impact of taxes documented was the sale of companies to convert an earnings stream that would otherwise be subject to personal income tax rates to capital gains which would be taxed at lower rates. His later studies of mergers developed an analysis of the historical influences on mergers during the major merger movements of the United States. In addition, a theoretical rationale for pure conglomerate mergers was also developed (1971). Many aspects of Lintner's interest in capital formation under inflation were brought together in his Presidential Address to the American Finance Association in December 1974 (1975). His subsequent work sought to develop further the major themes which he had set forth in his Presidential Address.

liquidity constraints

Stephen D. Williamson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Liquidity constraints affect the ability of an economic agent to exchange his or her existing wealth for goods and services or for other assets. These constraints arise because of frictions, including private information, limited commitment, transactions costs, and spatial considerations.

Keywords

cash-in-advance model; consumption smoothing; contingent claims markets; endowments; expected utility; incomplete markets; law of large numbers; limited commitment; liquidity constraints; precautionary savings; private information; risk sharing; search and matching models of monetary exchange

Article

A benchmark model

To explain what liquidity constraints are, and their implications for economic activity, it is useful to start with a simple benchmark model. Suppose a world with a continuum of households having unit mass. Time is indexed by $t = 0, 1, 2, \ldots$, and household $i$ has preferences given by

$$E_0 \sum_{t=0}^{\infty} \beta^t u(c_{it}),$$

where $E_0$ is the expectation operator conditional on period 0 information, $0 < \beta < 1$, $c_{it}$ is consumption,
and \( u(\cdot) \) is twice continuously differentiable, strictly concave, and has the property that \( u'(0) = \infty \).

Each household receives a random endowment of the perishable consumption good at the beginning of each period. That is, household \( i \) receives an endowment \( y_{it} \) in period \( t \) where \( y_{it} \) is assumed to be independent and identically distributed across households and over time. Assume that \( \underline{Y} \leq \underline{V}_{it} \leq \overline{Y} \), where \( \underline{Y} < \underline{V} < \overline{Y} \). The law of large numbers then implies that the aggregate endowment is a constant, which we will denote by \( \overline{Y} \). Therefore, this is an economy with no aggregate risk, but each household faces idiosyncratic risk associated with its endowment shocks.

Now, suppose that this economy has a complete set of markets. One market structure that gives completeness is contingent claims markets that open at \( t = 0 \) before households receive their period 0 endowments. All households trade on these markets, and a particular contingent claims market involves trade in claims to the consumption good deliverable at a particular date only under a particular realization for the path of endowment shocks for all households up to that date. Given this complete set of markets, what will be the equilibrium allocation of consumption across households at each date? All households are identical at the first date, and the result will be that, in equilibrium, \( c_{it} = \overline{Y} \) for all \( i \) and \( t \). The complete set of contingent claims markets provides perfect insurance for households. That is, they are able to share their risk efficiently, in that each household can shed the idiosyncratic risk associated with its endowment shocks. Indeed, the resulting equilibrium allocation of consumption is Pareto optimal.

Models with complete markets have proved to be very useful in economics, for example in the theory of asset pricing and in business cycle modelling. However, there are many applications where it is necessary that we depart from the complete markets paradigm, and the liquidity constraints literature is one such set of applications. To think about liquidity constraints we need to seriously address the frictions that will cause markets to work differently than in the complete markets case, and in some instances will cause some markets to shut down altogether. In the following sections we will explore some key departures from our benchmark model that illustrate the role of liquidity constraints.

**Incomplete markets: a Bewley model**

One approach to studying market incompleteness is to simply eliminate markets in the model under consideration, without asking questions about the underlying frictions which would cause incomplete markets. Bewley (1977) was a pioneer in this area, and Aiyagari (1994) provides a particularly clear treatment of the implications of incomplete markets.

As an example of the Bewley approach, suppose in our benchmark model that there is only one asset market, a market for non-contingent bonds on which trading occurs each period. Households can borrow and lend on this bond market. Assume that each bond is a one-period financial instrument. In period \( t \), a bond sells for one unit of consumption goods, and is a promise to pay \( 1 + r_{t+1} \) units of consumption goods in period \( t + 1 \). Since there is no aggregate risk, there will exist a steady state competitive equilibrium where \( r_{t+1} = \rho \), a constant, for all \( t \).

We now need to write down the series of constraints that a household faces in the steady state equilibrium. The first of these is the sequence of budget constraints
liquidity constraints: The New Palgrave Dictionary of Economics

\[ c_{it} + b_{i,t+1} = v_{it} + (1 + r)b_{i,t} \]

for \( t = 0, 1, 2, \ldots \), where \( b_{it} \) is the quantity of bonds acquired by household \( i \) in period \( t \), and \( b_{i0} = 0 \) for all \( i \). Typically in models of this type, there is also a borrowing constraint added, which could take the form

\[ b_{it} \geq b \]

(1)

Constraint (1) serves a technical purpose, in that it prevents a household from borrowing an infinite amount so as to finance infinite consumption. Further, the constraint will affect the household's ability to smooth consumption over time in the face of fluctuating income. Constraint (1) is a kind of liquidity constraint, as it potentially prevents the household from borrowing against its lifetime wealth.

A competitive equilibrium will have the property that the bond market clears, that is the net stock of bonds in the population is zero in each period. This model is a special case of Aiyagari (1994), and so his results apply here. With Aiyagari's regularity conditions on \( u(\cdot) \), a steady state competitive equilibrium will have the property that \( r < \frac{1}{\delta} - 1 \), that is, the equilibrium real interest rate is less than the rate of time preference. This reflects a precautionary savings motive, in that households wish to hold bonds to self-insure against having a string of bad luck, which in this case would be a string of low endowment shocks. Over time, a household will tend to increase its stock of bonds when its endowment is large, and to decrease the stock of bonds when its endowment is small. What we will observe in equilibrium is some distribution of bonds and consumption across the population of households. Households who have had good luck will tend to have a larger stock of bonds and higher consumption than those households who have had bad luck. The competitive equilibrium is therefore not in general Pareto optimal.

Another related application, from Bewley (1980), is to suppose that the single asset that is traded is money. For example, suppose that there is a fixed stock of money, \( M \), for all \( t \). Let \( P_t \) denote the price level in period \( t \), and consider the steady state equilibrium where \( P_t = \bar{P} \), a constant, for all \( t \). For the household, we can just reinterpret its constraints, in that \( b_{i,t+1} \) is the real quantity of money carried over by the household into period \( t + 1 \), and \( b = 0 \) as the household's money balances cannot fall below zero. An individual household in this set-up is even more severely liquidity-constrained than was the household in the Bewley model with borrowing and lending above. This is because the household cannot borrow at all, and cannot hold interest-bearing assets. Note that, in this monetary model, a household need only use money to buy consumption goods if it wishes to consume more than its endowment. Money is essentially held for insurance purposes, so as to smooth consumption over time.
Cash-in-advance

The idea for the basic cash-in-advance model seems to come from Clower (1967), but the important initial modelling work was done mainly by Robert Lucas, with a key contribution being Lucas (1980). Most cash-in-advance applications begin with the view that the basic frictions that might give rise to cash-in-advance constrained households need not be modelled, and that it is useful to proceed from the premise that money is necessary to purchase some goods and services. Here, suppose in our basic model that there are no assets other than money, and that the only exchanges are trades of money for goods. Assume that a household's purchases of goods during the current period must be financed with money carried over from the previous period, and also suppose that the household cannot consume its own endowment. Let $m_{it}$ denote the nominal money balances that household $i$ has at the beginning of period $t$, and let $P_t$ denote the price level. Then, the household's budget constraint in period $t$ is

$$P_t c_{it} + m_{it} + 1 = P_t y + m_{it}. \tag{2}$$

The cash-in-advance constraint for the household is

$$P_t c_{it} \leq m_{it}. \tag{3}$$

Thus, constraint (3) is another type of liquidity constraint. In this case, the interpretation is that some class of assets, which we refer to here as money, is necessary to carry out goods market spot exchanges. Now, suppose that there is a fixed nominal stock of money $M$. Also, suppose that in equilibrium constraint (3) binds for each household $i$. Then, since in equilibrium the entire stock of money is held by households at the beginning of period and is spent to purchase the aggregate endowment, $y$, the equilibrium price level is

$$P_t = \frac{M}{y}$$

for all $t$. Then, given (2) and (3) with equality, we have
liquidity constraints: The New Palgrave Dictionary of Economics

\[ m_{i,t+1} = M \frac{Y_{it}}{y}, \]

which then implies, from (3) with equality, that

\[ c_{it} = Y_{i,t-1}. \]

Therefore, in this environment, households have essentially no ability to smooth consumption relative to income, as a result of this extreme type of liquidity constraint. The distribution of consumption across households in period \( t \) is determined by the distribution of income across households in the previous period.

Economists who are serious about monetary theory often treat cash-in-advance models with some disdain (see, for example, Wallace, 1996). As they see it, the problem is not that one cannot write down a model that is explicit about frictions and gives rise to cash-in-advance as an endogenous phenomenon. For example, suppose that we modify our benchmark model to permit an absence-of-double-coincidence friction of the type considered by early monetary theorists such as Jevons (1875). That is, assume that households are of \( N \) types, with measure \( \frac{1}{N} \) households of each type, where type is indexed by \( j = 1, 2, \ldots, N \). Type \( j \) households are endowed with good \( j \), and consume the good which is endowed to type \( j + 1 \), modulo \( N \). Further, suppose that a household has two members, a shopper that takes money from the household to buy goods in another market each period, and a seller who stays at home to sell the household's endowment. There are \( N \) distinct markets, and in a given period a shopper from a household of type \( j \) goes to market \( j + 1 \), modulo \( N \), with money to buy goods, while a the seller stays behind and sells goods in market \( j \). Note that this is still not enough to give us cash-in-advance, as we need to close off the possibility of credit arrangements among households which could take place through centralized communication, as is made clear in Kocherlakota (1998). Credit can be shut down by assuming that no communication is possible across markets, with buyers and sellers in a given market having no information about each other, beside the fact that sellers have identifiable goods and buyers have identifiable money balances. With competitive pricing in each of the \( N \) markets, we get exactly the set-up outlined above in this section, with a cash-in-advance constraint for each household. Given symmetry, there is an equilibrium where prices are the same in every market, and so the equilibrium allocation of consumption is identical to what was specified above.

The key problem that must be addressed in cash-in-advance environments involves what happens when there are other assets than money. For example, if we permit borrowing and lending by households, why is it that goods cannot be purchased with credit? How can money be dominated in rate of return by other assets? Why is it that government bonds, for example, are not used in transactions rather than money? Many cash-in-advance applications leave these questions unanswered.
liquidity constraints: The New Palgrave Dictionary of Economics

Random matching

A useful way to extend our benchmark model at this point is to expand on the explicit cash-in-advance environment above to relate it more directly to the literature on monetary search and matching. The seminal work in this literature is by Jones (1976) and Kiyotaki and Wright (1989). Suppose as above that there is a double coincidence problem, but here assume that there is one agent in a household, and that each household is randomly matched with one other household each period. Households produce different goods, and no household can consume its own endowment. Now, for a given household, assume that the probability is $\alpha$ that it is matched with another household whose goods it consumes, with the other household not wanting its goods (a single coincidence meeting). As well, assume that there is a probability $\gamma$ that a household is matched with another household and there is a double coincidence of wants – each household consumes the other's goods. Suppose that $\alpha > 0$, $\gamma > 0$, and $2\alpha + \gamma < 1$. Suppose that a household in a bilateral match has no information about the other household, except that it can observe its quantity of money balances and its endowment. Thus, exchange can only involve bilateral exchanges of goods and money.

Now, suppose that household $i$ and household $k$ are matched. There is probability $\alpha$ that household $i$ is a seller and $k$ is a buyer. In this case, we have $\xi_{it} = 0$, $\xi_{kt} = \gamma_{it}$, and

$$m_{it_{t+1}} = m_{it} + m(y_{it}, m_{it}, m_{kt}), \quad m_{kt_{t+1}} = m_{kt} - m(y_{it}, m_{it}, m_{kt}),$$

where $m(y_{it}, m_{it}, m_{kt})$ is the quantity of money exchanged for the $y_{it}$ units of goods given up by the seller when the seller has $m_{it}$ units of money and the buyer has $m_{kt}$ units of money. As money balances must be non-negative, we have

$$-m_{it} \leq m(y_{it}, m_{it}, m_{kt}) \leq m_{kt}$$

(4)

and these constraints are essentially liquidity constraints. Similarly, with probability $\alpha$, household $i$ is the buyer and $k$ is the seller, in which case $\xi_{it} = \gamma_{kt}$, $\xi_{kt} = 0$, and

$$m_{i_{t+1}} = m_{it} - m(y_{kt}, m_{kt}, m_{it}), \quad m_{k_{t+1}} = m_{kt} + m(y_{kt}, m_{kt}, m_{it}),$$

with
liquidity constraints: The New Palgrave Dictionary of Economics

Finally, with probability $\gamma$ there is a double coincidence, and household $i$ and $k$ exchange goods, so that $c_{it} = \gamma_{kt}$, $c_{kt} = \gamma_{it}$, and

$$m_{it} + b(\gamma_{it}, \gamma_{kt}, m_{it}, m_{kt}) = m_{kt} - b(\gamma_{it}, \gamma_{kt}, m_{it}, m_{kt}),$$

where

$$-m_{it} \leq b(\gamma_{it}, \gamma_{kt}, m_{it}, m_{kt}) \leq m_{kt}.$$

Here, $b(\gamma_{it}, \gamma_{kt}, m_{it}, m_{kt})$ is the quantity of money passed from household $k$ to household $i$, which depends on the money balances and endowments of each household.

Note that this environment will give a clear sense in which money improves the equilibrium allocation. If money is not valued, then households can trade only when there is a double coincidence of wants, and this could severely limit exchange possibilities. In principle, the constraints \(4\), \(5\) and \(6\) will matter for the equilibrium allocation in important ways. However, the model as we have laid it out is quite intractable. It is possible to use a bargaining approach, as for example in Trejos and Wright (1995) or Shi (1995), to determine how much money is transferred in each type of match, but the key problem is in tracking the distribution of money balances in the population over time.

In some of the monetary search and matching literature, tractability is achieved through assuming that money and goods are indivisible (Kiyotaki and Wright, 1989) or that money is indivisible and goods are divisible (Trejos and Wright, 1995; Shi, 1995), and that there is an inventory constraint on money holdings. If a household can hold only one unit of money or nothing, and money is never disposed of, then the quantity of money outstanding tells us how many households have it and how much, and how many do not have it. Models with indivisible money yield some insights, but they are extremely awkward for dealing with some types of policy questions, such as those involving money growth and the effects of inflation. Some recent progress in the development of tractable search models of divisible money was achieved by Lagos and Wright (2005), who use a quasilinear utility setup with labour supply and alternating periods of centralized meeting and search. This type of model yields a result where, in the periods when centralized meeting takes place, economic agents optimally redistribute money among
themselves in such a way that the distribution of money balances becomes degenerate. Recent research using this type of model (for example, Williamson, 2006; Berentsen, Camera and Waller, 2005) has been quite productive.

Private information and limited commitment

As an alternative to shutting down markets in an ad hoc fashion, imposing borrowing constraints, assuming cash-in-advance constraints, or making extreme informational assumptions that shut down all trade except monetary exchange, there are available approaches to facing frictions head-on that lead to incomplete insurance and imperfect credit. These approaches involve economies with private information and limited commitment.

A well-developed approach to dealing with private information frictions in large economies follows the pioneering work of Green (1987), Atkeson and Lucas (1993) and others. Extending our benchmark model, suppose now that endowments are private information. In our baseline environment, we know that if endowments are public information, then a Pareto optimal allocation that treats households identically has \( c_{it} = \nu \) for all \( i,t \). What is optimal from a social planner’s point of view under private information?

It is clear that private information implies that the \( c_{it} = \nu \) allocation cannot be implemented by the social planner. To see this, note that to achieve this allocation requires that household \( i \) make a transfer of \( \nu_{it} = \nu \) to the planner in period \( t \). But it would then be incentive compatible for every household in every period to report that its endowment was \( \nu \), and so the planner could not achieve this allocation.

Following Green (1987) and Atkeson and Lucas (1995), one can solve for an optimal private information allocation by recursive methods. The state variable for any household is \( w_{it} \), which is the level of expected utility promised to the household as of the beginning of period \( t \). At the beginning of period \( t \), the household reports its endowment \( y_{it} \) to the social planner, and it must be optimal for the household to report the truth (that is, the allocation must be incentive compatible). The planner delivers consumption \( c(w_{it}, y_{it}) \) to the household, which depends on its state and reported endowment, and promises expected utility \( w(w_{it}, y_{it}) \) for next period. There is a functional equation that solves for a cost function \( V(w_{it}) \), which is the cost to the social planner of delivering expected utility \( w_{it} \) to a particular household. On the right-hand side of this functional equation is a cost minimization problem, and the minimization is subject, first, to a promise-keeping constraint, which is

\[
w_{it} = \int \{ u[c(w_{it}, y_{it})] + \beta w(w_{it}, y_{it}) \} dF(y_{it}),
\]

where \( F(y_{it}) \) is the distribution function for \( y_{it} \). The remaining constraints are incentive compatibility constraints, written as
liquidity constraints: The New Palgrave Dictionary of Economics

\[ u[c(w_{it}, y_{it})] + \beta w(w_{it}, y_{it}) \geq u[c(w_{it}, \tilde{y}) + y_{it} - \tilde{y}] + \beta w(w_{it}, \tilde{y}), \]

for all \( y_{it}, \tilde{y} \in \mathbb{Y} \). The optimal allocation will typically have the property that some incentive compatibility constraints bind. For efficient risk sharing, we want households with high (low) endowments to be making positive (negative) transfers to the social planner. To accomplish this in an incentive compatible manner requires that households with high (low) endowments receive increases (decreases) in their future expected utility promises. Thus, the distribution of consumption will tend to fan out over time. Under some conditions, a vanishing fraction of households will ultimately consume the entire endowment. However, under other conditions there will be a limiting distribution of expected utility promises with mobility and a lower bound on expected utilities. If a household hits this lower bound (which is not absorbing), then this is much like having a borrowing constraint bind for this household. Thus, this type of set-up can yield what are essentially endogenous borrowing constraints or liquidity constraints.

An alternative approach to modeling frictions in a serious way is to assume some form of limited commitment. One approach to limited commitment is that of Kehoe and Levine (1993), which has elements of competitive equilibrium. Extending our benchmark model to illustrate the flavour of this modelling approach, suppose that there is only one type of intertemporal trade, involving one-period bonds, and that we wish to study a steady state where the real interest rate is a constant, \( r \). Suppose that the key friction here is that a household may decide strategically to repudiate its debt, in which case it would be barred from the credit market for ever and would then consume its own endowment for ever. Thus, if a household does not repudiate its debt, then its budget constraint is given by

\[ c_{it} + b_{i,t+1} = y_{it} + (1 + r)b_{it}, \]

(7)

where \( b_{i,t+1} \) is the quantity of one-period bonds acquired in period \( t \) that each pay off \( 1 + r \) units of consumption in period \( t + 1 \). Let \( v(b_{it}, y_{it}) \) denote the expected utility of the household at the beginning of period \( t \) as a function of the household's asset position and endowment, determined by the functional equation

\[ v(b_{it}, y_{it}) = \max_{c_{it}, b_{i,t+1}} \left[ u(c_{it}) + \beta \int v(b_{i,t+1}, y_{i,t+1}) dF(y_{i,t+1}) \right] \]

subject to (7). To insure that the household does not repudiate its debt in equilibrium requires that the
value of not repudiating is no smaller than the value of repudiating, or

\[ \nu(b_{it}, y_{it}) \geq u(y_{it}) + \frac{\beta}{1-\beta} \int u'(\hat{y}) dF(\hat{y}). \] (8)

Note that constraint (8) is another type of borrowing constraint or liquidity constraint. Typically, \( \nu(b_{it}, y_{it}) \) must be strictly increasing in \( b_{it} \) and so, given \( y_{it} \), there will be some critical value of \( b_{it} \) for which the constraint binds. Thus, lenders cannot lend too much to a particular household, as doing so would imply debt repudiation.

Kocherlakota (1996) takes a somewhat different approach by examining a two-agent problem with limited commitment. In his set-up, two infinite-lived agents work out a risk-sharing arrangement subject to limited commitment. Kocherlakota's problem does not have some of the loose ends found in Kehoe and Levine (1993). In the Kehoe and Levine model, we are forced to accept an incomplete markets view of the world with no explanation for why the markets are missing, and it is not clear how credit market participants coordinate to discipline agents who repudiate their debts.

Aiyagari and Williamson (2000) integrate private information and limited commitment with a Bewley model of monetary exchange to study the relationship between money and credit. Credit arrangements are constrained by private information considerations, and if agents defect from credit arrangements their alternative is to be liquidity constrained in the manner of a Bewley-type consumer.

Abstract

An exogenous increase in the money supply is typically followed by a temporary fall in nominal interest rates. Flexible price macroeconomic models argue that this liquidity effect arises because asset markets are segmented. That is, only a fraction of the agents are present in the bond market when the central bank conducts an open market operation. However, to be quantitatively successful, segmented markets models assume frictions that are too large to be interpreted literally in terms of constraints faced by real-world firms and households. An important open question is: can a complicated array of microeconomic frictions imply one large aggregate friction of this kind?

Article

In macroeconomics, the term liquidity effect refers to a fall in nominal interest rates following an exogenous persistent increase in narrow measures of the money supply. According to the classical Fisher effect, however, an exogenous persistent increase in money is predicted to increase expected inflation and so increase nominal interest rates. Friedman (1968) argues that, in practice, both forces operate: a persistent increase in the money supply both reduces nominal interest rates and increases expected inflation so that the real rate – nominal minus expected inflation – also falls. Friedman (1968, pp. 5–7) speculates that nominal and real rates may fall below their typical levels for up to a year, but, over time, rates will then tend to increase before tending to the levels consistent with the inflation generated by the original monetary impulse.
Empirical macroeconomists have interpreted Friedman (1968) as follows. At long horizons real interest rates are determined by ‘fundamentals’ including the rate at which households discount the future and average productivity growth. Consequently, we should expect that long-horizon real interest rates are relatively stable and are unaffected by transitory monetary disturbances. Long-horizon nominal interest rates are this stable real rate plus expected inflation. At short horizons, however, Friedman's (1968) argument suggests that real and nominal interest rates are both volatile and positively correlated. His argument also suggests that short-horizon real rates and expected inflation are negatively correlated (Barr and Campbell, 1997, provide evidence consistent with this interpretation and Cochrane, 1989, provides specific evidence for liquidity effects at short horizons).

Perhaps the easiest way to interpret Friedman (1968) is in terms of the following market equilibrium scenario. Suppose that a monetary authority increases the money supply by conducting an unexpected outright purchase of bonds (an open market operation). At short horizons, nominal interest rates fall so that households are willing to hold a smaller quantity of bonds and a larger quantity of money. But this is only a partial equilibrium effect. As households spend their increased money holdings on goods, the price level increases and so real balances do not rise as fast as nominal balances. This general equilibrium effect mitigates the need for the nominal interest rate to fall. In many simple monetary models, households tend to spend money so ‘fast’ that the general equilibrium price level effect can completely overturn the partial equilibrium effect.

A textbook cash-in-advance (CIA) model with a constant aggregate endowment of goods (‘output’) and identically and independently distributed (IID) money growth shocks provides a stark example. In this model, households immediately spend an unexpected increase in money on a fixed quantity of goods. This increases the price level one-for-one with the increase in the money supply so that real balances are unchanged. In addition, because money growth is serially uncorrelated, expected inflation is constant. Taken together, constant real balances and constant expected inflation imply that the money market clears at a constant nominal interest rate. If instead monetary growth shocks are persistent then a positive shock increases expected inflation and nominal interest rates increase. In short, there is a Fisher effect but no liquidity effect. CIA models that are carefully calibrated to empirical processes for money growth and output, such as Hodrick, Kocherlakota and Lucas (1991) and Giovannini and Labadie (1991), lead to similar conclusions, as do studies of conceptually similar production economies, such as Cooley and Hansen (1989).

We now turn to departures from the standard CIA model in which a liquidity effect dominates at short horizons while a Fisher effect dominates at long horizons. Although models with nominal rigidities are in principle capable of generating these liquidity effects, we instead focus on flexible price models in which a liquidity effect is generated by an asset market friction of one form or another. Each of the models we discuss – Lucas (1990), Grossman and Weiss (1983), and Alvarez, Atkeson and Kehoe (2002) – captures, albeit in different ways, some of the spirit of Friedman's (1968) intuition. Lucas (1990) modifies the standard CIA endowment economy with a simple timing assumption: households have to allocate cash between a goods market and an asset market before observing the size of an open-market operation. Once that allocation has been made, there is a fixed quantity of cash sitting in the bond market. Now consider an unexpected purchase of bonds. Relative to the supply of bonds, there is now an unexpectedly large amount of cash available to purchase assets, so bond prices increase and the nominal interest rate falls.
Fuerst (1992) and Christiano and Eichenbaum (1995) integrate Lucas’s (1990) timing assumption into otherwise standard real business cycle (RBC) models. The key innovation of these papers is that, in each period, firms have to borrow cash from financial intermediaries in order to pay their workers. After a positive monetary shock, the nominal interest rate decreases so that firms find it optimal to borrow the unexpected increase in money balances. This increases firms’ labour demand and increases output. Thus, these models are consistent with the commonly held view that positive monetary shocks have a positive, albeit temporary, effect on output.

A limitation of models that use Lucas’s (1990) timing assumption is that the liquidity effect is very transitory even when monetary shocks are persistent. Households can adjust their allocation of cash every period. Therefore, the liquidity effect is entirely driven by serially uncorrelated ‘expectational errors’ in cash allocation.

We now turn to Grossman and Weiss (1983) and Alvarez, Atkeson and Kehoe (2002). These are general equilibrium models inspired by Baumol (1952) and Tobin’s (1956) ‘inventory-theoretic’ analyses of money demand. In this class of models, two key forces influence short-horizon liquidity effects. First, at any point in time, there are always some households that participate in asset markets and some households that do not. Second, because households do not acquire cash every period, they choose to spend their money holding slowly over time. The first force alone is sufficient to generate a liquidity effect; the second force provides an amplification mechanism.

In this setting, an open-market increase in the money supply must, in equilibrium, be held by the subset of households that are currently participating in asset markets. Therefore, even if the price level responds one-for-one with the increase in money supply, the share of aggregate real balances that must be held by these households increases. Hence, the nominal interest rate falls to clear the market. Also, because they hold a larger share of real balances, these households are able to increase their share of aggregate consumption and this drives down real interest rates. So, at short horizons, there is a liquidity effect. Moreover, if households spend their money slowly over several subsequent periods then the price level does not respond one-for-one to an increase in the money supply. Instead, the price level responds slowly. This implies that aggregate real balances rise (equivalently, in a model with constant output, velocity falls) and this provides a second force driving down nominal interest rates. The liquidity effect is amplified.

The influential model of Grossman and Weiss (1983) is a deterministic CIA endowment economy that exhibits both effects. Households are imperfectly synchronized and only participate in asset markets every second period. They spend money on consumption goods over two periods (Rotemberg, 1984, studies a production version of essentially the same environment).

Alvarez, Atkeson and Kehoe (2002) endogenize the fraction of households that participate in asset markets. They assume that households can participate if they pay a fixed cost. If a household’s individual real balances are neither too high nor too low, they do not pay the cost, do not participate in asset markets, and end up consuming their individual real balances. If their real balances are high, they pay the cost and invest money in the asset market. Similarly, if their real balances are low, they pay the cost in order to purchase goods with money invested in the asset market. The equilibrium amount of participation ends up depending on the curvature of the utility function, the expected growth rate of money and on the size of the fixed cost. For example, in a high-inflation economy almost all households pay the cost to participate in asset markets. Hence, increases in the money supply raise expected

inflation and nominal interest rates as in a basic CIA model. By contrast, in a low inflation economy, more households choose not to participate and the effects of incomplete participation are larger and may be big enough to cause a liquidity effect (that is, to dominate the Fisher effect at short horizons).

To simplify their analysis, however, Alvarez, Atkeson and Kehoe (2002) set up the model so that both active and inactive households spend all their money each period. No households save money to spend on consumption over multiple periods. Therefore, velocity is constant and the price level responds one-for-one with increases in the money supply. Alvarez, Atkeson and Kehoe (2002) can therefore generate a liquidity effect but without the amplification that is provided by a (transitory) fall in velocity. Alvarez, Atkeson and Edmond (2003) provide a stochastic counterpart to Grossman and Weiss (1983) where both forces are operative (but at the cost of reverting to an exogenous timing of transactions).

Limited participation models of the liquidity effect provide a number of important qualitative insights into the co-movements of money, interest, and prices (and, to a lesser extent, output). The quantitative insight provided by these models is, however, more debatable. To generate realistic co-movements of money, interest and prices, calibrated models of liquidity effects need ‘large’ asset market frictions. It is typically difficult to interpret the calibrated friction literally in terms of constraints faced by real-world firms and households (making it difficult, in the words of Manuelli and Sargent, 1988, p. 524, to ‘find the people’). For example, the most successful parameterizations in Alvarez, Atkeson and Edmond (2003) require the representative household to make withdrawals of money (broadly defined) from an asset market account once every 24–36 months. Alvarez, Atkeson and Edmond (2003) defend this with an appeal to the low frequency of asset market participation observed in the cross-section by Vissing-Jorgensen (2002). Thus, the size of the friction is defended by appealing to the likely size of the friction facing a household representative of the US economy rather than by appealing to direct evidence of the heterogeneous frictions facing individual observations of US households.

Cole and Ohanian (2002) provide another demonstration of the difficulty of interpreting such models literally. They note that the distribution of money holdings between US firms and households has been quite unstable over the post-war period. When this observation is embedded in a model of liquidity effects, it implies a corresponding instability in the effects of money shocks on output – an instability that seems to be counterfactual.

In our opinion, these limitations should not be interpreted as reasons for rejecting models of asset market segmentation. If anything, these limitations are instead reasons for rejecting an implicit aggregation hypothesis. Traditional macro models work with relatively crude frictions that are intended to summarize a complicated array of micro frictions facing individual households and firms. For example, the literature on models of liquidity effects assumes only one level of market segmentation – either between households and asset markets, or between firms and asset markets. However, asset market segmentation seems to occur at numerous levels of financial intermediation. A large body of empirical evidence shows that phenomena consistent with market segmentation arise within the financial system – a system that might best be viewed as a collection of partially integrated and relatively specialized ‘local’ asset markets (see, among many others, Collin-Dufresne, Goldstein and Martin, 2001).

This evidence motivates us to ask how a collection of small segmentation frictions cumulates in the aggregate, and whether they add up to a quantitatively significant macro friction. If they do, then the models of liquidity effects that we have discussed here would indeed be natural laboratories for the analysis of the monetary transmission mechanism.
In short, we conjecture that addressing segmentation at a disaggregative level is likely to provide important empirical and theoretical insights into the relationship between patterns of intermediation in financial markets and traditional macro questions – including the size and stability of liquidity effects at short horizons and the monetary policy transmission mechanism more generally.

liquidity preference

Carlo Panico

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Keynes's notion of liquidity preference stems from the fact that he made some specific sources of demand for monetary instruments depend upon the expected variations of the interest rate, and consequently on the expected variations in the capital value of financial assets. This source of demand was considered to be the cause of variations in the rate of interest. Economists close to Keynes realized that in the General Theory he had turned the analysis of liquidity preference into a new theory of the interest rate. Robertson defended the marginalist theory, while Hicks paved the way for the 'neoclassical synthesis'.

Article

The notion of 'liquidity preference' has become generally used in the literature on monetary issues (particularly that concerned with the interest rate) following Keynes's contributions in the 1930s. It concerns the motives for demanding monetary instruments or other close substitutes. Earlier, the analysis of the demand for monetary instruments was based on other motives and concepts and led to different conclusions.

The analysis of the motives for demanding monetary instruments plays a specific role within monetary theory. The literature dealing with the interest rate, for instance, has always distinguished two different analytical steps. The first deals with the variations in the 'market interest rate', that is, that actually
observed everyday: it describes how a change in this rate (or in the structure of the interest rates) comes about. To do that, it provides an analytical scheme which describes the behaviour of the money markets, by considering one after the other all different sources of demand for and supply of monetary instruments, pointing out the main causes of their variations. The second step deals with the level of the interest rate. It explains why this rate tends to remain, over a specific period of time, at a certain level, pointing out the factors determining it. The way in which these factors operate is then described by using the scheme provided in the first step of analysis. This clarifies the market mechanisms (that is, changes in the different components of demand and supply in the money markets) through which the prevailing level of the interest rate asserts itself.

The analysis of the motives for demanding monetary instruments thus properly belongs to the first step: it cooperates to describe the working of the money markets and the way in which variations in the interest rate (or in the structure of interest rates) occur.

This approach was followed by Smith, Ricardo, Tooke, J.S. Mill, Marx, Marshall, Wicksell, J.M. Keynes, Robertson, and so on, independently of the particular theory they proposed, that is whether the level of the ‘average interest rate’ (that prevailing over a specific period of time) was determined by the ‘forces of productivity and thrift’ or by other factors.

Prior to Keynes’s contributions in the 1930s, it was assumed that monetary instruments (in most cases, central bank money) are demanded for two reasons. First, they are demanded by the household sector for the ‘circulation of income’. Households, that is, hold in the form of currency a certain fraction of their income to carry out their daily consumption expenditure.

The second source of demand for central bank money, it was assumed, comes from the banking sector which requires liquid reserves to make payments to depositors and to meet the demand for bank loans of different maturity. Banks’ decisions, it was argued, are concerned with protecting themselves against the risk of running out of liquid means while minimizing cost. In such analyses, which did not use modern portfolio choice tools, the amount of reserves banks demand depends upon the composition of their portfolio (particularly the maturity of their loans) and upon the degree of uncertainty they feel as to the smooth operation of the credit payment system. On the basis of these two elements, banks fix the desired ratio between their reserves in central bank money and the amount of loans they can supply.

As some authors noticed, the presence of uncertainty among the elements affecting the decisions of financial operators makes the credit payment system unstable. The desired ratio of reserves to loans changes continuously and sometimes sharply. Financial markets become tighter precisely when more liquid means are required. A higher degree of uncertainty as to the smooth operation of the system, for instance, leads the business and the banking sectors to desire to ‘become more liquid’. The former tend to discount a larger amount of bills of exchange (that is, demand more short-term bank loans), while the latter set at a higher level the desired reserves–loans ratio, so supplying a smaller amount of bank loans.

The instability of the system and the variability of the interest rates were therefore recognized by some economists (a minority) and ascribed to the uncertainty felt by banks and business as to their ability to solve cash-flow problems.

This analysis of the demand for monetary instruments was dominant from Adam Smith onwards. Its basic points were still reflected in the famous ‘Cambridge equation’ presented by Pigou in his article ‘The value of money’ (1917) and in Keynes's A Tract on Monetary Reform (1923).
The analysis of the motives for demanding monetary instruments was considerably refined by J.M. Keynes in the 1930s. Developing the analysis inherited from Marshall and Pigou, Keynes distinguished three motives for demanding monetary instruments (by which was now meant member banks’ money, that is, bank deposits).

First, monetary instruments are demanded for transaction purposes. The amount demanded due to this motive is a stable function of the level of income.

The second source of demand for monetary instruments is for precautionary purposes, defined as the demand coming from different sectors as a protection against the possibility that some unexpected payment has to be made, or that some expected receipts cannot be realized. This definition has been differently interpreted. Some authors (and the majority of textbooks) have interpreted it in a restrictive way, by identifying it with the households’ holding of bank deposits as a precaution against extraordinary events (for example, payment of hospital bills). The precautionary demand for monetary instruments was typically lumped together with the transaction demand, both being an increasing function of the level of income. Other authors have instead given more extensive interpretation of this motive by including in it the demand coming from all financial operators feeling highly uncertain as to the future level of the interest rate. R. Kahn (1954) explained that people prefer holding part of their wealth in liquid means when their knowledge as to how the rate of interest is going to behave in the near future is so limited as to make it impossible to consider some future levels of this rate more probable than others.

This way of interpreting the precautionary motive makes it close to the third motive for demanding monetary instruments identified by Keynes: the speculative motive. Speculation in financial assets occurs because some agents expect with sufficient conviction that the rate of interest will move in a certain direction. The existence of uncertainty (that is, that lack of ‘complete knowledge’) is not denied. Yet the ‘limited knowledge’ available allows some agents to consider some future levels of the rate of interest more probable than others. Monetary instruments are so demanded (to avoid a loss in the capital value of financial assets) because a rise in the rate of interest is expected, and not because of the lack of any conviction as to the future of the rate of interest (as in the case of precautionary motive).

The novelty introduced by Keynes (some authors claim that it had been anticipated by Lavington, 1921) lies not in the fact that he recognized that money is also a ‘store of value’ (an element already present in previous literature), but in the fact that he made some specific sources of demand for monetary instruments depend upon the expected variations of the interest rate, and consequently on the expected variations in the capital value of financial assets.

On account of its magnitude, but principally on account of its high variability, which is due to the uncertain character of expectations about future events, this latter source of demand played a central role in Keynes's writing. It was considered to be the cause of variations in the rate of interest. Indeed, in subsequent years, some authors even identified the notion of liquidity preference with speculative motive, while many others put it at the centre of the intense debates on interest rate after the publication of the *General Theory of Employment, Interest and Money* (1936).

Keynes's innovations stimulated many controversies dealing with different aspects of the theory of interest and money. A central point in these debates was the evaluation of Keynes's own contribution: had he really presented a new theory of the rate of interest, alternative to the dominant marginalist one? In the preparatory works and in the *General Theory* itself, Keynes had so characterized his contribution.
He had tried to show the existence of logical inconsistency in the dominant real theory and, in opposition to it, had argued in favour of a monetary theory of the rate of interest based on historical and conventional factors.

The essential elements of the analysis of liquidity preference had already been introduced in *A Treatise of Money*, where the marginalist theory determining the ‘natural’ level of the interest rate on the basis of functions of demand for investment and supply of saving was still accepted. Here liquidity preference was integrated within the marginalist theory. In the *General Theory*, instead, the notion of a ‘natural’ interest rate was rejected. The ‘average’ level of the interest rate over a specific period of time was now determined by those factors able to affect the ‘common opinion’ as to the prevailing value of this rate in the future, and among these factors some importance was given to the policy of the monetary authority. Thus, while in *A Treatise on Money* the novelty of liquidity preference referred to the first step of the analysis of the interest rate (that describing how variations in this rate come about), in the *General Theory*, the novelty regarded the second step of analysis, that is the theory determining the level of this rate.

**Robertson's critique after the General Theory**

The group of economists close to Keynes in those years, with whom he discussed the proofs of the *General Theory*, fully realized that only in this book had he turned the analysis of liquidity preference, already present in the *Treatise*, into a new theory of the interest rate. Not all of them, however, agreed with him. Robertson, brought up in the same Marshallian tradition as Keynes, defended the marginalist theory, claiming that Keynes was in the *General Theory* overstating the role played by monetary factors (see Keynes, 1973a, pp. 499, and Robertson, 1936; 1940). He invited Keynes to attribute to monetary and real forces their proper place, as he had done in *A Treatise on Money*. The abandonment of the ‘forces of productivity and thrift’, when dealing with the determination of the ‘average’ interest rate over long periods of time, left the ‘expected normal value’ of this rate unexplained. Robertson could not accept that ‘the common opinion’ as to the future value of the interest rate should be explained in terms of factors changing from one historical period to the others, rather than by referring to one specific set of factors able to affect the course of events in different historical contexts. If we ask, Robertson stated, ‘what ultimately governs the judgement of wealthowners as to why the rate of interest should be different in the future from what it is today, we are surely led straight back to the fundamental phenomena of productivity and thrift’ (Robertson, 1940, p. 25).

To clarify his view, Robertson translated Keynes's arguments into a different analytical framework based on ‘flow’ concepts. The determination of the ‘market interest rate’ (that actually observed daily) and of the ‘average interest rate’ (the one prevailing over long periods of time) was analysed in terms of ‘loanable funds’, to show that in both cases (but especially in the long-period case) the influence of the demand function for investment and the supply of saving could not be ignored. Within this discussion, Robertson also pointed out the need for extra funds to finance new investment. The debate with Robertson was intense. Other economists also joined in to discuss the three issues raised: whether Keynes's theory left the determination of the average interest rate 'hanging in the air’ (or ‘hanging by its own bootstraps’); the role of speculative motive and saving and investment within a ‘loanable-funds’ approach; the ‘finance’ motive.
Hicks and the rise of the ‘neoclassical synthesis’

While the debate with Robertson moved on the common ground of the Marshallian tradition, those with other economists were characterized, from the beginning, by greater problems of understanding and communication.

A major figure in these debates was J.R. Hicks, whose reviews of the *General Theory* (Hicks, 1936; 1937) were discussed with Keynes in an exchange of correspondence (see Keynes, 1973b, pp. 71–83). This correspondence reveals Keynes's insistence on his inability to understand the meaning and the aim of Hicks's claim that the validity of Keynes's theory of interest did not prove other theories to be wrong. Hicks's aim was to integrate Keynes's ideas within an approach, different from the Marshallian one, based on a new version of the neoclassical theory of value which used the notion of *temporary* general equilibria. The rate of interest was determined, with the other distributive variables, relative prices and the level of activity, within an analysis characterized by interdependence between different markets and the simultaneous attainment of equilibrium between supply and demand in all of them. Equilibrium between saving and investment decisions was reached simultaneously with equilibrium between supply of and demand for monetary instruments. The application of ‘Walras's Law’ then made it possible to argue that the claim that the rate of interest is determined in the money market and the claim that it is determined in the market for saving and investment are equivalent.

Hicks's writings had a great impact on the literature. They opened the way to the interpretation of Keynes's work known as the ‘neoclassical synthesis’ and to the wide use of the famous IS–LM apparatus. Indeed, orthodox ‘Keynesian economics’ was derived from this line of development, rather than from Keynes's own writings, as the debate on interest rate shows.

The distinction between the two steps of an analysis of the interest rate was now obscured. In spite of Keynes's explicit claim to the contrary (Keynes, 1937, p. 215), the analysis of liquidity preference, which was intended as a means of describing the market mechanisms through which changes in the interest rate occur, became a theory determining the level of the interest rate. This theory was counterposed to others – the ‘loanable-funds theory’ and the ‘investment–saving theory’ – in a long debate which in the end established what Hicks had hinted in his reviews of the *General Theory*, that is, that in a general equilibrium analysis to attribute the determination of a price or of a distributive variable to the attainment of equilibrium in one specific market makes no sense.

Now, none of the orthodox Keynesian literature mentioned any more what Keynes had emphasized: the instability of the speculative demand for money due to the uncertain character of the expectations about the future level of the interest rate. The integration of the market for monetary instruments within a general equilibrium analysis requires that the data determining the functions of demand for and supply of money have to be as stable as those determining the demand and supply functions in other markets. The abandonment of Keynes's view of an unstable speculative demand for money was achieved by moving along two lines. First, the notion of an expected normal value of the interest rate was gradually abandoned. Second, the issue of stability was moved from a theoretical to an empirical level.

Already in *Value and Capital* (1939), Hicks had moved along the first line. After him, Modigliani (1944) derived a stable function of demand for money by referring to the risk of future increases in the interest rate, taking this risk as independent of people's specific expectations. The risk is thus *in general* low when the interest rate is high and high when the interest rate is low. Reference to specific
expectations of the future value of interest rate could, instead, make the risk high when the rate is high and low when the rate is low. Finally, Tobin (1958) with the explicit aim of making the theoretical treatment of uncertainty more precise in Keynesian analysis, proposed deriving the demand function for money by including, among the data, subjective probability distributions of the future level of the interest rate, not considering any particular variation in this rate more probable than others. (The similarity with Kahn's precautionary motive mentioned above is clear.) In this analysis, stability of the demand function for money can be achieved by adding one more assumption: any new piece of information acquired by agents does not change their subjective probability distribution. The meaning of this hypothesis is that agents have ‘complete knowledge’ of all relevant information, which amounts to assuming uncertainty away from the analysis. In his subsequent writings, Tobin did not return to this particular point, preferring to consider the issue of ‘stability’ an empirical, rather than a theoretical one. This line has been adopted by most followers of the orthodox Keynesian approach, thus avoiding complex theoretical problems. As a result, the possibility of reaching satisfactory conclusions on this issue appears more difficult.

Theories of the interest rate, which imply a departure from the dominant neoclassical tradition, whether Marshallian or modern general equilibrium versions, can also be found in the literature. They were held by authors close to Keynes during the preparation of the General Theory, like Joan Robinson and Kahn, and appear to reflect Keynes's original intentions more than other theories. Robinson and Kahn themselves, in subsequent years (see Robinson, 1937; 1951; Kahn, 1954) contributed to developing these analyses, which were also put forward by Kaldor (1939; 1970; 1982), and re-elaborated by a large group of economists, including Shackle (1967), Pasinetti (1974), Minsky (1975), Davidson (1978), Eatwell (1979), and Garegnani (1979).

Although there are some points of difference between these authors, they seem to agree on the instability of the speculative demand for money due to the uncertain character of the expectations about future level of the interest rate, and on the need to reject the neoclassical theory, for being either analytically inconsistent or for being based on the assumption of a simultaneous achievement of equilibrium in all markets, an assumption which neglects the different ways in which these markets are organized and operate.

The analyses of these authors have contributed to the development of a treatment of monetary issues which breaks with the traditional causal links between ‘monetary’ and ‘real’ variables, and where institutional elements, such as the way financial markets are organized over a certain period of time, play a central role. These analyses make it possible to argue in favour of a ‘monetary’ determination of the interest rate, based on historical and conventional factors, thus supporting Robinson's claim that any opinion ‘that is widely believed tends to verify itself, so that there is a large element of “thinking makes it so” in the determination of the interest rates’ (Robinson, 1951, p. 258).

The instability of the financial system and the variability of the interest rates are therefore recognized today, too, by some economists, who also allow for the influence of monetary factors on the level of activity and within the theory of value and distribution, in opposition to the dominant marginalist approach.

liquidity trap

Gauti B. Eggertsson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A liquidity trap is defined as a situation in which the short-term nominal interest rate is zero. The old Keynesian literature emphasized that increasing money supply has no effect in a liquidity trap so that monetary policy is ineffective. The modern literature, in contrast, emphasizes that, even if increasing the current money supply has no effect, monetary policy is far from ineffective at zero interest rates. What is important, however, is not the current money supply but managing expectations about the future money supply in states of the world in which interest rates are positive.

Article

A liquidity trap is defined as a situation in which the short-term nominal interest rate is zero. In this case, many argue, increasing money in circulation has no effect on either output or prices. The liquidity trap is originally a Keynesian idea and was contrasted with the quantity theory of money, which maintains that prices and output are, roughly speaking, proportional to the money supply.

According to the Keynesian theory, money supply has its effects on prices and output through the nominal interest rate. Increasing money supply reduces the interest rate through a money demand equation. Lower interest rates stimulate output and spending. The short-term nominal interest rate, however, cannot be less than zero, based on a basic arbitrage argument: no one will lend 100 dollars unless she gets at least 100 dollars back. This is often referred to as the ‘zero bound’ on the short-term nominal interest rate. Hence, the Keynesian argument goes, once the money supply has been increased to a level where the short-term interest rate is zero, there will be no further effect on either output or prices, no matter by how much money supply is increased.

The ideas that underlie the liquidity trap were conceived during the Great Depression. In that period the short-term nominal interest rate was close to zero. At the beginning of 1933, for example, the short-term nominal interest rate in the United States – as measured by three-month Treasuries – was only 0.05 per cent. As the memory of the Great Depression faded and several authors challenged the liquidity trap, many economists begun to regard it as a theoretical curiosity.

The liquidity trap received much more attention again in the late 1990s with the arrival of new data. The short-term nominal interest rate in Japan collapsed to zero in the second half of the 1990s. Furthermore, the Bank of Japan (BoJ) more than doubled the monetary base through traditional and non-traditional measures to increase prices and stimulate demand. The BoJ policy of ‘quantitative easing’ from 2001 to 2006, for example, increased the monetary base by over 70 per cent in that period. By most accounts, however, the effect on prices was sluggish at best. (As long as five years after the beginning of quantitative easing, the changes in the CPI and the GDP deflator were still only starting to approach positive territory.)
The modern view of the liquidity trap

The modern view of the liquidity trap is more subtle than the traditional Keynesian one. It relies on an intertemporal stochastic general equilibrium model whereby aggregate demand depends on current and expected future real interest rates rather than simply the current rate as in the old Keynesian models. In the modern framework, the liquidity trap arises when the zero bound on the short-term nominal interest rate prevents the central bank from fully accommodating sufficiently large deflationary shocks by interest rate cuts.

The aggregate demand relationship that underlies the model is usually expressed by a consumption Euler equation, derived from the maximization problem of a representative household. On the assumption that all output is consumed, that equation can be approximated as:

\[
Y_t = E_t Y_{t+1} - \sigma (i_t - E_t \pi_{t+1} - r^e_t)
\]  

(1)

where \(Y_t\) is the deviation of output from steady state, \(i_t\) is the short-term nominal interest rate, \(\pi_t\) is inflation, \(E_t\) is an expectation operator and \(r^e_t\) is an exogenous shock process (which can be due to host of factors). This equation says that current demand depends on expectations of future output (because spending depends on expected future income) and the real interest rate which is the difference between the nominal interest rate and expected future inflation (because lower real interest rates make spending today relatively cheaper than future spending). This equation can be forwarded to yield

\[
Y_t = E_t Y_{T+1} - \sigma \sum_{s=t}^{T} E_s (i_s - \pi_{s+1} - r^e_s)\]

which illustrates that demand depends not only on the current short-term interest rate but on the entire expected path for future interest rates and expected inflation. Because long-term interest rates depend on expectations about current and future short-term rates, this equation can also be interpreted as saying that demand depends on long-term interest rates.

Monetary policy works through the short-term nominal interest rate in the model, and is constrained by the fact that it cannot be set below zero,

\[
i_t \geq 0.
\]  

(2)

In contrast to the static Keynesian framework, monetary policy can still be effective in this model even when the current short-term nominal interest rate is zero. In order to be effective, however, expansionary monetary policy must change the public's expectations about future interest rates at the point in time when the zero bound will no longer be binding. For example, this may be the period in which the deflationary shocks are expected to subside. Thus, successful monetary easing in a liquidity trap involves committing to maintaining lower future nominal interest rates for any given price level in the future once deflationary pressures have subsided (see, for example, Reifschneider and Williams, 2000; Jung, Teranishi and Watanabe, 2005; Eggertsson and Woodford, 2003; Adam and Billi, 2006).

This was the rationale for the BoJ's announcement in the autumn of 2003 that it promised to keep the interest rate low until deflationary pressures had subsided and CPI inflation was projected to be in positive territory. It also underlay the logic of the Federal Reserve announcement in mid-2003 that it would keep interest rates low for a ‘considerable period’. At that time, there was some fear of deflation in the United States (the short-term interest rates reached one per cent in the spring of 2003, its lowest level since the Great Depression, and some analysts voiced fears of deflation).

There is a direct correspondence between the nominal interest rate and the money supply in the model reviewed above. There is an underlying demand equation for real money
balances derived from a representative household maximization problem (like the consumption Euler equation 1). This demand equation can be expressed as a relationship between the nominal interest rate and money supply

\[
\frac{M_t}{P_t} \geq \zeta(Y_t, i_t)
\]

(3)

where \(M_t\) is the nominal stock of money and \(P_t\) is a price level. On the assumption that both consumption and liquidity services are normal goods, this inequality says that the demand for money increases with lower interest rates and higher output. As the interest rate declines to zero, however, the demand for money is indeterminate because at that point households do not care whether they hold money or one-period riskless government bonds. The two are perfect substitutes: a government liability that has nominal value but pays no interest rate. Another way of stating the result discussed above is that a successful monetary easing (committing to lower future nominal interest rate for a given price level) involves committing to higher money supply in the future once interest rates have become positive again (see, for example, Eggertsson, 2006a).

Irrelevance results

According to the modern view outlined above, monetary policy will increase demand at zero interest rates only if it changes expectations about the future money supply or, equivalently, the path of future interest rates. The Keynesian liquidity trap is therefore only a true trap if the central bank cannot stir expectations. There are several interesting conditions under which this is the case, so that monetary easing is ineffective. These ‘irrelevance’ results help explain why BoJ’s increase in the monetary base in Japan through ‘quantitative easing’ in 2001–6 may have had a somewhat more limited effect on inflation and inflation expectations in that period than some proponents of the quantity theory of money expected.

Krugman (1998), for example, shows that at zero interest rates if the public expects the money supply in the future to revert to some constant value as soon as the interest rate is positive, quantitative easing will be ineffective. Any increase in the money supply in this case is expected to be reversed, and output and prices are unchanged.

Eggertsson and Woodford (2003) show that the same result applies if the public expects the central bank to follow a ‘Taylor rule’, which may indeed summarize behaviour of a number of central banks in industrial countries. A central bank following a Taylor rule raises interest rates in response to above-target inflation and above-trend output. Conversely, unless the zero bound is binding, the central bank reduces the interest rate if inflation is below target or output is below trend (an output gap). If the public expects the central bank to follow the Taylor rule, it anticipates an interest rate hike as soon as there are inflationary pressures in excess of the implicit inflation target. If the target is perceived to be price stability, this implies that quantitative easing has no effect, because a commitment to the Taylor rule implies that any increase in the monetary base is reversed as soon as deflationary pressures subside.

Eggertsson (2006a) demonstrates that, if a central bank is discretionary, that is, unable to commit to future policy, and minimizes a standard loss function that depends on inflation and the output gap, it will also be unable to increase inflationary expectations at the zero bound, because it will always have an incentive to renege on an inflation promise or extended ‘quantitative easing’ in order to achieve low ex post inflation. This deflation bias has the same implication as the previous two irrelevance propositions, namely, that the public will expect any increase in the monetary base to be reversed as soon as deflationary pressures subside. The deflation bias can be illustrated by the aid of a few additional equations, as illustrated in the next section.

The deflation bias and the optimal commitment

The deflation bias can be illustrated by completing the model that gave rise to (1), (2) and (3). In the model prices are not flexible because firms reset their price at random intervals. This gives rise to an aggregate supply equation which is often referred to as the ‘New Keynesian’ Phillips curve. It can be derived from the Euler equation of the firm’s maximization problem (see, for example, Woodford, 2003)

\[
\pi_t = \kappa(Y_t - Y_t^*) + \beta E_t \pi_{t+1}
\]

(4)
where $\gamma^e_t$ is the natural rate of output (in deviation from steady state), which is the ‘hypothetical’ output produced if prices were perfectly flexible, $\beta$ is the discount factor of the household in the model and the parameter $\kappa > 0$ is a function of preferences and technology parameters. This equation implies that inflation can increase output above its natural level because not all firms reset their prices instantaneously.

If the government’s objective is to maximize the utility of the representative household, it can be approximated by

$$\sum_{t=0}^{\infty} \beta^t \left\{ \pi_t^2 + \kappa \gamma_t (\gamma_t - \gamma^e_t)^2 \right\}$$

where the term $\gamma^e_t$ is the target level of output. It is also referred to as the ‘efficient level’ or ‘first-best level’ of output. The standard ‘inflation bias’ first illustrated by Kydland and Prescott (1977) arises when the natural level of output is lower than the efficient level of output, that is, $\gamma^*_t < \gamma^e_t$.

Eggertsson (2006a) shows that there is also a deflation bias under certain circumstances. While the inflation bias is a steady state phenomenon, the deflation bias arises to temporary shocks. Consider the implied solution for the nominal interest rate when there is an inflation bias of $\gamma^e_t$. It is

$$\pi_t = \gamma^e_t + \gamma^e_t.$$ 

This equation cannot be satisfied in the presence of sufficiently large deflationary shocks, that is, a negative $\gamma^e_t$. In particular if $\gamma^e_t < -\gamma^e_t$ this solution would imply a negative nominal interest rate. It can be shown (Eggertsson, 2006a) that a discretionary policymaker will in this case set the nominal interest rate to zero but set inflation equal to the ‘inflation bias’ solution $\gamma^e_t$ as soon as the deflationary pressures have subsided (that is, when the shock is $\gamma^e_t \geq -\gamma^e_t$). If the disturbance $\gamma^e_t$ is low enough, the zero bound frustrates the central bank’s ability to achieve its ‘inflation target’ $\gamma_t$ which can in turn lead to excessive deflation. (While deflation and zero interest rates are due to real shocks in the literature discussed above, an alternative way of modelling the liquidity trap is that it is the result of self-fulfilling deflationary expectations; see, for example, Benhabib, Schmitt-Grohe and Uribe, 2001.)

To illustrate this consider the following experiment. Suppose the term $\gamma^e_t$ is unexpectedly negative in period 0 ($\gamma^e_t = \gamma^e_t < 0$) and then reverts back to its steady state value $\gamma^e_t$ with a fixed probability $\alpha$ in every period. For simplicity assume that $\gamma^e_t = 0$. Then it is easy to verify from eqs. (1), (4), the behaviour of the central bank described above and the assumed process for $\gamma^e_t$ that the solution for output and inflation is given by (see Eggertsson, 2006a, for details)

$$\pi_t = \frac{1}{\alpha (1 - \beta (1 - \alpha)) - \sigma \kappa \gamma^e_t} \gamma^e_t \text{ if } \gamma^e_t = \gamma^e_t \text{ and } \pi_t = 0 \text{ otherwise}$$
Figure 1 shows the solution in a calibrated example for numerical values of the model taken from Eggertsson and Woodford (2003). Under this calibration $\alpha = 0.1$, $\kappa = 0.02$, $\beta = 0.99$, and $r^*_L = \frac{0.02}{4}$, but the model is calibrated in quarterly frequencies. The dashed line shows the solution under the contingency that the natural rate of interest reverts to a positive level in 15 periods. The inability of the central bank to set negative nominal interest rate results in a 14 per cent output collapse and 10 per cent annual deflation. The fact that in each quarter there is a 90 per cent chance of the exogenous disturbance to remaining negative for the next quarter creates the expectation of future deflation and a continued output depression, which creates even further depression and deflation. Even if the central bank lowers the short-term nominal interest rate to zero, the real rate of interest is positive, because the private sector expects deflation. The same results applies when there is an inflation bias, that is, $\bar{T} > 0$, but in this case the disturbance $r^*_L$ needs to be correspondingly more negative to lead to an output collapse.

Figure 1
Response of the nominal interest rate, inflation and the output gap to a shocks that lasts for 15 quarters. Note: The dashed line shows the solution under policy discretion, the solid line shows the solution under the optimal policy commitment.

The equation is:

$$\gamma_t = \frac{1 - \beta(1 - \alpha)}{\alpha(1 - \beta(1 - \alpha)) - \sigma_k(1 - \alpha)} \sigma r^*_L \text{ if } r^*_t = r^*_L \text{ and } \gamma_t = 0 \text{ otherwise}$$
The solution illustrated in Figure 1 is what Eggertsson (2006a) calls the deflation bias of monetary policy under discretion. The reason why this solution indicates a deflation bias is that the deflation and depression can largely be avoided by the correct commitment to optimal policy. The solid line shows the solution in the case that the central bank can commit to optimal future policy. In this case the deflation and the output contraction are largely avoided. In the optimal solution the central bank commits to keeping the nominal interest at zero for a considerable period beyond what is implied by the discretionary solution; that is, interest rates are kept at zero even if the deflationary shock has subsided. Similarly, the central bank allows for an output boom once the deflationary shock subsides and accommodates mild inflation. Such commitment stimulates demand and reduces deflation through several channels. The expectation of future inflation lowers the real interest rate, even if the nominal interest rate cannot be reduced further, thus stimulating spending. Similarly, a commitment to lower future nominal interest rate (once the deflationary pressures have subsided) stimulates demand for the same reason. Finally, the expectation of higher future income, as manifested by the expected output boom, stimulates current spending, in accordance with the permanent income hypothesis (see Eggertsson and Woodford, 2003, for the derivation underlying this figures. The optimal commitment is also derived in Jung, Teranishi and Watanabe, 2005, and Adam and Billi, 2006, for alternative processes for the deflationary disturbance).

The discretionary solution indicates that this optimal commitment, however desirable, is not feasible if the central bank cannot commit to future policy. The discretionary policymaker is cursed by the deflation bias. To understand the logic of this curse, observe that the government’s objective involves minimizing deviations of inflation and output from their targets. Both these targets can be achieved at time when the optimal commitment implies targeting positive inflation and generating an output boom. Hence the central bank has an incentive to renege on its previous commitment and achieve zero inflation and keep output at its optimal target. The private sector anticipates this, so that the solution under discretion is the one given in (6) and (7); this is the deflation bias of discretionary policy.

**Shaping expectations**

The lesson of the irrelevance results is that monetary policy is ineffective if it cannot stir expectations. The previous section illustrated, however, that shaping expectations in the correct way can be very important for minimizing the output contraction and deflation associated with deflationary shocks. This, however, may be difficult for a government that is expected to behave in a discretionary manner. How can the correct set of expectations be generated?

Perhaps the simplest solution is for the government to make clear announcements about its future policy through the appropriate ‘policy rule’. This was the lesson of the ‘rules vs. discretion’ literature started by Kydland and Prescott (1977) to solve the inflation bias, and the same logic applies here even if the nature of the ‘dynamic inconsistency’ that gives rise to the deflation bias is different from the standard one. To the extent that announcements about future policy are believed, they can have a very big effect. There is a large literature on the different policy rules that minimize the distortions associated with deflationary shocks. One example is found in both Eggertsson and Woodford (2003) and Wolman (2005). They show that, if the government follows a form of price level targeting, the optimal commitment solution can be closely or even completely replicated, depending on the sophistication of the targeting regime. Under the proposed policy rule the central bank commits to keep the interest rate at zero until a particular price level is hit, which happens well after the deflationary shocks have subsided.

If the central bank, and the government as a whole, has a very low level of credibility, a mere announcement of future policy intentions through a new ‘policy rule’ may not be sufficient. This is especially true in a deflationary environment, for at least three reasons. First, the deflation bias implies that the government has an incentive to promise to deliver future expansion and higher inflation, and then to renege on this promise. Second, the deflationary shocks that give rise to this commitment problem are rare, and it is therefore harder for a central bank to build up a reputation for dealing with them well. Third, this problem is even further aggravated at zero interest rates because then the central bank cannot take...
liquidity trap: The New Palgrave Dictionary of Economics

any direct actions (that is, cutting interest rate) to show its new commitment to reflation. This has led many authors to consider other policy options for the government as a whole that make a reflation credible, that is, make the optimal commitment described in the previous section ‘incentive compatible’.

Perhaps the most straightforward way to make a reflation credible is for the government to issue debt, for example by deficit spending. It is well known in the literature that government debt creates an inflationary incentive (see, for example, Calvo, 1978). Suppose the government promises future inflation and in addition prints one dollar of debt. If the government later reneges on its promised inflation, the real value of this one dollar of debt will increase by the same amount. Then the government will need to raise taxes to compensate for the increase in the real debt. To the extent that taxation is costly, it will no longer be in the interest of the government to renege on its promises to inflate the price level, even after deflationary pressures have subsided in the example above. This commitment device is explored in Eggertsson (2006a), which shows that this is an effective tool to battle deflation.

Jeanne and Svensson (2007) and Eggertsson (2006a) show that foreign exchange interventions also have this effect, for very similar reasons. The reason is that foreign exchange interventions change the balance sheet of the government so that a policy of reflation is incentive compatible. The reason is that, if the government prints nominal liabilities (such as government bonds or money) and purchases foreign exchange, it will incur balance-sheet losses if it reneges on an inflation promise because this would imply an exchange rate appreciation and thus a portfolio loss.

There are many other tools in the arsenal of the government to battle deflation. Real government spending, that is, government purchases of real goods and services, can also be effective to this end (Eggertsson, 2005). Perhaps the most surprising one is that policies that temporarily reduce the natural level of output, \( \gamma \), can be shown to increase equilibrium output (Eggertsson, 2006b). The reason is that policies that suppress the natural level of output create actual and expected reflation in the price level and this effect is strong enough to generate recovery because of the impact on real interest rates.

Conclusion: the Great Depression and the liquidity trap

As mentioned in the introduction, the old literature on the liquidity trap was motivated by the Great Depression. The modern literature on the liquidity trap not only sheds light on recent events in Japan and the United States (as discussed above) but also provides new insights into the US recovery from the Great Depression. This article has reviewed theoretical results that indicate that a policy of reflation can induce a substantial increase in output when there are deflationary shocks (compare the solid line and the dashed line in Figure 1: moving from one equilibrium to the other implies a substantial increase in output). Interestingly, Franklin Delano Roosevelt (FDR) announced a policy of reflating the price level in 1933 to its pre-Depression level when he became President in 1933. To achieve reflation FDR not only announced an explicit objective of reflation but also implemented several policies which made this objective credible. These policies include all those reviewed in the previous section, such as massive deficit spending, higher real government spending, foreign exchange interventions, and even policies that reduced the natural level of output (the National Industrial Recovery Act and the Agricultural Adjustment Act: see Eggertsson, 2006b, for discussion). As discussed in Eggertsson (2005; 2006b) these policies may greatly have contributed to the end of the depression. Output increased by 39 per cent during 1933–7, with the turning point occurring immediately after FDR’s inauguration, when he announced the policy objective of reflation. In 1937, however, the administration moved away from reflation and the stimulative policies that supported it – prematurely declaring victory over the depression – which helps explaining the downturn in 1937–8, when monthly industrial production fell by 30 per cent in less than a year. The recovery resumed once the administration recommitted to reflation (see Eggertsson and Puglsey, 2006). The modern analysis of the liquidity trap indicates that, while zero short-term interest rates made static changes in the money supply irrelevant during this period, expectations about the future evolution of the money supply and the interest rate were key factors determining aggregate demand. Thus, recent research indicates that monetary policy was far from being ineffective during the Great Depression, but it worked mainly through expectations.

List, Friedrich (1789–1846)

K. Tribe
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

economic nationalism; infant-industry protection; international division of labour; List, F.; national economy; productive powers; Zollverein

Article

Known chiefly as a proponent of economic nationalism and protection to ‘infant industries’, List's career followed a colourful, not to say disorderly course, from his engagement on behalf of a customs union in the early 1820s to exile and residence in the United States, agitation on behalf of railway construction, energetic economic journalism, and finally to his death by suicide in November 1846, depressed by his lack of success in promoting a commercial agreement between Prussia and Britain and also by chronic financial insecurity. Born into the family of a tanner on or about 6 August 1789 in Reutlingen, Württemberg, List's early life was unremarkable. After briefly working in his father's business, he entered service in the state administration as a clerk and in 1811 secured a position in Tübingen. There he began attending the occasional law lecture, giving up his appointment in 1813 to concentrate on his legal studies. He never sat for the final lawyers’ examination, instead taking and passing the actuaries’ examination in September 1814.

Re-entering the administration as an accountant, he was promoted in 1816 to the position of Chief Examiner of Accounts. At the same time he became involved in the publication of a reformist journal, contributing articles on the reform of local administration. Through his connections in Stuttgart he also became involved in proposals for the creation of a new faculty for state economy at the University of Tübingen; teaching began in January 1818 and List was appointed full professor of administrative practice. List seems to have made little effort to compensate for his lack of formal academic qualification for the post, and he was dismissed in mid-1819 for absenteeism.

It is at this point that List's ‘life’ begins; for it transpired that his absence during April 1819 was on account of his attendance at the founding meeting of the German Association for Trade and Commerce, a body dedicated to the abolition of internal barriers to trade and which appointed List consular secretary. During the following year List travelled on behalf of the Association, and was also elected to...
the Württemberg representative assembly as Deputy for Reutlingen. As a result of his activities in the latter role he was tried and sentenced for sedition in 1822; appealing from the sanctuary of Baden, he failed to get the verdict altered and began a life of exile, travelling in 1823 to Paris where he made the acquaintance of Lafayette. In May 1824, believing that he had been reprieved, List returned to Stuttgart, was promptly imprisoned and, in January 1825, exiled.

Acting on a suggestion of Lafayette, List set sail for America with his family in April 1825. Taking advantage of a tour that Lafayette was undertaking at the time, List travelled and studied, making the acquaintance of several leading political figures. Settling in Pennsylvania, where he briefly tried his hand at farming, he assumed in 1826 the editorship of a German-language newspaper, the Readinger Adler, and became closely associated with the Pennsylvania Society for the Encouragement of Manufactures and Mechanic Arts. Through this involvement he became a supporter of the ‘American system’ of protective tariffs, and published in late 1827 his first serious economic work, Outlines of American Political Economy, which was a critique of Thomas Cooper's free-trade Elements of Political Economy. Such was the success of this that the Pennsylvania Society asked List to write a school textbook on political economy, but only the first chapter of this work was ever written.

As a result of an interest in coal deposits List became involved in a railway construction company which eventually opened its railroad in 1831. By this time, List had supported the presidential campaign of Jackson in 1828 and had become an American citizen; he returned to Europe, settling there permanently in late 1832 and in 1834 was appointed American Consul in Leipzig. There he became involved with the construction of the Leipzig–Dresden railway and founded the Eisenbahnjournal (1835), but he parted with his fellow projectors in 1837 and moved to Paris, where he spent the next three years writing a prize essay and pursuing various journalistic projects.

After his period in Paris, he moved to Augsburg and then resumed his agitation on behalf of German economic unity and south German protectionism. As before, this was largely conducted through the medium of newspapers, one of these being the Zollvereinsblatt, founded in 1843. These last restless years brought literary success with the publication of his National System of Political Economy, but little effective influence on the formation of contemporary commercial policy.

List's contribution to the formation of the Zollverein was limited to the period between 1819 and 1820, when he travelled German courts representing the cause of tariff reform. His theoretical proposals concerning protection and ‘infant industries’ date from his American period and are indeed a direct result of his American experience of tariff debates in the later 1820s. Much of his writing is repetitive of simple themes, as one would expect of work produced in haste for newspapers, journals and pamphlets arguing for specific reforms. However, the general logic of his position can be summarized in the following terms.

The Smithian principle of ‘natural liberty’ and commercial freedom was a ‘cosmopolitan doctrine’ which erroneously generalized the situation of Britain to the rest of the world. Commercial freedom in this sense was a freedom for Britain to dominate the world economy, thanks to the degree of development of the British economy. Free trade and economic liberty were highly desirable for a true world economy, but were only appropriate to a world of economic equals. Such a world could be created only if those countries which were in the process of development could protect their key industries against premature competition. On the international front it was necessary to create a system of treaties and agreements which would regulate trade and competition in such a way that protective tariffs and other protectionist measures would one day be redundant. On the national level, it was important to
abolish internal limitations to development, such as duties between German states which hindered trade and communication. A powerful device for the creation of strong national economies was the railway, perceived not so much for its freight capacity as for its role in promoting the freedom of movement of active populations. While the abolition of internal duties opened up the fiscal geography of an economy, this space was to be given shape by a railway network which would link major centres of population – and it is this emphasis on a communications *network* that distinguishes List's work in the 1830s.

List's writing on railway development is scattered in several articles and was never presented systematically, but his conception of economic liberty and world economic development is developed in the two books he published, and the prize essay which he wrote in Paris. His *Outlines of American Political Economy* clearly contrasts a ‘Smithian’ economy of individuals and of mankind with ‘national economy’. The error of Smith was to believe that the promotion of ‘individual economy’ – the satisfaction of individual wants – would lead to ‘the economy of mankind’ or cosmo-political economy – securing the necessities and comforts of life to the whole human race. List argued that this would not happen; the true path to the economy of mankind lay through national economy, the consideration of measures and conditions appropriate to actually existing nations. The general laws of economics outlined by Smith and his followers could manifest themselves only through these nations, which necessarily modified the operation of these laws by force of their specific ‘productive powers’. The strength and independence of a national economy was secured through the control of the interior market, enabling the economy to flourish on the basis of its natural and human endowments.

*The Natural System of Political Economy* was written in 1837 as a response to questions concerning the ways of reconciling the interests of producers and consumers on the introduction of commercial liberty. This recapitulates the argument on individual and cosmopolitan economy already developed in the *Outlines*, but goes further in elaborating a general theory of economic development as a series of stages of agricultural, manufacturing and commercial activity. While the first stage involves a basic reliance on agriculture, by the fourth and final stage raw materials are imported for manufacture and re-export, while food is also imported.

*The National System of Political Economy* was published in 1841 and represents a rounding out of arguments already exposed in his earlier writing. Importantly, List now placed his arguments in a general conception of the civilizing process of international trade, underlining the fact that his opposition to free trade was by no means a narrowly nationalistic one. Also added to the original arguments is a conception of the international division of labour elaborated on the basis of the distinction of manufacture and agriculture. List divided the world into temperate zones naturally oriented towards manufacture, and hot zones with a natural advantage in the production of agricultural goods. A balanced development of the world economy, or in other words the civilizing process, requires that the nations in the temperate zone be in equilibrium with each other and that they neither singly nor jointly exploit the lands of the hot zone, which would otherwise become dependent on manufacturing powers.

Much of the *National System* is given over to a historical account of economic development which today is very dated, while List's critique of classical economics is likewise limited by the primarily non-academic readership to which he appealed. Nonetheless, his emphasis on productive powers rather than ‘value and capital’, and his insistence on the specificity of national endowments and conditions in considering world economic development remain of interest. While List's primary interest lay in political and economic reform, and his audience was emergent ‘informed popular opinion’, he nevertheless developed conceptions of economic space and economic development that have lasting
intellectual merits.

litigation, economics of

Kathryn E. Spier
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article begins by introducing the basic economic framework for studying litigation and out-of-court settlement. One set of issues addressed is positive (or descriptive) in nature. Under what conditions will someone decide to file suit? When do cases settle out of court? Normative issues are also addressed. Are these private litigation decisions in the interest of society more broadly? Next, the article surveys some of the more active areas in the litigation literature including rules of evidence, loser-pays rules, appeals, contingent fees for attorneys, alternative dispute resolution, class actions, and plea bargaining.

Keywords

adverse selection; alternative dispute resolution; asymmetric information; bargaining; contingent fees; dispute resolution; English Rule; Environmental Protection Agency; insurance contracts; liability; litigation, economics of; moral hazard; most-favoured-nation clauses; negative expected value; patents; Posner, R.; Superfund; symmetric information; transaction costs

Article

Litigation refers to the process of taking an argument to a court of law where a decision will be made. The discipline of economics has provided researchers – economists and legal scholars alike – with useful tools and frameworks for thinking about litigation. Is there too much litigation or too little? Why do some lawsuits go to trial while many others settle before trial? Should the losing party be required to reimburse the winning party's legal expenses? The first part of this article presents the main frameworks for studying the economics of litigation. The second part surveys just some of the active topics in the literature.

This article is largely a condensed version of Spier (2005). Previous surveys of this topic include Cooter and Rubinfeld (1989), Hay and Spier (1998), and Daughety (2000).
The decision to litigate

Suppose there are two litigants: one plaintiff and one defendant. The plaintiff is the injured party who seeks compensation; the defendant is the party who is potentially responsible for the plaintiff's injuries. A plaintiff will rationally choose to bring suit when the expected gross return from litigation, $x$, exceeds the cost of pursuing the case, $c_p$. The gross return, $x$, represents the expected judgment at the end of a long and costly trial or a settlement that takes place at some time prior to the trial. It could also reflect other issues, such as the impact that a court decision will have on future cases or the plaintiff's concern for her business reputation. In general, the plaintiff's cost of pursuing the case, $c_p$, and the defendant's cost of fighting back, $c_d$, would influence the gross return, $x$, and could be modelled in a similar way to other economic contests (Dixit, 1987). For the moment, however, we will treat them as exogenous.

The plaintiff's incentive to bring suit typically diverges from what is best for society as a whole (see Shavell, 1982b; 1997). Consider a situation where accidents are totally avoided if the defendant makes a small investment in precautions. If the plaintiff were expected to sue following an accident, the defendant would rationally take the precautions. No accidents would occur and no litigation costs would be incurred. If $c_p > x$, however, then the plaintiff lacks a credible threat to sue. Knowing this, the defendant has no incentive to take the precautions (however inexpensive). In this example, the plaintiff's private incentive to sue is socially insufficient. This is not always the case, however. Suppose that the defendant's investment is totally ineffective: accidents occur whether or not the defendant takes precautions. Following an accident, the plaintiff will sue the defendant when $c_p < x$. The plaintiff's incentive to bring suit is socially excessive in this example. Litigation is a socially wasteful activity here because there is nothing the defendant could have done to avoid the accident.

Settlement

Not surprisingly, the overwhelming majority of lawsuits settle before trial. (Fewer than four per cent of civil cases that are filed in the US State Courts go to trial; see Ostrom, Kauder and La Fountain, 2001, p. 29). To use our earlier notation, the plaintiff will receive a net payoff of $x - c_p$ if the case goes to court and the defendant will receive $-x - c_d$. Although $x$ represents a simple transfer from the defendant to the plaintiff, the litigation costs, $c_p + c_d$, represent a deadweight loss. Any out-of-court transfer $s \in (x - c_p, x + c_d)$ from the defendant to the plaintiff would be a Pareto improvement. The precise outcome of settlement negotiations will hinge on a variety of factors, including the timing of offers and counteroffers, the information and beliefs of the two litigants, and the nature of the broader legal and strategic environment.

Settlement with symmetric information

Suppose that the litigants are symmetrically informed and play an alternating-offer game with $T-1$ rounds of bargaining before trial in round $T$. At trial, the defendant pays $x$ to the plaintiff and the
litigation costs, $c_p$ and $c_d$, are incurred. The litigants share a common discount factor, $\delta$.

This game is easily solved by backwards induction. Suppose that the plaintiff is designated to make the last settlement offer in period $T-1$. The defendant will accept any offer that is better than going to trial, so the plaintiff will offer $S_{T-1} = \delta(x + c_d)$, minus a penny perhaps. If the case hasn't settled earlier, it will certainly settle on the courthouse steps. If we work backwards, the litigants are willing to settle for $S_{T-2} = \delta^2(x + c_d)$ in period $T-2$, and (by an extension of this logic) are willing to settle for $S_1 = \delta^{T-1}(x + c_d)$ in period 1.

Two observations about this example are in order. First, the allocation of the bargaining surplus is sensitive to the timing of the settlement offers. If the defendant were the one to make the last offer instead, then the case would settle for $S_{T-1} = \delta(x - c_p)$ in the last round and, working backwards, we would have $S_1 = \delta^{T-1}(x - c_p)$. In other words, the party who makes the last offer succeeds in extracting all of the bargaining surplus. The bargaining surplus would, of course, be more evenly allocated in a random-offer or framework where the two litigants flip a coin to determine who makes an offer.

Second, this simple example does not predict exactly when settlement will take place. The litigants are, in fact, indifferent between settling for $S_1 = \delta^{T-1}(x + c_d)$ in period 1 and for $S_{T-1} = \delta(x + c_d)$ on the courthouse steps. The reason for this is straightforward: there is no inefficiency associated with delay when the litigation costs are entirely borne at trial. (Settlement models differ from the related models of bilateral trade. There, discounting causes the pie to shrink. Here, discounting by itself does not affect the size of the pie.) If the costs of litigation were incurred gradually over time instead, so the first $T-1$ rounds of bargaining were costly as well, then there would be a unique subgame-perfect equilibrium with settlement in period 1 (Bebchuk, 1996).

**Settlement with asymmetric information**

Asymmetric information is common in litigation settings. Plaintiffs often have first-hand knowledge about the damages they have suffered; defendants often have first-hand knowledge about their degree of involvement in the accident. Litigants also receive private signals concerning the credibility of their witnesses and the quality and work ethic of their lawyers. Some of this information will become commonly known over time – the parties surely learn a great deal through pretrial proceedings and discovery. Other information may never come to light at all, but can nevertheless affect trial outcomes. Suppose that the defendant has private information about $x$, the expected judgment at trial. A similar analysis would follow if the plaintiff were privately informed instead. Formally, suppose $x$ drawn from a nicely behaved probability density function $f(x)$ on $[\bar{x}, \overline{x}]$ with cumulative density $F(x)$. Starting with P'ng (1983) and Bebchuk (1984), many papers assume that the uninformed player – the plaintiff in our example – makes a single take-it-or-leave-it settlement offer, $S$, before trial. The defendant accepts $S$ if it is lower than what he would expect to pay at trial, $\delta < \delta(x + c_d)$. The offer generates a ‘cut-off,’ $\hat{x} = \delta^{-1}(x - c_d)$, where defendant types above the cut-off accept the offer and those below the cut-off reject the offer and go to court.

The plaintiff's optimization problem may be written as a function of the cutoff, $\hat{x}$:
Maximize \[
\int_{\hat{x}}^{\infty} [\delta(x - c_p) f(x) dx + (1 - F(\hat{x})) \delta(\hat{x} + c_d)]
\]. The first term represents the plaintiff's net payoff associated with those types who reject the settlement offer, and the second term reflects the settlement payments from the defendant types above the cut-off, \(\hat{x}\), who accept the offer. Any interior solution is characterized by the following first-order condition:

\[
1 - F(\hat{x}) - (c_p + c_d) f(\hat{x}) = 0.
\]

At least some cases will settle – the plaintiff will certainly make a settlement offer that is accepted by the most liable defendants – and an interior solution exists when \((c_p + c_d)\) is not too high.

Bebchuk's basic model has been extended in a variety of ways. Nalebuff (1987) argues that the plaintiff may no longer have a credible commitment to take the case to trial following the rejection of the settlement offer, and explicitly incorporates a credibility constraint. Spier (1992) allows the plaintiff to make a sequence of settlement offers before trial. When litigation costs are all borne at trial (so there is no efficiency loss from delay), the plaintiff waits until the very last moment to offer \(S_T - 1 = \delta(\hat{x} + c_d)\), where \(\hat{x}\) is defined above. (The deadline effect is less pronounced when there are pretrial costs as well.) Reinganum and Wilde (1986) let the informed litigant made a single take-it-or-leave-it offer before trial and characterize a perfect Bayesian equilibrium – unique under the D1 refinement of Cho and Kreps (1987). The defendant's equilibrium offer \(S(x) = \delta(x - c_p)\) perfectly reveals his type. Making the correct inference, the plaintiff is indifferent and accepts the settlement offer with probability

\[
\pi(x) = e^{-(\hat{x} - x)/(c_p + c_d)}.
\]

Note that this probability is increasing in the defendant's expected liability, \(x\). This is implied by incentive compatibility; the defendant must be rewarded in equilibrium for making higher settlement offers with a higher rate of acceptance by the plaintiff.

Some scholars have used mechanism-design techniques to study settlement and have shown, among other things, that some cases will necessarily go to trial when the litigation costs are not too large (Spier, 1994a). In contrast to Myerson and Satterthwaite's (1983) analysis of bilateral trade, settlement bargaining breaks down with one-sided incomplete information and despite common knowledge that gains from trade exist. (Schweizer, 1989, and Daughety and Reinganum, 1994, explore extensive form games with two-sided asymmetric information.) Finally, it is important to mention an older literature where litigants have different priors about the outcome at trial. Landes (1971), Posner (1973), and Gould (1973) show that settlement negotiations may fail when the two sides are sufficiently optimistic. (See Loewenstein et al., 1993, for empirical evidence on self-serving biases.)
Normative implications

There are strong normative arguments in favour of settlement. Through a private settlement, the parties can avoid their litigation costs and (if they are risk averse) the risk premium associated with trials. All else equal, private settlement serves society's interest. What makes this topic more interesting – and sometimes exceptionally challenging – is that all else is not equal. First, settlement dilutes a defendant's incentives to avoid accidents. Following an accident, the defendant is better off if he has the option to settle his claim. Anticipating settlement on relatively advantageous terms, the defendant has less incentive to take precautions to avoid the lawsuit to begin with (Polinsky and Rubinfeld, 1988). (This not necessarily a bad thing: when cases settle out of court the litigation costs are avoided so the social cost of an accident is lower. Therefore, the defendant should be taking less care than if all cases went to trial.) Spier (1997) shows that the defendant's incentives are diluted even further if the defendant has private information. Second, the plaintiff is made better off through settlement than she would be going to trial and is therefore more likely to bring the suit. Therefore, the anticipation of settlement raises the overall volume of cases that are pursued.

Topics

Accuracy

Several papers present formal analyses of the social value of accuracy in legal settings. Kaplow and Shavell (1996) argue that the ex post accurate verification of the victim's damages is socially valuable if the injurer knew the victim's damages at the time when he chose his precaution level. Accuracy is not valuable, however, if the victim's damages could not have been known by the injurer ex ante. The 'scheduling' of damages, or standardizing awards for injuries that fall into particular categories (as in workers’ compensation), may be desirable in these cases. Scheduling also makes the future outcome of the case more transparent – there is less to argue about – and can help to promote settlement (Spier, 1994b). Kaplow and Shavell (1992) argue that accuracy gives injurers an incentive to learn about the injuries that their activities might cause and will subsequently fine-tune their precautions. (Accurate information created by earlier trials may also help future actors fine-tune their actions; Hua and Spier, 2005.)

Alternative dispute resolution

Alternative dispute resolution (ADR) refers to the formal and informal proceedings that help parties resolve their disputes outside of formal litigation. Unlike settlement, which is typically achieved by the litigants themselves (and their lawyers), ADR proceedings often involve third parties who offer opinions and/or advice. Many of these systems are part of the court system, but many others are designed by the parties themselves (for example, ADR clauses in commercial contracts). In either case, ADR reflects the need to reduce the transaction costs of litigation and to make accurate decisions (Shavell, 1994; Mnookin, 1998). Farber and White's (1991) empirical study of medical malpractice claims suggests that...
non-binding arbitration provides an informative signal and encourages subsequent settlement. Yoon (2004) confirms this result, but finds that ADR neither reduces litigation costs nor significantly shortens the delay. The importance of this topic and the relative dearth of research – both theoretical and empirical – makes ADR a ripe topic for further investigation.

Appeals

In most legal systems, a litigant who is dissatisfied with a lower court's decision can appeal to a higher court. In Shavell (1995), appeals can be an efficient means of correcting the errors made at the lower-court level. Appeals harness the private information of the litigants themselves: an incorrectly convicted defendant is more likely to appeal an earlier ruling since the probability of reversal is higher. In this way, resources are saved relative to random auditing. (See also Spitzer and Talley, 2000.) Daughety and Reinganum (2000a) consider a Bayesian model of appeals where the upper court perceives the private decision to appeal as informative and tries to rule ‘correctly’ given its posterior beliefs.

Bifurcation

Landes (1993) was the first to formally analyse ‘bifurcated’ trials where the court establishes the defendant's negligence before determining the plaintiff's damages. One benefit of bifurcation is that, once the defendant is absolved of liability, no further costs are incurred. The effect on the settlement rate is ambiguous, however. Chen, Chien and Chu (1997) consider these issues in a model with asymmetric information. Daughety and Reinganum (2000b) endogenize the level of litigation spending. White (2002), in her empirical analysis of asbestos trials, shows bifurcation raises the plaintiffs’ expected returns and increases the number of cases that are filed.

Case selection

The cases that go to trial are the tip of the iceberg – the vast majority of cases are settled before trial. These tried cases are likely to differ – perhaps systematically – from the cases that never reach the courtroom. Suppose the defendant is privately informed about the expected judgment at trial. Both the screening (Bebchuk, 1984) and signalling (Reinganum and Wilde, 1986) approaches discussed earlier predict that defendants with weak cases are more likely to settle out of court than defendants with strong cases. Intuitively, a defendant who expects an adverse judgment is more likely to accept a settlement offer. This result would be reversed if the plaintiff has private information instead. Many authors have explored case selection using models with non-common priors instead of asymmetric information. Most notably, Priest and Klein (1984) predicted that, for tried cases, the plaintiff win rate will tend towards 50 per cent. This stark result depends on the symmetry of the litigants, among other things. (With asymmetric information, Shavell, 1996, shows that any plaintiff win rate is possible.) More generally, however, the Priest–Klein framework suggests ways that trial rates may be systematically related to plaintiff win rates. Waldfogel (1995) estimates a structural model and finds results roughly consistent with the Priest–Klein theory.
Class actions

When an injurer has harmed a group of victims, these victims may (under some circumstances) join their claims for the purpose of litigation and/or settlement. One advantage of consolidation is the scale economies associated with common proceedings and legal representation. Che (1996) assumes that plaintiffs who join a class forgo a fine-tuned award and receive instead the average damage of the group. Absent settlement, it is clear that plaintiffs with weak cases are more likely to join a class. This adverse selection problem is mitigated when plaintiffs are privately informed. Weak plaintiffs have an incentive to remain independent, too, in an attempt to ‘signal’ that they have strong cases and, in equilibrium, fewer weak plaintiffs join the class. Che (2002) argues that classes may form to increase the members’ bargaining power via information aggregation. The defendant is more generous when bargaining with the class as a whole than when bargaining with individuals.

Contingent fees

In the United States, plaintiffs’ attorneys are often paid on a contingent basis, receiving a third (say) of any settlement or judgment but nothing if the case is lost. The use of contingent fees is regulated in the US. In particular, lawyers are prohibited from purchasing cases from their clients (Santore and Viard, 2001). Many European countries prohibit contingent fees altogether. There are many economic rationales for contingent fees. First, they give liquidity-constrained plaintiffs a way to finance their cases and shift some of the risk to the attorney. They also mitigate moral hazard (Danzon, 1983) and adverse selection problems. In Rubinfeld and Scotchmer (1993), attorneys have private information about their abilities and signal high quality through a willingness to accept contingent payment. Menus of contingent fees also arise when the clients have private information. (See also the mechanism-design model of Klement and Neeman, 2004.) In Dana and Spier (1993), the attorney has private information about the merits of the plaintiff's case. With contingent fees, the plaintiff can rest assured that the attorney will decline cases that are sure to lose. Finally, contingent fees can also be used strategically to make plaintiffs into ‘tougher’ negotiators (Hay, 1997; Bebchuk and Guzman, 1996). In empirical studies, Danzon and Lillard (1983) show a higher drop rate with contingent fees, and Helland and Tabarrok (2003) find that contingent fees are associated with higher-quality cases and faster case resolution.

Decoupling

It may be socially desirable to tax or subsidize the plaintiff's damage award. In Polinsky and Che (1991), a defendant chooses his level of precautions and, if injured, the plaintiff decides whether to bring suit. The optimal decoupled scheme taxes the plaintiff’s award so that only a handful of cases are brought, but, at the same time, it makes the award very large so that the defendant's incentives are maintained. Since the defendant's stakes are large relative to the plaintiff's, the defendant will tend to spend more at trial (Kahan and Tuckman, 1995; Choi and Sanchirico, 2004). Daughety and Reinganum (2003)
consider these issues in a model with asymmetric information.

**Disclosure and discovery**

Litigants may voluntarily share information before trial. Indeed, the ‘unravelling’ logic of Grossman (1981) implies that all private information would come to light because an adverse inference would be drawn from silence. Full unravelling cannot occur, however, when hard evidence is simply unavailable. Guilty defendants have an incentive to pool with the innocent defendants who are unable to prove their innocence, for example. This suggests an important role for laws that require litigants to share information before trial. ‘Discovery’ can improve the accuracy of later court decisions (Hay, 1994; Cooter and Rubinfeld, 1994) and facilitate settlement negotiations before trial by narrowing the scope of asymmetric information (Shavell, 1989). (In contrast, Schrag, 1999, argues that discovery can lead to higher litigation costs and longer delays.) In Farber and White's (1991) sample of medical malpractice cases, many lawsuits are settled or dropped following discovery. Using a survey of attorneys in federal civil cases, Shepherd (1999) finds defendants increase their discovery efforts, ‘tit-for-tat’, in response to heightened discovery requests by the plaintiff.

**The English Rule**

In the United States, litigants bear their own costs of litigation – the ‘American Rule’. In contrast, the ‘English Rule’ shifts the winner's costs to the loser. Shavell (1982a) and Katz (1990) show that the English Rule discourages the filing of low-probability-of-prevailing cases but encourages high-probability-of-prevailing cases. (Kaplow, 1993, and Polinsky and Rubinfeld, 1998, discuss the normative implications.) The English Rule also tends to raise the litigation rate when parties disagree about the probability of winning (Bebchuk, 1984; Shavell, 1982a). Intuitively, the scope for disagreement is even higher because the parties have different beliefs about who will bear the litigation costs. Finally, the English Rule tends to raise the level of litigation spending (Braeutigam, Owen and Panzar, 1984; Hause, 1989; Katz, 1987). Intuitively, the marginal cost associated with spending is lower since the costs are partially externalized.

**Inquisitorial versus adversarial systems**

In adversarial systems, each side gathers and processes information separately. In inquisitorial systems – such as those found in continental Europe – these activities are more centralized and often presided over by a judge (see the discussion in Parisi, 2002). Adversarial systems are often criticized for giving litigants an incentive to hide relevant information from each other and from the court. They also can lead to the wasteful duplication of effort. On the other hand, adversarial systems may provide better incentives for information gathering (Dewatripont and Tirole, 1999). Milgrom and Roberts (1986) present a persuasion game where the parties have equal access to all of the relevant evidence and show that accuracy is not compromised in equilibrium. This stark result may no longer hold when parties have asymmetric access to evidence or when evidence is costly to gather and disclose; see also Shin (1998),
Insurance contracts

It is common for insurance contracts to place an upper bound on the level of coverage. This creates a potential conflict between the defendant and his insurer when deciding to settle a case (Meurer, 1992; Sykes, 1994). The insurance company is averse to settling because the defendant will bear the downside of a very large judgment at trial. Nevertheless, the defendant may delegate settlement authority to his insurer as a strategic commitment to be ‘tough’ in settlement negotiations. By reducing the most that the insurer is willing to pay in settlement, the insurance contract serves to extract value from the plaintiff. These contracts may be undesirable from a social welfare perspective, however, since the toughness of the insurer can increase the litigation rate (and the associated litigation costs). Formally, these ideas are related to Aghion and Bolton’s (1987) analysis of contracts as a barrier to entry. (Spier and Sykes, 1998, show that corporate debt has a similar strategic value.)

Joint and several liability

There are many situations where a single victim is harmed by the actions of many injurers (for example, toxic-tort and price-fixing cases). Common rules for allocating responsibility include non-joint liability, where each losing defendant is responsible for his own share of damages, and joint and several liability, where a single losing defendant can be held responsible for the entirety of the plaintiff’s damages. Kornhauser and Revesz (1994) analyse settlement incentives when the liability of a non-settling defendant is reduced, dollar for dollar, by the value of the previous settlements. (If the plaintiff’s damages are $80 and one defendant settles for $S, the remaining defendant may be responsible for $80 − $S.) This rule encourages settlement when the cases are positively correlated but discourages settlement when the cases are independent. Some empirical support has been found in disputes between the Environmental Protection Agency (EPA) and Superfund defendants (Chang and Sigman, 2000).

Most-favoured-nation clauses

Settlement contracts in environments with multiple plaintiffs sometimes include ‘most-favoured-nation’ (MFN) clauses. They work in the following way: if an early settlement agreement includes an MFN clause and the defendant settles later with another plaintiff for more money, the early settlers receive the better terms, too. Spier (2003a) argues that MFN clauses economize on delay costs when a single defendant makes repeated offers to privately informed plaintiffs. MFNs may also be used to extract value from future plaintiffs (Spier, 2003b; Daughety and Reinganum, 2004). Intuitively, an MFN commits the defendant to be tough in future negotiations, allowing the defendant and the early plaintiffs to capture a greater share of the future bargaining surplus. The welfare effects of most-favoured-nation clauses are ambiguous. They can make early settlement negotiations more efficient but may lead later negotiations to fail.
Negative expected value claims

Suppose that a plaintiff has a negative expected value (NEV) claim – he stands to lose money if the case proceeds all the way to trial. Could this plaintiff succeed in extracting a settlement from the defendant? Interestingly, the divisibility of litigation costs over time can make the plaintiff's threat to litigate the NEV claim credible (Bebchuk, 1996). Here is the intuition. With divisibility, the bulk of the costs are sunk once the case reaches the courthouse steps. At that point, the plaintiff's threat to litigate is credible, so the defendant will settle. If we work backwards, the plaintiff's threat to continue may be credible at all stages of the game. Furthermore, a privately informed plaintiff with a NEV claim may mimic a plaintiff with a positive expected value claim and the defendant (not knowing for sure) may capitulate (Bebchuk, 1988; Katz, 1990). Finally, Rosenberg and Shavell (1985) present a model where the defendant must sink some defence costs or risk a summary judgment before trial.

Offer-of-judgment rules

Under Rule 68 of the United States Rules of Civil Procedure, if a plaintiff rejects a settlement offer and later receives a judgment that is less favourable, then the plaintiff is forced to bear the defendant's post-offer costs. Other rules allow for two-sided cost shifting. Spier (1994a) shows that these rules raise the settlement rate when liability is acknowledged but there is private information about damages. Intuitively, the rule serves to discipline aggressive settlement tactics (but see Farmer and Pecorino, 2000, and Miller, 1986). Bebchuk and Chang (1999) show that offer-of-judgment rules level the playing field in bargaining and lead to settlements that more accurately reflect the expected judgment at trial.

Patent litigation

Suppose that a patentee and an imitator are trying to settle a dispute. At trial, the patent may be invalidated, in which case the imitator will compete on equal footing with the patentee. Settlement provides an opportunity for collusion. Shapiro (2003) discusses these mechanisms and proposed criteria for judicial approval of patent settlements; see also Meurer (1989). Marshall, Meurer and Richard (1994) argue that the mere threat of patent litigation may be enough to soften competition in a patent race; see also Choi (1998). Lanjouw and Schankerman (2001) document interesting correlations between litigation decisions and the characteristics of the patents. In particular, a patent is more likely to be litigated if it serves as the ‘base of a cumulative chain’ or, in other words, there are more rents to be captured from future innovators.

Plea bargaining

In criminal cases in the United States, the prosecutor and the defendant often negotiate a guilty plea in exchange for a lighter sentence – a process known as plea bargaining. Landes (1971), in the first formal analysis of plea bargaining, assumes that the prosecutor maximizes the sum of expected sentences subject to a resource constraint. Grossman and Katz (1983) assume that the defendant privately observes
his guilt and the uninformed prosecutor makes a single take-it-or-leave-it offer of a reduced sentence in exchange for a guilty plea. In the screening equilibrium, the guilty defendants accept the offer and the innocent defendants reject the offer and go to trial. This is, of course, similar to Bebchuk's (1984) analysis of civil settlement. In Reinganum (1988), the prosecutor's offer signals the prosecutor's private information and, as in Reingaum and Wilde's (1986) analysis of civil settlement, the offers with high sentences are rejected more. In contrast to Grossman and Katz (1983), trials are more likely when the defendant is guilty. (In Reinganum, 2000, an informed defendant makes an offer to an uninformed prosecutor.)

**Precedent**

In Anglo-American legal systems, laws can be created and changed by judges over time. Cooter, Kornhauser and Lane (1979) present an early formal model where the courts learn about – and subsequently adjust – standards of care for injurers and victims. Landes and Posner (1976) consider the possibility of judicial bias, but argue that the threat of being overruled mitigates a judge's incentive to pursue his own agenda. Gennaioli and Shleifer (2005) present a formal model with a different conclusion. Rasmusen (1994) formalizes strategic interactions among a sequence of judges in a dynamic framework and shows that judges may cooperate in equilibrium and follow past precedents because violations would lead to future breakdowns where their own precedents would be violated by others; see also Schwartz (1992), Daughety and Reinganum (1999b) and Kornhauser (1992). Levy (2005) presents a model where judges have career concerns and go against precedent to signal their abilities. (A set of related rules and doctrines, ‘collateral estoppel’, applies when at least one litigant is involved in multiple suits; see Spurr, 1991, and Che and Yi, 1993.)

**Secret settlement**

It is not uncommon lawsuits to settle secretly, where neither the existence of the suit nor the terms of the settlement are observed by the public. Secrecy may be facilitated through ‘gag orders’ or through private contracts. In Daughety and Reinganum (1999a; 2002), open settlements publicize the defendant's involvement in a case and increase the likelihood that other plaintiffs will file suit in the future. They also provide future plaintiffs with information about the expected value of their claims. Daughety and Reinganum (1999a) show that, because of the publicity effect, early plaintiffs can extract ‘hush money’ from defendants, enriching themselves at the expense of later plaintiffs. Importantly, secrecy can compromise firms’ behaviour and product safety choices in a market setting (Daughety and Reinganum, 2005).

**Standards of proof**

How confident should a judge or jury be before convicting a defendant or finding in favour of a plaintiff? Rubinfeld and Sappington (1987) present a framework where the defendant can manipulate the signal received by the court, and shows how the optimal standard of proof balances litigation costs and
ex ante deterrence concerns. Sanchirico (1997) presents a model where plaintiffs, as well as defendants, make investments in their cases. Demougin and Fluet (2006) explores the trade-offs when the defendant's wealth is limited. See Bernardo, Talley and Welch (2000) and Hay and Spier (1997) for discussions of the burden of proof.

Article

Lloyd was Drummond Professor of Political Economy at the University of Oxford from 1832 to 1837. During those years he delivered a series of lectures which display marked originality and willingness to differ from the current canons of received wisdom among political economists. Twelve of the lectures were published. The manuscripts of the remaining lectures, approximately 24 in number, have not been found (Romano, 1977).

Among the published lectures, that of 1833 and the second set of 1836 are quite outstanding. His lecture on Value (1833) has moved some leading historians of economic thought to hail Lloyd as one of the first writers to articulate the marginal utility theory of value. Less celebrated, but equally notable, is his analysis of the manner in which the operations of the contemporary British economy condemn unskilled labourers to poverty. Against the popular Malthusianism of his day, he argues in favour of the principle of poor laws and of the proposition that relief of the poor is a matter of social justice (rather than individual charity).

In the course of his 1836 lectures Lloyd constructs a model of the British economy which, he believes, demonstrates that the present situation of unskilled labourers is akin to that of slaves. Further, he observes, contemporary British society is dividing progressively into two mutually exclusive classes, and the degree of concentration of ownership and control of capital in the nation is increasing. Under existing circumstances, the unskilled worker is obliged to give ever greater quantities of his ‘power of labouring’ in order to obtain in return a subsistence wage.

As a person, Lloyd remains an elusive, even enigmatic, figure. He followed an older brother Charles (later, Regius Professor of Divinity and Bishop of Oxford) to Christ Church in 1812. There he studied mathematics and classics, took an MA in 1818 and was ordained in 1822. Before Lloyd succeeded Richard Whately in the Drummond Chair, he was Reader in Greek (1823) and lecturer in mathematics.

In 1834 he was elected a Fellow of the Royal Society. At the end of his period as Professor of Political Economy, Lloyd left Oxford to live at Prestwood, Great Missenden, Buckinghamshire, where he died in 1852. During his last 15 years Lloyd appears to have lived very quietly and published nothing. There is as yet no satisfactory explanation as to why this able and well-connected scholar chose to remain silent.

Selected works

Twelve of Lloyd's lectures, 1834–36, were published collectively as Lectures on Population, Value, Poor Laws and Rent, London, 1837; reprinted, New York: A.M. Kelley, 1968. The collection includes: Two Lectures on the Checks to Population, delivered in 1834; A Lecture on the Notion of Value as Distinguishable not only from Utility, but also from Value in Exchange, delivered in 1833; Four Lectures on Poor Laws, delivered in Hilary term, 1836; Two Lectures on the Justice of Poor-Laws, and One Lecture on Rent, delivered in Michaelmas term, 1836. Earlier, Lloyd had published Prices of Corn in Oxford in the Beginning of the Fourteenth Century: Also from the Year 1583 to the Present Time, Oxford, 1830.

The term ‘loanable funds’ was used by the late D.H. Robertson, the chief advocate of the loanable funds theory of the interest rate, in the sense of what Marshall used to call ‘capital disposal’ or ‘command over capital’, (Robertson, 1940, p. 2). In a money-using economy where money is the only accepted means of payment, however, loanable funds are simply sums of money offered and demanded during a given period of time for immediate use at a certain price.

The loanable funds theory of interest is the theory which maintains that the interest rate, i.e. the price for the use of such funds per unit of time, must be determined by the supply and demand for such funds. The insistence on the flow nature of loanable funds is based upon the crucial conception that in a money-using world the major bulk of money normally exists in a continuous circular flow. It is constantly passing out of the hands of one person as the means of payment for his expenditures into the hands of others as the embodiment of their incomes and sales proceeds, which will in turn be expended, and so on ad infinitum. A part of the money in this endless circular flow, however, is observed to be constantly being diverted into a side stream leading to the money market, where it constitutes the supply of loanable funds. From there borrowers of loanable funds would then take them off and in general would put them back into the main circular flow of expenditures and incomes (receipts).

This emphasis on the flow nature of loanable funds does not imply that the loanable funds theory would be unaware that there are sometimes money balances held inactive, like stagnant puddles lying off the main stream of the money flow. The loanable funds theory, however, would maintain that the stocks of money off the circular flow, as well as the stock of money inside the circular flow, have no direct influence on the money market. It is only when people attempt to divert money from the circular flow into the money market (saving), or into the stagnant puddles (hoarding), or conversely try to withdraw the inactive money from the stagnant puddles for re-injection into the circular flow or into the money market (dishoarding), that the interest rate will be directly affected. In other words, only adjustments in the idle balances (hoarding or dishoarding) together with the flows of savings and investment exert direct influences on the interest rate.

Since flows must be measured over time, we must choose a convenient unit to measure time. To take account of the fact that money does not circulate with infinite velocity, Robertson defined the unit period
as one ‘during which, at the outset of our inquiry, the stock of money changes hands once in final exchange for the constituents of the community’s real income or output’ (Robertson, 1940, p. 65). In my opinion, however, it would be more consistent and convenient to define the unit period as one during which, at the outset, the stock of money changes hands once in exchange for all commodities and services instead of restricting the objects of exchange to final products only (Tsiang, 1956, esp. pp. 545–7). The reason for this will be clear later. Based on our new definition of the unit period, all gross incomes and sales proceeds from goods and services received during the current period cannot be spent on anything until the next period when they are then said to be ‘disposable’.

The definition of the unit period, however, does not preclude the funds borrowed or realized from sales of financial assets from being expendable during the same period. This differential treatment of the proceeds of sales of financial assets as distinguished from the proceeds of sales from goods and services is also an attempt to simulate the real situation in our present world; for the velocity of circulation of money against financial assets is in fact observed to be many times faster than that against goods and services. Assuming that there is a fixed unit period in our short period analysis does not necessarily imply that we are ipso facto assuming the invariability of the velocity of circulation of money; for short period variations in the velocity of money can be taken care of in terms of increases or decreases in the idle balances held.

Under this definition of the unit period and the implicit assumptions behind it, each individual, therefore, faces a financial constraint in that during a given unit period he can spend only his disposable income and his idle balances (the sum of the two constitutes the entire stock of money he possesses at the beginning of the period) plus the money he can currently borrow on the money market. Buying on credit is to be treated as first borrowing the money and then spending it. Thus when he plans to spend more than his disposable income and the amount he is willing to dishoard from his idle balances, he must borrow the excess from the money market to satisfy his total demand for finance. Since additions to the demand side are equivalent to deductions from the supply side, and vice versa, we need not dispute with Robertson when he classifies the demand for, and the supply of, loanable funds on the money market as follows (Robertson, 1940, p. 3).

On the demand side, he lists, with terminology slightly changed:

- D1 funds required to finance current expenditures on investment of fixed or working capital;
- D2 funds required to finance current expenditures on maintenance or replacement of existing fixed or working capital (note here that if our unit period were defined in the way Robertson defined it, i.e., as the period during which the total stock of money changes hands only once in the final exchange for the constituents of the community’s real income, then the current expenditure on maintenance and replacement, i.e., on intermediate products, cannot be said to require a dollar for dollar provision of finance as would expenditures on final products);
- D3 funds to be added to inactive balances held as liquid reserves;
- D4 funds required to finance current expenditures on consumption in excess of disposable income. Correspondingly, on the supply side, he gives:
- S1 current savings defined as disposable income minus planned current consumption expenditure;
- S2 current depreciation or depletion allowances for fixed and working capital taken out of the gross sales proceeds of the preceding period;
loanable funds: The New Palgrave Dictionary of Economics

- S3 dishoarding withdrawn from previously held inactive balances of money;
- S4 net creation of additional money by banks.

The function of the money market is to match the flow demands for loanable funds to the flow supplies, and the instrument with which it operates to achieve equilibrium between the two sides is the vector of interest rates. It is to be noted that in the flow equilibrium condition the total stock of money does not figure at all.

Nevertheless, it must be pointed out that the flow equilibrium condition of the money market as conceived by the loanable funds theorists can imply the stock equilibrium condition as conceived by the liquidity preference theorists, provided two necessary conditions are satisfied. Of the four demands for loanable funds listed above, D1, D2 and D4 are the additional demands for transactions balances (or what Keynes in 1937 called the finance demand for liquidity) needed by some firms and consumers to finance their current planned expenditures. And of the four sources of supply of loanable funds, S1 and S2 are but the reductions in demand for finance which other consumers of firms can spare during the current period. Therefore, D1, D2 and D4 minus S1 and S2 must be equal to the net aggregate increase which the community as a whole would want to add to their transaction balances. Similarly, D3 minus S3 is the net increase which the community would want to add to their inactive balances (including precautionary, speculative, and investment balances).

Thus the equilibrium condition of the demand for and supply of loanable funds, i.e.,

$$D1 + D2 + D3 + D4 = S1 + S2 + S3 + S4,$$

which can be rearranged as:

$$[D1 + D2 + D4 - (S1 + S2)] + (D3 - S3) = S4,$$

implies that the total increases in aggregate demand for transaction balances (finance) and for inactive balances equal the net current increases in money supply created by banks. Provided it may be presumed (a) that the previous stock supply of and demand for money were originally equal to each other, and (b) that the current increases (or decreases) in supply and demand for money (treated above as flow supply and demand for loanable funds) represent the full unlagged adjustments of the previous stock supply and demand to their new equilibrium values, the flow equilibrium of the loanable funds should necessarily imply a new stock equilibrium (Tsiang, 1982).

The two necessary provisos used to be taken for granted by the liquidity preference theorists, who generally think that full stock equilibrium can be achieved instantaneously at any point in time. However, Professor James Tobin, in his Nobel lecture given in 1981 (Tobin, 1982), has come to recognize that the money market cannot operate within a dimensionless point of time, but must operate
in finite time periods, which he called slices of time. Furthermore, he recognized that the equilibrium which can be expected in such a short slice of time can only be that between the adjustments in the stock demanded and in the stock supplied during the period. Since adjustments in stocks per time period are flows, Tobin's new approach is thus really a sort of flow equilibrium analysis.

Moreover, Tobin, at the same time, also admitted that in such a short period as a slice of time, portfolios of individual agents cannot adjust fully to new market information. Lags in response are inevitable and rational in view of the costs of transactions and decisions. Thus neither of the two necessary conditions is satisfied in the real world. Consequently, even when the money market has brought the flow demand for and supply of loanable funds to equality, the stock demand for money and the total money stock need not have reached mutual equilibrium, which the Keynesians and the stock-approach economists used to assume as being attainable at every point of time.

Finally, it should be realized that the demand for finance for planned investment expenditure, which Keynes (1937, p. 667) admitted he should not have overlooked in his General Theory, is of the nature of a flow generated by a flow decision to invest. It is not just a partial adjustment of the stock demand for money towards its new equilibrium value as treated in Tobin's new theory (Tobin, 1982). As Keynes put it in his reply to Ohlin (1937), “Finance” is a revolving fund... As soon as it is used in the sense of being expended, the lack of liquidity is automatically made good and the readiness to become temporarily unliquid is available to be used over again” (Keynes, 1937, p. 666). This is essentially a reaffirmation of the traditional conception of the circular flow of money, which loanable funds theorists had emphasized from the outset, but which Keynes himself had pushed into the dark background with his emphasis that the entire stock of money is being held voluntarily in portfolio allocation.

The rediscovery of the demand for finance by Keynes and the more recent unheralded switch on the part of Tobin towards the flow approach from his usual stock approach indicate that the loanable funds theory is perhaps the more appropriate approach at least for short period dynamic analysis.

local public finance

John M. Quigley
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The mobility of consumers and producers in response to fiscal incentives gives the study of local public finance its distinctive character. Households and firms are partitioned into spatial units on the basis of preferences, costs and the incentives provided by local tax and expenditure policies. These fiscal incentives are, in turn, chosen by the members of each of these jurisdictions or clubs. Externalities within and between these localities greatly affect the efficiency of taxation and the provision of public goods and services.

Keywords

Article

Economic analysis of the taxation and expenditure policies of local public authorities has become far more sophisticated as theoretical enquiry has directed attention towards the uniquely local aspects of public finance and as national policies have increased the importance of the local public sector. Many of the issues that arise in the analysis of the local public sector are familiar reflections of the important questions in public finance that have been addressed at the national level; for example, the incidence of taxation and the welfare losses from revenue instruments; the effect of government expenditures on consumer welfare and the distribution of well-being; the effect of public sector distortions on resource allocation and relative prices.
However, the principal difference between the economic analysis of public finance at the national and at
Local public finance: The New Palgrave Dictionary of Economics

The local levels is the potential for mobility among jurisdictions by the transport of final products and inputs, and especially by residents who finance local government and consume public output. Critically, this mobility may be endogenous to the revenue or expenditure actions taken by the local public authority, and this must be considered in any economic analysis of local finance. This insight, as it affects efficiency in the allocation of local public output and the incidence of local taxes, goes back at least to the fifth edition of Marshall's *Principles* (1907, Appendix G). Marshall presented a lucid discussion of the effect of local public expenditures on residential mobility (‘A high rate spent on providing good primary and secondary schools may attract artisan residents while repelling the well-to-do’ – Marshall, 1920, p. 794). He also noted the effects of mobility upon the incidence of local taxes.

Given the increased complexity of decentralized taxation and expenditure patterns when compared to national government policies, one may begin by asking which economic functions of government ought to be undertaken by the central (national) government rather than by local authorities. Consider the original Musgrave (1959) taxonomy of public sector functions: distribution, stabilization and allocation. It seems clear that a system of local taxes and expenditures is inappropriate for achieving distributional or stabilization goals. After the adoption of any system of taxation and redistribution by a locality, even one which reflects a unanimous view of the citizens, it will be in the interests of those bearing the burden of the tax to relocate in other jurisdictions and in the interests of potential beneficiaries of the redistribution to move into the jurisdiction. Similarly, locally adopted monetary and fiscal policies are unlikely to further stabilization objectives, even if such objectives are uniformly held by local citizens. Import leakages are so large that the local benefits of stabilization policies (for example, local public employment programmes) are almost certain to be less than their costs.

It is precisely the mobility of households, goods and factors across jurisdictions that defeats local stabilization and redistribution policies. Conversely, however, the same ‘openness’ of the local economy means that the decentralized local provision of public goods will in many cases improve the allocative efficiency of the economy. In particular, the smaller and more homogeneous a community in a system of local government, the more likely is it that the provision of public goods by any community will be consistent with the demands of its citizens. In the limit, of course, if public goods are financed by a head tax, and if there are neither economies of scale in production nor externalities in consumption, then provision by a system of small jurisdictions, each with citizens of homogeneous tastes and incomes, will result in an efficient allocation.

If, however, there are economies of scale in production, it makes sense to have larger jurisdictions. But when the public good is produced by a larger entity, ‘congestion’ may result; that is, the quality of the good may decline as it is shared with more people. In larger jurisdictions, moreover, citizen demands may be more heterogeneous. The problem of balancing the benefits of cost-sharing in production, on the one hand, with the sacrifice in well-being by compromising individual consumers’ demands or by introducing ‘congestion’ in public goods consumption, on the other, has been central to the normative analysis of the local provision of public goods.

Consider, for example, a ‘club’ providing some collective benefit to identical individuals (Buchanan, 1965). Suppose an organization supplies some public output $Q$ subject to congestion, or equivalently, suppose it supplies a good whose standardized cost $C(N)$ increases with population $N$. Individuals of income $Y$ are assessed the average cost of service provision and allocate their remaining income to some numeraire good $X$. A community of $N$ identical individuals will choose public output to maximize
utility, \( U(Q,X) \), subject to the individual budget constraint, \( Y = X + \left[ \frac{C(N)}{N} \right] Q \). This implies the familiar Samuelson (1954) condition:

\[
N \left[ \frac{\partial U}{\partial Q} / \frac{\partial U}{\partial X} \right] = C(N).
\]

(1)

The level of public good provision is chosen by the club of fixed size \( N \) so that the sum of the individual marginal rates of substitution (MRS) between private and public goods equals the marginal rate of transformation (MRT) in production. Given this level of public output, from the budget constraint it also follows that choice of club size to maximize utility is:

\[
C'(N) = \frac{C(N)}{N}.
\]

(2)

The optimum size of the club is the membership at which the average cost of public output is equal to the marginal cost of adding another member. From equations (1) and (2) it follows that for a pure public good, that is, \( C'(N) = 0 \), the optimal size of the club is unbounded, while for a private good, where \( C(N) = PN \), the individual MRS is equal to the MRT and the size of the club is indeterminate.

Applied to local public finance, the model indicates that a system of communities, each with identical individuals and of that size which minimizes average cost, would be a stable and efficient mechanism for public service provision. Homogeneity of demands is necessary for efficiency even if the tax structure (or club dues) is of the Lindahl variety. Each group in a heterogeneous community would be better off by moving to a jurisdiction with identical tax shares.

Theoretical analyses of local public economies are much more complicated when the partitioning of individuals into political jurisdictions is ‘non-anonymous’, that is, when the characteristics of the other members (in addition to their incomes) matter to those in the club. In many cases, an equilibrium allocation of residents to jurisdictions may not exist at all (Scotchmer, 1997). As noted below, non-anonymous crowding may also affect the costs of public goods provision and the interpretation of demands for local public goods.

The ‘club’ model of the provision of local public goods is a special case of the so-called Tiebout (1956) model, probably the most influential idea in the modern analysis of local public finance. Tiebout's stylized and informal analysis assumes that residential mobility is costless, that local jurisdictions provide public goods at minimum average cost and that local government is financed by non-distortionary lump-sum taxes. Under these circumstances, Tiebout argues that the provision of public goods by a system of competitive local governments may be no less efficient than the allocation of private goods by the market economy. The conclusion of this argument also depends crucially upon the
availability to citizens of a sufficiently large number of jurisdictions offering differing packages of local public goods and upon the absence of inter-jurisdictional externalities, as well as more conventional assumptions about full information. In reality, in most metropolitan areas, local public output is supplied by a small number of communities (small, at least, relative to the number of types of demanders); local mobility is quite costly and is motivated by many non-fiscal concerns. Individuals often live in one jurisdiction and work in another, and there are externalities among jurisdictions. Finally, revenues are raised, not by head taxes but by a variety of local levies, especially *ad valorem* taxes on real property.

Each of these factors limits the economic efficiency of the local public sector in important ways. The externalities or ‘spillouts’ of the benefits of public service provision mean that such goods will be underprovided without coordination by local communities – since each community will only consider the benefits accruing to its own citizens in choosing the level of service provision. For public goods and services with substantial spillouts of benefits, efficient levels of production can be stimulated by a system of open-ended matching grants to localities by the central government. As Pigou (1932) originally demonstrated, if the matching rate (the fraction of local spending reimbursed by higher government) corresponds to the fraction of local public output, which spills out to non-residents, then the externality will be internalized. It is, of course, rather difficult to implement this maxim of local public finance (Oates, 1972).

The heavy reliance upon local property taxes for financing the local public sector, especially in Britain, Canada and the United States, is another source of allocative inefficiency in local finance. Clearly, a property tax alters the housing consumption decision and leads to underconsumption of housing as well as to inefficiency in public goods consumption. Until rather recently the system of local property taxes was viewed as a system of excises (Netzer, 1966), regressive levies on property and housing consumption, in contrast to the original Henry George (1879) position on land taxes. Modern theoretical analyses (following Mieszkowski, 1972), which assume that capital is mobile across jurisdictions and that the supply of capital is insensitive to its rate of return, have led to a reconsideration of the regressive nature of the tax. The inelastic supply of aggregate capital means that a national system of local property taxes will reduce returns to capitalists by the average level of the tax. The geographical mobility of capital implies that capital will flee from high-tax jurisdictions, raising marginal productivity and pre-tax returns, to low-tax jurisdictions, depressing pre-tax returns. Thus the incidence of the system of property taxes depends upon the magnitude of the average level of the tax, relative to the deviations from that average, as well as distribution of households among high-tax and low-tax jurisdictions. Despite the ambiguities in resolving these detailed empirical issues, this theoretical argument suggests that the burden of property taxation is heavily skewed towards the owners of capital. Empirically, this conclusion is probably modified by regressive appraisal and administrative procedures. It should be noted, moreover, that from local governments’ perspective an increase in the level of the property tax to finance service provision is an excise on property users (since a change in any one community's property tax rate can have only a negligible effect on the average level of rates for the nation).

The distortion inherent in property tax financing may lead to local policies of exclusionary zoning. If, for example, the benefits of the local public sector were roughly equal per household, then it would be in the interests of current residents to force incoming households to consume more housing than the average household. Current residents may attempt to enforce this by imposing minimum lot-size restrictions or by other exclusionary practices to increase the housing consumption of newcomers. Of course, as noted before, unless there are sufficient communities so that the households residing within a
jurisdiction are literally identical, those who chose to consume less housing will typically enjoy a fiscal residual.

Despite these clear examples of allocative inefficiency in the system of local public finance and service provision, there is a substantial body of evidence that variations in property tax rates are reflected in property values and that variations in public services (for example, school quality) are capitalized into the sale prices of residential property. These findings are certainly consistent with the process of ‘voting with one's feet’ implied by the Tiebout model, but the capitalization of taxes and services is not necessary to efficiency in local government, nor does efficient service provision necessarily imply capitalization.

The observation that individuals register their demands for publicly financed services in their choices of community has other important implications, however. Specifically, information about the public goods provided by different jurisdictions, together with information about the characteristics of the residents of those jurisdictions, may be sufficient to identify consumer demands for public services. Extensive analyses of these issues have been undertaken, combining economic theories of the local political process with aggregate data on local public finance and choice of output. Under rather restrictive assumptions, the political process which determines the level of service provision can be modelled as the choice of the median voter of the community. Given the characteristics of that individual (or rather, estimates obtained from aggregate information), the ‘tax price’ that individual confronts, and the level of public output chosen, the parameters of the demand curve are estimated econometrically. The ‘tax price’ is the marginal cost to the individual of purchasing an additional dollar of public output. With property tax financing, this is typically approximated by the median voter's house value as a fraction of the community's taxable real property per household.

As noted above, the residents of localities may ‘care’ about the characteristics of other residents simply because their characteristics affect the cost of producing public services. One example may involve local schools, which absorb the largest share of local government spending on public services. To the extent that peers ‘matter’ in the production of educational outputs in primary school, policies of matching grants to local governments based on disadvantaged residents are called for (see Nechyba, 2003). The specification of empirical models of the demand for local public services is much more problematic when the demographic characteristics reflect either tastes for public goods or the costs of supplying them, or both.

Nevertheless, the results of these empirical investigations have proven useful in the positive analysis of citizen demands for public services and in the analysis of local finance. Nevertheless, the underlying economic model of local government behaviour is open to questions, both technical (for example, the requirement that preferences exhibit single peakedness) and substantive (for example, the neglect of the role of bureaucracy in government decisions). For example, if the median voter determines the demand for local public output, then the propensity for a community to spend out of lump-sum aid from higher government ought to be no different from the propensity to spend out of income generated by local taxation. Yet empirical evidence suggests that the propensity of communities to spend out of untied grant income greatly exceeds the propensity to spend out of ordinary income. A variety of alternative models of local finance have been espoused to help explain this ‘flypaper’ effect (‘money sticks where it lands’) in the context of bureaucratic decision-making. Chief among them are the so-called Leviathan models of a government that exploits its citizens by maximizing revenues extracted by taxation (Brennan and Buchanan, 1980). Clearly, however, more theoretical work needs to be done to resolve the
contradictions between mobile consumers of local public output and sluggish suppliers. Finally, it has been suggested that the inherent nature of local output and the traditional financing mechanisms of local government combine to exacerbate the economic and administrative problems of the local public sector (Baumol, 1967). Local output consists largely of labour-intensive services, where technical change is inherently slow, and is typically financed by income-inelastic tax instruments. Under reasonable demand conditions, these may produce a more or less continuous ‘crisis’ in local public finance, as service costs escalate more rapidly than revenue increments. Given these characteristics of the local financing mechanism, as well as the redistributive nature of many local services, there may thus be a strong case for revenue or tax-base sharing at the national level.

Local regression models

Oliver B. Linton
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses local regression models, that is, regression models where the parameters are allowed to vary with some covariates either in a completely unrestricted fashion or in an intermediate way with some exclusion restrictions that make some parameters vary only with some covariates. Special cases are nonparametric regression and additively separable nonparametric regression.

Keywords

additive models; Cobb–Douglas parametric model; conditional expectation; conditional variance; GARCH models; generalized additive models; identification; linear models; local regression models; parametric models

Article

Local regression models are regression models where the parameters are ‘localized’, that is, they are allowed to vary with some or all of the covariates in a general way. Suppose that \((Y, X)\) are random variables and let

\[
E(Y|X = x) = m(x) \tag{1}
\]

when it exists. The regression function \(m(x)\) is of primary interest because it describes how \(X\) affects \(Y\). One may also be interested in derivatives of \(m\) or averages thereof or in derived quantities like conditional variance \(\text{var}(Y|X = x) = E(Y^2|X = x) - E^2(Y|X = x)\). In cases of heavy-tailed distributions,
the conditional expectation may not exist, in which case one may instead work with other location functionals like trimmed mean or median. The conditional expectation is particularly easy to deal with but a lot of what is done for the mean can also be done for the median or other quantities.

A parametric regression model for \( m(x) \) is a family of functions \( M(x; \theta) \), \( \theta \in \Theta \subset \mathbb{R}^p \), where for each \( \theta \), \( M(\cdot; \theta) \) is a known function. The true parameter \( \theta_0 \) for which \( M(x_0; \theta_0) = m(x) \) for all \( x \in X \) is unknown and has to be estimated from data. For example, \( M(x; \theta) = x^T \theta \) would correspond to the linear regression case, which is the central model of econometrics. A key concept is that of identifiability: \( M \) is identifiable when distinct parameter values lead to different values of \( M \) for at least some \( x \) values. See Rothenberg (1971) for discussion. Parametric models arise frequently in economics and are of central importance. However, such models arise only when one has imposed specific functional forms on utility or production functions. Without these ad hoc assumptions one only gets much milder restrictions on functional form like concavity, symmetry, homogeneity and so on. The nonparametric approach is based on the belief that parametric models are usually mis-specified and may result in incorrect inferences. In this approach one treats the regression function \( m(x) \) as being of unknown functional form. One usually assumes that \( m \) is a continuous function or even differentiable, although there are cases of interest where \( m(x) \) is, say, continuous only from the right (left) with limits on the left (right), that is, there may be jumps at certain known or unknown locations in the support \( X \) of \( X \) (see Delgado and Hidalgo, 2000). By not restricting the functional form one obtains valid inferences for a much larger range of circumstances. In practice, the applicability depends on the sample size and the quality of data available. The theory and methods for carrying out such estimation are well understood, and are reviewed elsewhere (Härdle and Linton, 1994). Local regression models are one way of interpreting the nonparametric approach.

A local regression model is a family of functions

\[
M(x; \theta(x)), \quad \theta \in \Theta = \{ \theta : x \rightarrow \mathbb{R}^p \},
\]

where \( M(x; \theta) \) is a known function of both arguments. The true (functional) parameter \( \theta_0(\cdot) \) for which \( M(x, \theta_0(x)) = m(x) \) for all \( x \in X \) is unknown. It is usually assumed to be smooth. In other words this is a standard parametric regression model except that the parameters vary with the covariate value. There are a number of special cases. At one extreme lies the parametric model in which \( \theta(x) = \theta \) for all \( x \in X \subset \mathbb{R}^d \), but the true \( \theta_0 \) is unknown. At the other extreme lies the fully nonparametric case where \( \theta(\cdot) \) is not subject to any exclusion restrictions.

Many different \( M \) functions will generally do. For example, the local constant case corresponds to \( M(x; \theta) = \theta \) and the local linear case corresponds to \( M(x; \theta) = \theta_0 + \theta_1 x \). These cases along with higher-order polynomials have been widely studied (see, for example, Fan and Gijbels, 1996). There are also other possibilities. Consider the Cobb–Douglas parametric model
local regression models: The New Palgrave Dictionary of Economics

which is widely used in studies of production. By making \( \theta = (\theta_0, \theta_1, \ldots, \theta_d) \) vary freely with \( x \) one can match with any function \( m(x) \) so long as the supports coincide (see, for example, Charnes, Cooper and Schinnar, 1976). For binary data where it is known that \( m(x) \in [0, 1] \) it is appropriate to take

\[
M(x; \theta) = \theta_0 x_1 \cdots x_d,
\]

(3)

where \( x_1 \leq \cdots \leq x_d \) are the relevant components of \( x \). This example illustrates some pitfalls; for example, when \( m(x) > 1 \) for some \( x \) of interest. In that case, taking \( M(x; \theta) = \theta_0 + \theta_1 x \) will not be satisfactory.

The statistical justification for using local constant, local linear, and more generally local polynomial models is that any smooth function \( m(x) \) can be approximated near the point \( x_0 \) by Taylor series expansions, so for \( p \)-times continuously differentiable scalar functions we have

\[
m(x) = \sum_{j=0}^{p} \frac{1}{j!} \frac{d^jm}{dx^j}(x_0)(x - x_0)^j + R(x, x_0),
\]

(4)

where the remainder term satisfies \( R(x, x_0) / |x - x_0|^p \to 0 \) as \( x \to x_0 \). Thus the function \( m \) is locally well approximated by a polynomial of order \( p \), \( \sum_{j=0}^{p} \alpha_j (x - x_0)^j \), where \( \alpha_j \) can be identified with \( j!^{-1} \frac{d^jm}{dx^j}(x_0) / j! \). This justifies using local polynomial regression. But why should one ever work with local regression models outside the local polynomial class? First, any other local parametric model \( M(x; \theta) \) that is \( p \)-times continuously differentiable in \( x \) at \( x_0 \), satisfies a similar expansion to (4), \( \sum_{j=0}^{p} \beta_j (x - x_0)^j \), where \( \beta_j \) are functions of \( \theta \). By equating coefficients one obtains the same leading terms as long as there are ‘enough’ parameters in \( \theta \). Therefore, the same approximating objectives are reached by any such model. In some cases other equivalent classes may provide better approximations. Polynomials can sometimes violate some known features, like for example \( m(x) \in [0, 1] \). In that case, taking \( M(x; \theta) \) to be a c.d.f. of a polynomial provides the same approximation (so long as the c.d.f. chosen is also smooth enough) but imposes the boundedness restriction. Second, the local parameters may also be of interest in themselves. In the Cobb–Douglas case, the \( \theta_j(x) \) can be interpreted as local elasticities. A third benefit is that the local model nests the parametric model. This leads to better statistical properties for estimators and test statistics when the model is true or approximately true, the ‘home turf’ case (see Hjort and Glad, 1995). When the default parametric model in the area of interest is
nonlinear, as is true in many fields, there are some advantages to taking a localization of this in the nonparametric approach.

The issue of identification in local regression models is not well explored but some results are known (see Gozalo and Linton, 2000). The expansion (4) is clearly crucial for identification. If the function \( m \) is continuous but not differentiable, then only a single parameter is identifiable, which corresponds to the first term in (4); additional parameters remain unidentified. It is also necessary that there is a neighbourhood of the estimation point that contains enough observations (this is guaranteed when the marginal density exists and is positive).

Estimation of local regression models can be carried out by localization of the usual estimation criteria adopted for estimation of the corresponding parametric model like maximum likelihood or the method of moments where the localization is carried out by multiplying the contribution of observation \( i \) to the sample average objective function by the weight \( w_{ni} = K((x - X_i) / h) \), where \( K \) is called the kernel and usually satisfies at least \( \int k(u) du = 1 \), while \( h = h(n) \) is the bandwidth, a sequence designed to go to zero with sample size. The effect of the weighting factor \( w_{ni} \) is to emphasize observations close to the point of interest \( x \) and to de-emphasize observations far from \( x \), whence the appellation ‘localization’.

In the multivariate case, the expansion (4) becomes much more complicated: there are \( d \) first order partial derivatives, \( \frac{d(d-1)}{2} \) second order partial derivatives, and so on. With \( p = 5 \) and \( d = 10 \) the local parametric model would have over 1,000 parameters, which is too many for practical use. There are many interesting and important cases lying between the two extremes of parametric and fully nonparametric models, where some of the \( \theta_j \) vary with only a subset of \( x \). In this case, the local parametric model is imposing exclusion restrictions on the function \( m \) and the expansion is reduced. We next give some examples.

A function \( m(x) \) is additively separable if

\[
m(x) = \sum_{j=1}^{d} m_j(x_j)
\]

for some functions \( m_j \). In terms of the framework of the previous section \( p = d \) and

\[
M(x; \theta) = \sum_{j=1}^{d} M_j(x_j; \theta_j); \quad \theta_j(x) = \theta_j(x_j).
\]

The functions \( \theta_j(x_j) \) are one-dimensional but of unknown form. This implies that

\[
m(x) = \sum_{j=1}^{d} m_j(x_j), \quad \text{where} \quad m_j(x_j) = \theta_j(x_j).
\]

In this case, each function \( \theta_j(x) \) has \( d - 1 \) exclusion
local regression models: The New Palgrave Dictionary of Economics

restrictions. This is consistent with strong separability as defined in Goldman and Uzawa (1964). A generalization of this is to the so-called generalized additive models where

\[ M(x, \theta) = G \left( \sum_{j=1}^{d} M_j(x_j, \theta_j) \right) \]

where \( \theta_j(x) = \theta_j(x_j) \), in which \( G \) is a known ‘link’ function, while \( \theta_j \) are univariate functions as before. For example, \( G \) could be the c.d.f. of a random variable like the normal or logit. Linton and Nielsen (1995) discuss estimation of additive models.

In time series one is often interested in the relationship

\[ E[y_t|t-1] = m(l_{t-1}) \]

where the information set \( l_{t-1} = \{y_{t-1}, \ldots\} \) includes all past variables, either for estimation or forecasting purposes. This situation is complicated because \( I_{t-1} \) contains infinitely many variables and apart from the important class of Markov models \( m \) generally depends on all of them. A common assumption here is some kind of mixing condition that guarantees that the effect of \( y_{t-k} \) on \( y_t \) dies out as \( k \to \infty \). For example, an invertible MA(1) process has

\[ m(l_{t-1}) = \sum_{j=1}^{\infty} \theta^{j-1} y_{t-j} \]

for some \( |\theta| < 1 \). A natural generalization of this is the model

\[ m(l_{t-1}) = \sum_{j=1}^{\infty} m_j(y_{t-j}) \]

where \( m_j \) is a sequence of functions such that the sum is well defined, that is, \( m_j(\cdot) \) must decline in importance as \( j \to \infty \). This model is hard to analyse and to estimate. Instead, consider the more restrictive version

\[ m(l_{t-1}) = \sum_{j=1}^{\infty} \theta^{j-1} m(y_{t-j}) \]

for some unknown function \( m(\cdot) \) and parameter \( \theta \). When \( m(y) = y \) this includes the MA(1) process as a special case, but includes many other nonlinear models. By taking a local parametric model

\[ M(y) = a_0(y) + a_1(y) y + a_2(y) y^2 \]

for \( m \) one can nest the GARCH(1, 1) model of Bollerslev (1986). Linton and Mammen (2005) have recently developed a theory of estimation for this class of models. Another popular approach is the locally stationary models pioneered by Dahlhaus (1997). A locally stationary AR(1) process is

\[ y_t = \rho(t/T) y_{t-1} + \varepsilon_t \]

where \( \varepsilon_t \) is i.i.d. and \( \rho(\cdot) \) is a smooth but unknown form. By taking the local parametric model \( M(y) = a_0 \) one can nest the conventional autoregression, although there are other possibilities. Dahlhaus actually deals with a more general class of linear processes with

\[ y_t = \sum_{j=0}^{\infty} c_j(t/T) \varepsilon_{t-j} \]

where \( c_j(\cdot) \) are unknown but smooth functions.

location theory

Jacques-François Thisse

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Location theory deals with what is where. ‘What’ refers to any possible type of economic activity involving stores, dwellings, plants, offices, or public facilities. ‘Where’ refers to areas such as regions, cities, political jurisdictions, or custom unions. The objective of location theory is to explain why particular economic activities choose to establish themselves in particular places. Here we focus on spatial competition theory between firms, where locations are subject to attracting and repelling forces. We then extend this framework in order to account for the residential choices made by consumers.

Keywords

agglomeration forces; clusters; collusion; dispersion forces; general equilibrium; globalization; Hotelling, H.; land use; local labour markets; location theory; Nash equilibrium; new economic geography; oligopolistic competition; partial equilibrium; Principle of Differentiation; product differentiation; spatial competition; Stigler, G.; transportation costs; urban economics

Article

From a historical perspective, location theory has been at both the centre and the periphery of economic theory. It has been at the centre to the extent that it has followed the tradition taking its roots in Hotelling’s classical paper ‘Stability in Competition’ (1929) and has used the spatial framework as a metaphor to explain issues involving heterogeneity and diversity across agents (Rosen, 2002). Examples include the supply of differentiated products, electoral competition between political parties, the matching process on the labour market, competition between communities to attract residents or firms, and the number and size of jurisdictions. Location theory has been at the periphery to the extent that space has not been a major concern for most economists. Indeed, it is rare to find a principles textbook in which location issues are covered, let alone mentioned. This is despite their obvious importance for the way actual markets function, as shown, for instance, by the debate raging in many industrialized
countries about the consequences of globalization for the location of jobs. The theory of optimal location for a firm has long been dominated by the minisum model in which the firm aims at minimizing its total transportation costs (Weber, 1909). Formally, this is achieved by minimizing the weighted sum of distances to a finite number of points, which represent input and output markets. When the length of the shortest path connecting any two points of a transportation network measures the distance between these points, the firm's optimal location is an input/output market, or a node of the network, or both (Hurter and Martinich, 1988). Hence, the locational choice of a firm is either sluggish or catastrophic. Another interesting feature of that model is that the firm's optimal location is the outcome of the interplay of a system of forces pulling the firm in different directions. When several competing firms are to be located, the system of forces becomes richer in that it involves what are called 'agglomeration' and 'dispersion' forces.

Spatial competition between firms

To see how such a system of forces works, we consider the framework developed by Hotelling (1929). The market of a homogeneous good is made up of consumers who request one unit of the good. Because any single consumer is negligible to firms, Hotelling assumes that consumers are continuously distributed along a linear and bounded segment: think of Main Street. For simplicity, consumers are also supposed to be uniformly distributed along the linear segment. Two stores, aiming to maximize their respective profits, seek a location along the same segment. Because they are dispersed across locations, consumers differ in their access to the same store. In such a context, firms anticipate correctly that each consumer will buy from the store posting the lower full price, namely, the price at the firm's gate, called 'mill price', augmented by the travel costs that consumers must bear to go to the store they patronize. Accordingly, once they are located firms have some monopoly power over the consumers located in their vicinity, which enables them to choose their price. Of course, this choice is restricted by the possibility that consumers have to supply themselves from the competing firm. Note that any firm is supposed to have a single location – that is, an address – because increasing returns and indivisibilities do not allow it to run a large number of outlets dispersed along Main Street without incurring major losses (Koopmans, 1957).

Since each firm is aware that its price choice affects the consumer segment supplied by its rival, spatial competition is inherently strategic. This is one of the main innovations introduced by Hotelling, who uses a two-stage game to model the process of spatial competition. In the first stage, stores choose their location non-cooperatively; in the second, these locations being publicly observed, firms select their selling price. The use of a sequential procedure means that firms anticipate the consequences of their locational choices on their subsequent choices of prices, thus imparting to the model an implicit dynamic structure. The game is solved by backward induction. For an arbitrary pair of locations, Hotelling starts by solving the price subgame corresponding to the second stage. The resulting equilibrium prices are introduced into the profit functions, which then depend only upon the locations chosen by the firms. These functions stand for the payoffs that firms will maximize during the first stage of the game. Such an approach anticipates by several decades the concept of subgame perfect Nash equilibrium introduced by Selten (1965).

Whereas the individual purchase decision is discontinuous – a consumer buying only from one firm –
Hotelling finds it reasonable to suppose that firms’ aggregated demands are continuous with respect to prices. Supposing that each consumer is negligible solves the apparent contradiction between discontinuity at the individual level and continuity at the aggregated level. In other words, when consumers are continuously distributed across locations aggregated demands are ‘often’ continuous. The hypothesis of the continuum that had been popularized much later by Aumann (1964) is found here to represent the idea that competitive agents have a negligible impact on the market outcome. However, Hotelling considers a richer setting involving both ‘dwarfs’ – consumers – whose behaviour is competitive and ‘giants’ – firms – whose behaviour is strategic because they can manipulate the market outcome.

Hotelling’s claim was that the process of spatial competition leads firms to agglomerate at the market centre. If true, this provides us with a rationale for the observed spatial concentration of firms selling similar goods (such as restaurants, movie theatres, or fashion clothes shops). But Hotelling’s analysis is undermined by a mistake that invalidates his main conclusion: when firms are sufficiently close, the corresponding subgame does not have a Nash equilibrium in pure strategies, so that the payoffs used by Hotelling in the first stage are wrong (d’Aspremont, Gabszewicz and Thisse, 1979). This negative conclusion has led d’Aspremont et al. to slightly modify the Hotelling setting by assuming that the travel costs borne by consumers are quadratic in the distance covered, instead of being linear as in Hotelling. This new assumption captures the idea that the marginal cost of time increases with the length of the trip to the store. In this modified version, d’Aspremont et al. show that any price subgame has one and only one Nash equilibrium in pure strategies. Plugging these prices into the profit functions, they show that firms choose to set up at the two extremities of the linear segment. Firms do so because this allows them to relax price competition and to restore their profit margins. Indeed, when prices are fixed and equal the quest for customer proximity – or, equivalently, for a larger market area – leads the two firms to agglomerate at the market centre. The tendency for firms to choose distinct locations or products has been confirmed by many works, and has led Tirole (1988) to call it the ‘Principle of Differentiation’.

Consequently, price competition is a dispersion force, whereas the market area effect is an agglomeration force. What the Principle of Differentiation tells us is that the dispersion force always dominates the agglomeration force, at least when firms sell a homogeneous product and compete in price. Hence, the Hotelling setting is to be enriched if we want to be able to understand why firms selling similar products often form spatial clusters. This has been accomplished by following two different research strategies. In the first, the purpose is to identify market mechanisms allowing firms to relax price competition without being spatially separated. From this perspective, the most natural approach is to assume that firms sell products that are differentiated in the space of characteristics. It combines both spatial and product differentiation per se. An alternative approach, however, is to appeal to some form of collusion between firms that permits them to avoid the devastating effects of price competition. This is especially relevant when products can hardly be differentiated. The second research strategy is based on Stigler (1961) and develops the idea that consumers are imperfectly informed about the places where the existing varieties are made available. In such a context, consumers must undertake some search before finding a good match.

Product differentiation and collusion
Several papers have shown that firms selling differentiated varieties choose to agglomerate at the market centre when products are sufficiently differentiated, transportation costs borne by the consumers are low enough, or both (de Palma et al., 1985). This can be understood as follows. When consumers have different tastes and when residential locations and tastes are not correlated (or, alternatively, when individuals exhibit a love of variety), each firm supplies what is the best match for consumers who are otherwise dispersed across all locations. Price competition is relaxed by product differentiation, so that firms may afford to set up at the place offering the best accessibility to their potential customers. Such a place is obviously the market centre when the consumer distribution along Main Street is uniform. In addition, it is never profitable for a firm to leave the cluster when transportation costs are low because the benefit of a good match dominates the additional transportation costs that the consumer must bear to buy her best match. All of this seems to fit modern economies characterized by more and more variety and decreasing travel costs. In a nutshell, we may then safely conclude that one of the main reasons for agglomeration is that firms substitute product differentiation for spatial separation, very much as *Newsweek* and *Time* are supplied in the same stores but differentiated by their cover stories (Irmen and Thisse, 1998).

The welfare analysis of such an outcome is somewhat unexpected. At the optimum, prices are set equal to the common marginal cost so that consumers’ well-being depends only upon firms’ locations. In the case of a homogeneous good, maximizing total welfare boils down to minimizing aggregate transportation costs. However, once we introduce differentiation across varieties, consumers no longer patronize the nearest firm on each trip because they now benefit from intrinsic differentiation between stores. In this context, one needs a more general approach accounting for both distance and product diversity effects, the appropriate measure being the consumers’ indirect utility. As a result, the formation of a cluster need not be socially sub-optimal. Quite the opposite: when products are sufficiently differentiated, transportation costs are low, or both, it is socially desirable to have all firms agglomerated within a cluster. Hence, unlike what Hotelling thought, such an extreme concentration may be socially optimal.

Under what became known as ‘semi-collusion’, it has been shown that firms that anticipate some form of collusion in the price stage, which is typically repeated, will choose to locate together at the market centre (Jehiel, 1992; Friedman and Thisse, 1993). In this case, selling a homogenous product makes it easier to sustain price collusion because the punishment for a defecting firm is more severe. Of course, collusion is not easy to maintain in the long run, so that firms face a positive probability that price collusion will break down. In this case, firms select separated locations but do not seek to maximize their spatial differentiation. Specifically, Jehiel, Friedman and Thisse (1995) have established that the higher the probability that the price agreement will break down, the larger is the distance between firms.

**Search**

When firms sell differentiated products, it is reasonable to assume that consumers are incompletely informed about the varieties that are supplied. Even though the typical consumer knows which varieties are available in the market, she is unsure about which variety is offered where (and at which price). If consumers have to compare alternatives before buying, they must undertake *search* among firms. Stated differently, when the only way for consumers to find out which variety is on offer in a particular store is
to visit this store, they must bear the corresponding travel cost. Gathering information being costly, each consumer must compare the cost of an additional bit of information with the expected gain in terms of surplus. In a spatial setting, both the cost and the gain vary with consumers’ and firms’ locations.

When several stores are located together, it is reasonable to assume that the typical consumer knows the location and size of the cluster but not its composition. Once she arrives at the cluster, the travel costs are sunk and she can visit any store at a very low cost. But she must pay the transportation cost to each isolated store she visits. Spatial clustering of stores is, therefore, a particular means by which firms can facilitate consumer search. Indeed, a consumer is more likely to visit a cluster of stores than an isolated one because of the higher probability she faces of finding there a good match and a good price. When firms realize this fact, each of them understands that it might be in its own interest to form a marketplace with others. When a firm considers the possibility of joining competitors within the same marketplace, it thus faces a trade-off between a negative competition effect and a positive market area effect, both being generated by the pooling of firms selling similar products.

In the case of a market with a fixed size, Wolinsky (1983) has shown that the market outcome involves all firms forming a single marketplace once transportation costs are sufficiently low and when there are enough stores to make the cluster attractive. It is worth noting that the agglomeration may arise away from the market centre. Any point such that no single firm is able to find an alternative location far enough to induce some consumers to visit it before the cluster is a spatial equilibrium. Of course, the cluster cannot be too far from the market centre because stores need to offer a good accessibility to all consumers. Accordingly, once the urban area extends far away into the same direction, this implies that some firms will want to create a new cluster away from the original one.

Schulz and Stahl (1996) show that it is possible to uncover additional and surprising results by considering a market of variable size. To this end, they consider an unbounded space that allows them to capture the idea that more competition within the cluster may attract new customers coming from more distant locations, thus allowing the demand for each variety to increase. More concretely, the entry of a new variety may lead to an increase in the cluster's demand that outweighs the decrease in market area inflicted on existing varieties. Although price competition becomes fiercer, it appears here that firms may take advantage of the extensive margin effect to increase their prices in equilibrium. Clearly, when the number of varieties is not too large, such positive effects associated with the gathering of firms strengthen the agglomeration force that lies behind the cluster. Though collectively several firms might want to form a new market, it may not pay an individual firm to open a new market in the absence of a coordinating device. Consequently, a new firm entering the market will choose instead to join the incumbents, thus leading to a larger agglomeration. In this case, the entry of a new firm creates a positive externality for the existing firms by making total demand larger. This in turn explains the common fact that department stores encourage the location of competing firms within the shopping centre.

The relationship with new economic geography

It appears that location theory and new economic geography have a lot in common, a fact that has been overlooked in the literature. Such a relationship between the two domains is worth noting because economic geography models are developed in general equilibrium frameworks involving monopolistic competition on the product market, whereas location theory uses partial equilibrium models under
location theory: The New Palgrave Dictionary of Economics

oligopolistic competition. Indeed, one of the main conditions identified in spatial competition for a cluster of firms to emerge corresponds with the main finding established in ‘new economic geography’, that is, firms agglomerate when trade costs are sufficiently low (Krugman, 1991; Fujita, Krugman and Venables, 1999). Likewise, product differentiation fosters agglomeration whereas, by its mere existence, a cluster generates a lock-in effect similar to those encountered in economic geography. In both settings, the absence of increasing returns would lead to the emergence of ‘backyard capitalism’ in which each household produces its own consumption bundle. Finally, the market size effect uncovered in search models is similar to the agglomeration effect identified by Krugman and others.

Spatial competition and urban economics

So far, consumers have been able to seek where to buy but not where to live. Yet it is reasonable to assume that consumers adjust their residential choices to the locations selected by large firms and/or by public facilities. For the resulting distribution to be non-degenerate, a land market must be introduced in which consumers compete for land use. In such a context, the demand of a consumer for the firm's output becomes in turn endogenous in that it depends on the income left after the land rent is paid. This brings into the picture some general equilibrium ingredients in that firms and households locations are interdependent. Fujita and Thisse (1986) consider a setting in which firms choose their locations, anticipating consumers’ residential choices, this sequence reflecting the fact that firms have market power whereas consumers adjust their locational choices to those made by firms. Because they compete for land, consumers are spread around firms in a way such that no consumer can find a better place to live. In the case of two firms selling a homogeneous good at a common given price, the agglomeration of the two firms is always a Nash equilibrium. However, dispersed equilibria may also coexist when travel costs are sufficiently high. This is because the decrease in individual consumption resulting from a move toward the rival dominates the market area effect. In other words, firms may not find it advantageous to agglomerate, thus showing that competition for land acts a major dispersion force.

Public facilities

Cities provide a large variety of local public goods. Because its location interacts with the locational choices of firms and households, a large public facility which consumers wish to access influences the nature of the urban structure. In particular, one expects the presence of a major equipment to act as an agglomeration force on the private sector (Thisse and Wildasin, 1992). When topographical boundaries have no impact on the location of the public facility, this one is always established at the centre of the urban area and there is a tendency for this facility to draw the private firms together as income rises with respect to transportation costs. When the facility is set up near the edge of the area available for urban use – think of an urban area on the coast of a body of water – the resulting asymmetry has a significant impact on the locational interactions between firms: the two private firms are located together at the centre of the urban area. Hence, the public facility may serve as the center of a dispersed spatial configuration, or it may induce the agglomeration of firms in a location different from that of the public facility itself. In both cases, it vastly contributes to the shaping of the city structure.
Local labour markets

Due to the evolution of technological progress and the concomitant expansion of metropolitan areas, the urban labour force has become more heterogeneous whereas the labour market has been segmented in thinner sub-markets. The force inducing the formation of local labour markets finds its origin, at least partially, in the skill and geographical heterogeneity of workers (Brueckner, Thisse and Zenou, 2002). When workers have heterogeneous skills, firms have different job requirements because they have incentives to differentiate their job offers in order to gain market power in the labour market. This in turn implies that the labour market works as an *oligopsony* in which firms with different skill needs and different urban locations compete for mobile and skill-heterogeneous workers. In terms of urban economics, each firm may be considered as a company town attracting workers who also choose to reside near this firm. As in the case of firms selling consumption goods, firms are separated in the geographical space because this allows them to enjoy market power over the workers situated in their vicinity. Consequently, the economy may be viewed as a system of cities in which each firm/city competes to attract workers who are also residents. *The fact that each firm is anchored in a distinct location is a fundamental reason for the emergence of local labour markets.*

When workers bear the training cost that allows them to erase any mismatch between their innate skills and the skill needs of their employer, the net wage is lower for workers whose ‘skill distance’ from their employer is larger. Firms understand that, in the residential equilibrium, commuting distance is positively related to a worker's skill distance from the firm. In such a context, the equilibrium residential location of workers is governed by the quality of their match in the labour market. Knowledge of the connection between skill and commute distances affects the firm's interaction with its rivals as it competes for labour. The critical issue is that the equilibrium wage depends on the commuting cost parameters, yielding a link between the urban structure and the labour market. More precisely, low-skill workers incur high commuting costs, which may in turn lead low-skill workers not to take a job. Unemployment may arise, therefore, because some workers turn out to be too ‘distant’ from firms in *both* the skill and urban spaces. As in the foregoing, two different spatial components interact to shape the social structure of cities.

Bibliography

**How to cite this article**

The logit function is the reciprocal function to the sigmoid logistic function. It maps the interval \([0,1]\) into the real line and is written as:

\[
\text{logit}(p) = \ln\left(\frac{p}{1 - p}\right).
\]
Two traditions are involved in the modern theory of logit models of individual choices. The first one concerns curve fitting as exposed by Berkson (1944), who coined the term ‘logit’ after its close competitor ‘probit’ which is derived from the normal distribution. Both models are by far the most popular econometric methods used in applied work to estimate models for binary variables, even though the development of semiparametric and nonparametric alternatives since the mid-1970s has been intensive (Horowitz and Savin, 2001).

In the second strand of literature, models of discrete variables and discrete choices as originally set up by Thurstone (1927) in psychometrics have been known as ‘random utility models’ (RUM) since Marschak (1960) introduced them to economists. As the availability of individual databases and the need for tools to forecast aggregate demands derived from discrete choices were increasing from the 1960s onwards, different waves of innovations, fostered by McFadden (see his Nobel lecture, 2001) elaborated more and more sophisticated and flexible logit models. The use of these models and of simulation methods has triggered burgeoning applied research in demand analysis in recent years. Those who wish to study the subject in greater detail are referred to Gouriéroux (2000), McFadden (2001) or Train (2003), where references to applications in economics and marketing can also be found.

Measurement models

As Berkson (1951, p. 327) put it, logit (or probit) models may be seen as ‘merely a convenient way of graphically representing and fitting a function’. They are used for any empirical phenomenon delivering a binary random variable $Y_i$, taking values 0 and 1, to be analysed. In a logit model, it is postulated that its probability distribution conditional on a vector of covariates $X_i$ is given by:

$$\Pr(Y_i = 1|X_i) = \frac{\exp(X_i \beta)}{1 + \exp(X_i \beta)}$$

where $\beta$ is a vector of parameters. This model can also be derived from more general frameworks in statistical mechanics or spatial statistics (Strauss, 1992).

With the use of cross-sectional samples, the parameter of interest is estimated using maximum likelihood or by generalized linear models (GLM) methods where the link function is logit (McCullagh and Nelder, 1989). Under the maintained assumption that it is the true model and other standard assumptions, the maximum likelihood estimator (MLE) is consistent, asymptotically normal and efficient (Amemiya, 1985). Nevertheless, the MLE may fail to exist, or more exactly be at the bounds of the parameter space, when the samples are uniformly composed of 0•s or 1•s, for instance (Berkson, 1955).

When repeated observations are available, the method of Berkson delivers an estimator close to MLE since they are asymptotically equivalent. Observe first that the logit function of the true probability obeys the linear equation:
logit models of individual choice: The New Palgrave Dictionary of Economics

\[ \logit(Pr(Y_c = 1|X_c)) = X_c\beta \]

where the covariates \(X_c\) now take a discrete number of values defining each cell, \(c\). Second, use the observed frequency in each cell, \(\hat{p}_c\), and contrast it with the theoretical probability, \(p_c\), as:

\[ \logit(\hat{p}_c) = X_c\beta + (\logit(\hat{p}_c) - \logit(p_c)) = X_c\beta + \varepsilon_c. \]

The random term \(\varepsilon_c\) properly scaled by the square root of the number of observations in cell \(c\) is asymptotically normally distributed with variance equal to \(1 / (p_c(1 - p_c))\). The method of Berkson then consists in using minimum chi-square, that is, a method of moments, to estimate \(\beta\), an instance of what is know as minimum distance or asymptotic least squares (Gouriéroux, Monfort and Trognon, 1985).

When measurements for a single individual are repeated, Rasch (1960) suspected that individual effects might be important and proposed to write:

\[ \logit(Pr(Y_{it} = 1|X_{it})) = X_{it}\beta + \delta_i \]

where \(t\) indexes the different items that are measured and \(\delta_i\) is an individual specific intercept or fixed effect. Items can be different questions in performance tests or different periods. In the original Rasch formulation, parameters were allowed to be different across items, \(\beta_t\), and there were no covariates. Given that the number of items is small, it is well known that the estimation of such a model runs into the problem of incidental parameters (see Lancaster, 2000). As the number of parameters \(\delta_i\) increases with the cross-section dimension, the MLE is inconsistent (Chamberlain, 1984). Nevertheless, the nuisance parameters \(\delta_i\) can be differenced out using conditional likelihood methods (Andersen, 1973) because:

\[ \logit(Pr(Y_{it} = 1|X_{it}, Y_{it} + Y_{it'} = 1)) = (X_{it'} - X_{it})\beta. \]

The conditional likelihood estimator of \(\beta\) is consistent and root \(n\) asymptotically normal but it is not
efficient, although no efficient estimator is known. Furthermore, when binary variables $Y_{it}$ are independent, conditionally on $X_i$, the only model where a root $n$ consistent estimator exists is a logit model (Chamberlain, 1992). Extensions of Rasch rely on the fact that root $n$ consistent estimators exist if and only if $Y_{it} + Y_{it}'$ is a sufficient statistic for the nuisance parameters $\delta_i$ (Magnac, 2004). When the number of items or periods becomes large, profile likelihood methods where individual effects are treated as parameters seem to be accurate in Monte Carlo experiments as soon as the number of periods is four or five (Arellano, 2003).

Multinomial logit (or in disuse ‘conditional logit’) is to binary logit what a multinomial is to a binomial distribution (Theil, 1969). Given a vector $Y_i$ consisting of $K$ elements which are binary random variables and lie in the $\mathbb{R}^K$-simplex (their sum is equal to 1), it is postulated that:

$$\Pr(Y_i^{(k)} = 1|X_i) = \frac{\exp(X_i\beta^{(k)})}{1 + \sum_{k=2}^{K}\exp(X_i\beta^{(k)})}$$

where by normalization, $\beta^{(1)} = 0$. Ordered logit has a different flavour since it applies to rank-ordered data such as education levels (Gouriéroux, 2000).

As probits, logit models are very tightly specified parametric models and can be substantially generalized. Much effort has been exerted to relax parametric and conditional independence assumptions, starting with Manski (1975). Manski (1988) analyses the identifying restrictions in binary models, and Horowitz (1998) reviews estimation methods. In some cases, Lewbel (2000) and Matzkin (1992) offer alternatives.

**Random utility models**

The theory of discrete choice is directly set up in a multiple alternative framework. A choice of an alternative $k$ belonging to a set $C$ is assumed to be probabilistic either because preferences are stochastic or heterogenous, or because choices are perturbed in a random way. By definition, choice probability functions map each alternative and choice sets into the simplex of $\mathbb{R}^K$.

A strong restriction on choices is the axiom of Independence of Irrelevant Alternatives (IIA, Luce, 1959). The axiom states that the choice between two alternatives is independent of any other alternative in the choice set. The version that allows for zero probabilities (McFadden, 2001) states that for any pair of choice set $C, C'$ such that $\{k, k'\} \in C$ and $C \subseteq C'$:

$$\Pr(k \text{ is chosen in } C') = \Pr(k \text{ is chosen in } C) \cdot \Pr(\text{An element of } C \text{ is chosen in } C').$$
Under this axiom, choice probabilities take a multinomial generalized logit form. Moreover, assume that choices are associated with utility functions, \( \{u^{(k)}\}_k \) that depend on determinants \( X_i \) and random shocks:

\[
u^{(k)} = \chi \beta^{(k)} + \epsilon^{(k)},\]

and that the actual choice of the decision maker yields maximum utility to her. Then, the IIA axiom is verified if and only if \( \epsilon^{(k)} \) are independent and extreme value distributed (McFadden, 1974). Extensions of decision theory under IIA were proposed in the continuous case (Resnick and Roy, 1991) or in an intertemporal context (Dagsvik, 2002).

The IIA axiom is a strong restriction as in the famous red and blue bus example where, if IIA is assumed, the existence of different colours affects choices of transport between bus and other modes while introspection suggests that colours should indeed be irrelevant. Several generalizations which proceed from logit were proposed to bypass IIA. Hierarchical or tree structures were the first to be used. At the upper level, the choice set consists of broad groups of alternatives. In each of these groups, there are various alternatives which can consist themselves of subsets of alternatives, and so on. The best-known model is the two-level nested logit, where alternatives are grouped by similarities. For instance, the first level is the choice of the type of the car, the second level is the make of the car. The formula of choice probabilities for nested logit,

where alternative \( k \) belongs to \( B_s \), is not illuminating but the logic of construction is clear. Choices at each level are modelled as multinomial logit (Train, 2003). General extreme value distributions (McFadden, 1984) provide more extensions, although they do not generate all configurations of choice probabilities. In contrast, mixed logit does, as shown by McFadden and Train (2000). Instead of considering that parameters are deterministic, make them random or heterogeneous across agents. The result is a mixture model where individual probabilities of choice are obtained by integrating out the random elements as in
Integrals are computed using simulation methods (MacFadden, 2001). The same principle is used by Berry, Levinsohn and Pakes (1995) with a view to generalizing the aggregate logit choice models using market data. Logit models are still very much in use in applied settings in demand analysis and marketing, and are equivalent to a representative consumer model (Anderson, de Palma and Thisse, 1992). Mixed logits permit much more general patterns of substitution between alternatives and should probably become the standard tool in the near future.

If there is a number, θ, such that Y = logₑ(X - θ) is normally distributed, the distribution of X is lognormal. The important special case of θ = 0 gives the two parameter lognormal distribution, X ~ \(\Lambda(\mu, \sigma^2)\) with Y ~ \(N(\mu, \sigma^2)\), where \(\mu\) and \(\sigma^2\) denote the mean and variance of \(\log_e X\). The classic work on the subject is by Aitchison and Brown (1957). A useful survey is provided by Johnson, Kotz and Balakrishnan (1994, ch. 14). They also summarize the history of this distribution: the pioneer contributions by Galton (1879) on its genesis, and by McAlister (1879) on its measures of location and dispersion, were followed by Kapteyn (1903), who studied its genesis in more detail and also devised an analogue machine to generate it. Gibrat's (1931) study of economic size distributions was a most important development because of his law of proportionate effect. Since then there has been an immense number of applications of the lognormal distribution in the natural, behavioural and social sciences.

Why does the lognormal distribution appear to occur so frequently? One plausible answer is based on the central limit theorems used to explain the genesis of a normal curve. If a large number of random shocks, some positive, some negative, change the size of a particular variable, X, in an additive fashion, the distribution of that variable will tend to become normal as the number of shocks increases. But if these shocks act multiplicatively, changing the value of X by randomly distributed proportions instead of absolute amounts, the central limit theorems apply to Y = \(\log_e X\) which tends to be normally distributed. Hence X has a lognormal distribution.

The substitution of multiplicative for additive random shocks generates a positively skew, leptokurtic, lognormal distribution instead of the symmetric, mesokurtic normal curve. But the degree of skewness and kurtosis of the two-parameter lognormal curve depends solely on \(\sigma^2\), so if this is low enough, the lognormal approximates the normal curve. The important difference is that X cannot take zero or negative values which may make the lognormal distribution a more appropriate representation of...
variables, such as height and weight, which must take positive values. Clearly, the widespread occurrence of positive variables in practice, coupled with the great flexibility of the shape of the lognormal, provide further reasons for its frequent application.

long memory models

P.M. Robinson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Time series exhibiting varying forms of strong dependence are considered. Stationary parametric and semiparametric models, and their estimation, are first discussed. We go on to review nonlinear, nonstationary and multivariate models.

Keywords

ARMA processes; cointegration; Fourier frequencies; fractional autoregressive integrated moving average (FARIMA); fractional noise; generalized method of moments (GMM); long memory models; maximum likelihood; multivariate models; nonlinear models; nonstationary models; semiparametric estimation; statistical inference; time series analysis; Whittle estimates

Article

Much analysis of economic and financial time series focuses on stochastic modelling. Deterministic sequences, based on polynomials and dummy variables, can explain some trending or cyclic behaviour, but residuals typically exhibit serial dependence. Stochastic components have often been modelled by stationary, weakly dependent processes: parametric models include stationary and invertible autoregressive moving average (ARMA) processes, while a non-parametric approach usually focuses on a smooth spectral density. In many cases, however, we need to allow for a greater degree of persistence or ‘memory’. This is characterized by stationary time series whose autocorrelations are not summable or whose spectral densities are unbounded, or by non-stationary series evolving over time. The latter are partly covered by unit root processes, but considerably greater flexibility is possible.

Basic models

Early empirical evidence of slowly decaying autocorrelations emerged long ago, in analyses of
long memory models: The New Palgrave Dictionary of Economics

astronomical, chemical, agricultural and hydrological data, and then in economics and finance. A stationary parametric model which attracted early interest is ‘fractional noise’. Let \( x_t, t = 0, \pm 1, \ldots \), be a covariance stationary discrete time process, so its autocovariance \( \text{cov}(x_t, x_{t+u}) \) depends only on \( u \), and thus may be denoted by \( \gamma_u \). Then fractional noise \( x_t \) has autocovariance

\[
\gamma_u = \gamma_0 \left\{ |u+1|^{2d+1} - 2|u|^{2d+1} + |u-1|^{2d+1} \right\}, \quad u = 0, \pm 1, \ldots,
\]

(1)

where the parameter \( d \) is called the ‘memory parameter’, and satisfies \(-\frac{1}{2} < d < \frac{1}{2}\). When \( d = 0 \) (1) implies that \( \gamma_u = 0 \) for \( u \neq 0 \), so \( x_t \) is white noise. But if \( 0 < d < \frac{1}{2} \), we have

\[
\gamma_u \sim 2d \left( d + \frac{1}{2} \right) \gamma_0 |u|^{2d-1}, \quad \text{as } |u| \to \infty,
\]

(2)

where ‘\( \sim \)’ means that the ratio of left- and right-hand sides tends to one. It follows from (2) that \( \gamma_u \) does decrease with lag \( u \), but so slowly that

\[
\sum_{u=-\infty}^{\infty} \gamma_u = \infty.
\]

(3)

In the frequency domain, when \( x_t \) has a spectral density \( f(\lambda), \lambda \in (-\pi, \pi) \) given by

\[
f(\lambda) = (2\pi)^{-1} \sum_{u=-\infty}^{\infty} \gamma_u \cos(u\lambda), \quad \lambda \in (-\pi, \pi),
\]

the property (3) is equivalent to
\[
    f(0) = \infty,
    \]
    \hspace{1cm} (4)

and more precisely a fractional noise process \( x_t \) has spectral density satisfying

\[
    f(\lambda) \sim C\lambda^{-2d}, \text{ as } \lambda = 0^+.
    \hspace{1cm} (5)
\]

In general we can regard (3) and (4) as basic indicators of a ‘long memory’ process \( x_t \), and (2) and (5) as providing more detailed description of autocorrelation structure at long lags, or spectral behaviour at low frequencies. By contrast, if \( x_t \) were a stationary ARMA, \( \gamma_u \) would decay exponentially and \( f(\lambda) \) would be analytic at all frequencies. The structure (5) is similar to Granger’s (1966) ‘typical spectral shape of an economic variable’.

The model (1) is connected with the physical property of ‘self-similarity’, and, so far as economic and financial data are concerned, found early application in work of Mandelbrot (1972) and others. However, (1) imposes a very rigid structure, with autocorrelations decaying monotonically and depending on a single parameter. In addition, though a formula for \( f(\lambda) \) corresponding to (1) can be written down, it is complicated, and (1) does not connect well mathematically with other important time series models, and does not lend itself readily to forecasting.

An alternative class of ‘fractionally integrated’ processes leads to a satisfactory resolution of these concerns. This is conveniently expressed in terms of the lag operator \( L \), where \( Lx_t = x_t - 1 \). Given the formal expansion

\[
    (1 - s)^d = \sum_{j=0}^{\infty} \frac{\Gamma(j + d)}{\Gamma(d)\Gamma(j + 1)} s^j,
\]

we consider generating \( x_t \) from a zero-mean stationary sequence \( u_t, t = 0, \pm 1, \ldots \), by

\[
    (1 - L)^d(x_t - \mu) = v_t
    \hspace{1cm} (6)
\]
where \( \mu = E x_t \) and

\[
|d| < \frac{1}{2}.
\]

If \( v_t \) has absolutely summable autocorrelations, that satisfy some mild additional conditions, both the properties (2) and (5) hold. In the simplest case of (6), \( v_t \) is a white noise sequence. Then \( \gamma_u \) decays monotonically when \( d \in (0, \frac{1}{2}) \) and indeed behaves very much like (1). This model may have originated in Adenstedt (1974), though he stressed the case \( d \in (-\frac{1}{2}, 0) \), where \( x_t \) is said to have ‘negative dependence’ or ‘antipersistence’. Taking \( v_t \) to be a stationary and invertible ARMA process, with autoregressive order \( p \) and moving average order \( q \), gives the FARIMA \((p, d, q)\) process of Granger and Joyeux (1980). In principle, the short memory process \( v_t \) in (6) can be specified in any number of ways so as to yield (2) and/or (5); a process satisfying this condition is sometimes called \( I(d) \).

**Statistical inference**

Given observations \( x_{t,t} = 1, \ldots, n \) there is interest in estimating \( d \). If \( v_t \) has parametric autocorrelation, as when \( x_t \) is a FARIMA \((p, d, q)\), one can form a Gaussian maximum likelihood estimate of \( d \) and any other parameters. This estimate has the classical properties of being \( n^{1/2} \)-consistent and asymptotically normal and efficient. Computationally somewhat more convenient estimates, called Whittle estimates, have the same asymptotic properties. Indeed, for standard FARIMA \((p, d, q)\) parameterizations, say, the estimates of \( d \) and of ARMA coefficients have asymptotic variance matrix that is unaffected by many departures from Gaussianity. Though these asymptotic properties are of the same type as one obtains for estimates of short memory processes, such as ARMA, their proof is considerably more difficult (see Fox and Taqqu, 1986), due to the spectral singularity (4). In econometrics, generalized method of moments (GMM) estimation has become very popular, and GMM estimates have been proposed for long memory models. However, unless a suitable weighting is used, they are not efficient under Gaussianity, are not more robust asymptotically to non-Gaussianity, and are not even asymptotically normal when \( d > \frac{1}{4} \).

If the parametric autocorrelation is mis-specified, for example if in the FARIMA \((p, d, q)\) \( p \) or \( q \) are chosen too small or both are chosen too large, then the procedures described in the previous paragraph will generally produce inconsistent estimates of \( d \), as well as of other parameters. Essentially, the attempt to model the short memory component of \( x_t \) damages estimation of the long memory component. This difficulty can be tackled by a ‘semiparametric’ approach, if one regards the local or asymptotic specifications (2) or (5) as the model, and estimates \( d \) using only information in low
frequencies or in long lags. Frequency domain versions are by far the more popular here, having the nicest asymptotic statistical properties. In the log periodogram estimate of $d$, logged periodograms are regressed on a logged local approximation to $f(\lambda)$, over the $m$ Fourier frequencies closest to the origin (Geweke and Porter-Hudak, 1983), $m$ having the character of a bandwidth number similar to those used in smoothed nonparametric functional estimation. An alternative approach optimizes a local Whittle function, again based on the lowest $m$ Fourier frequencies (Künsch, 1987). In the asymptotics for both types of estimate (see Robinson, 1995a; 1995b) $m$ must increase with $n$, but more slowly (to avoid bias); both the log periodogram and local Whittle estimates are $m^{1/2}$-consistent and asymptotically normal, with the latter the more efficient (though it is computationally more onerous, being only implicitly defined). Because both converge more slowly than estimates of correctly specified parametric models, a larger amount of data may be necessary for estimates to be reasonably precise. Moreover, estimates are sensitive to the choice of $m$. However, automatic and other rules are available for determining $m$; and semiparametric methods of estimating memory parameters have become very popular not only because of the robust character of the asymptotic results, but because of their relative simplicity.

The long memory processes we have been discussing exhibit an excess of low frequency power (5). But one can also consider parametric or semiparametric models for a spectral density with one or more poles at non-zero frequencies. These models can be used to describe seasonal or cyclic behaviour (see Arteche and Robinson, 2000). It is also possible to estimate the unknown location of a pole, that is, cycle (see Giraitis, Hidalgo and Robinson, 2001).

**Nonlinear models**

In non-Gaussian series, not all information is contained in first and second moments. In particular, in many financial series observations $x_t$ may appear to have little or no autocorrelation, but instantaneous nonlinear functions, such as squares $x_t^2$, exhibit long memory behaviour. We can develop models to describe such phenomena. For example, let

$$x_t = \varepsilon_t h_t,$$

(7)

where $x_t$ is a sequence of independent and identically distributed random variables with unit variance, whereas $h_t$ is a stationary autocorrelated sequence, such that $\varepsilon_s$ and $h_t$ are independent for all $s \neq t$. Then for all $u \neq 0$, $\text{cov} = (x_t, x_{t+u}) = 0$ but $\text{cov}(x_t^2, x_{t+u}^2) = \text{cov}(h_t^2, h_{t+u}^2)$, which in general can be non-zero. In particular, if $h_t^2$ has long memory, so has $x_t^2$. In a more fundamental modelling we can take $h_t$ to be a nonlinear function of an underlying long memory Gaussian processes, with the functional form of $h$ determining the extent of any long memory in $h_t^2$; these issues were discussed in some generality by
Robinson (2001). The models form a class of long memory stochastic volatility models, whose estimation has been discussed by Hurvich, Moulines and Soulier (2005), for example. The fractional class (6) can be modified or extended to describe a wide class of nonstationary behaviour. For \( d \geq \frac{1}{2} \) the variance of \( x_t \) (6) explodes, but we can consider truncated versions such as

\[
x_t = (1 - L)^{-d} \{ v_t 1(t \geq 1) \}
\]

where \( 1(\cdot) \) is the indicator function, or

\[
x_t = (1 - L)^{-k} \{ w_t 1(t \geq 1) \}
\]

for integer \( k \geq 1 \), where \( w_t \) is a stationary \( I(c) \) process, \( |c| < \frac{1}{2} \), and \( d = k + c \). In either case we might call \( x_t \) a (nonstationary) \( I(d) \) process, for \( d \geq \frac{1}{2} \). Both models include the unit root case \( d = 1 \) that has proved so popular in econometrics. However, the fractional class \( I(d) \), for real-valued \( d \), bridges the gap between short memory and unit root processes, allowing also for the possibility of arbitrarily long memory \( d \). The ‘smoothness’ of the \( I(d) \) family is associated with classical asymptotic theory, which is not found in autoregressive based models around a unit root. Robinson (1994) showed that Lagrange multiplier tests for the value of \( d \), and any other parameters, have asymptotic null \( \chi^2 \) distributions for all real \( d \). Also, under nonstationary suitably modified parametric and semiparametric methods of estimating \( d \), extending those for the stationary case, tend still to be respectively \( n^{1/2} \) – and \( m^{1/2} \) – consistent, and asymptotically normal, unlike, say, the lag-one sample autocorrelation of a unit root series.

**Multivariate models**

Often in economics and finance we are concerned with a vector of jointly dependent series, so \( x_t \) is vector-valued. Such series can be modelled, either parametrically or semiparametrically, to have long memory, with different elements of \( x_t \) possibly having different memory parameters, and being stationary or nonstationary. Methods of statistical inference developed for the univariate case can be extended to such settings. However, multivariate data introduces the possibility of (fractional) cointegration, where a linear combination of \( x_t \) (the cointegrating error) can have smaller memory parameter than the elements of \( x_t \). Cointegration has been extensively developed for the case \( x_t \) is \( I(1) \) and cointegrating errors are \( I(0) \), and methods developed for this case can fail to detect fractional
cointegration. Moreover, it is possible for stationary series, not only nonstationary ones, to be fractionally cointegrated, as seems relevant in financial series. In either case, methods of analysing cointegration that allow memory parameters of observables and cointegrating errors to be unknown (see, for example, Hualde and Robinson, 2004) afford considerable flexibility.

The notion of long-run and short-run equilibrium was introduced by Marshall in 1890 and reflected the ‘long-period method’ of analysis in use among classical political economists since the 18th century. In the early 1930s, dissatisfaction with some of the neoclassical conclusions led to a shift to different methods of analysis and to the introduction of new equilibrium notions. These changes, together with the tendency to use old terminology for new equilibrium concepts, have deprived the terms ‘short-period’ and ‘long-period’ of a uniform meaning and have been a source of confusion and misunderstandings in recent debates on theoretical and applied work.

Article

The distinction between long-run and short-run (or long-period and short-period) equilibrium, introduced by Marshall (see Marshall, 1890, pp. 363–80; hints at this distinction are also to be found in some of Marshall's early works, dated 1870–71, recently re-presented in Whitaker, 1975, pp. 119–64), reflected a method which was the generally accepted one at the time, and essentially the same as the method of the classical political economists and of Marx. The use of the method was not affected by the deep change undergone by the theory of value and distribution around the 1870s with the advent of what is nowadays called the ‘neoclassical’ school. This method, called ‘method of long-period
positions’ (Garegnani, 1976), however, has been abandoned in much of the modern mainstream work on value. Further, there is no uniform meaning attributed to the terms ‘short-period’ and ‘long-period’, but rather a variety of usages depending on the theoretical framework of the writer, a situation responsible for many misunderstandings and debates at cross purposes.

**The classical political economists**

Since its origin in the writings of 18th-century authors, economic theory has used what has been subsequently named the ‘long-period method’ of analysis to investigate how production, distribution and accumulation take place within a market economy. According to Quesnay and A. Smith, the system ‘market economy’ produces results which are ‘independent of men’s will’ (Quesnay, 1758).

Competition, Smith thought, tends to establish uniformity in the ‘average’ or ‘natural’ rates of wages, profits and rent. ‘Market’ prices, that is, observed prices, thus tend to gravitate towards their ‘natural’ levels (also called ‘average prices’ or ‘prices of production’), defined as those which allowed the payment of wages, profits and rents at their average or natural rates (Smith, 1776, pp. 57–61).

According to the classical political economists, a divergence between the ‘market’ and the ‘natural’ price of a commodity is caused by a divergence between the amount supplied by producers and the ‘effectual demand’ for it, that is, ‘the demand of those who are willing to pay the natural price of the commodity, or the whole value of rent, labour and profit, which must be paid in order to bring it thither’ (Smith, 1776, p. 58). This divergence implies windfall profits or losses for that commodity. If supply coincides with ‘effectual demand’, ‘market’ price corresponds to ‘natural’ price. The rate of profit earned in that sector is equal to the one which is uniformly earned in the whole economy. Equilibrium conditions are said to prevail. Within this approach, therefore, fluctuations of supply and demand explain nothing but the deviations of ‘market’ prices from ‘natural’ prices.

The idea that the interaction of competitive market forces pushes the actual level of economic variables towards their ‘natural’ or ‘average’ level was applied to different fields of economic theory. Marx, for instance, applied it to the analysis of the ‘market’ and the ‘average’ interest rate (see Marx, 1972, pp. 355–66). The latter rate, according to Marx, was determined by ‘the average conditions of competition, the balance between lender and borrower’ (Marx, 1972, p. 363) in the money market over a certain historical period (Marx, 1972, p. 363). He rejected previous views determining this rate in terms of ‘natural’ laws, like the rate of growth of timber in central Europe forests (Marx, 1972, p. 363 n.) or in terms of the rate of return on capital invested in the productive sectors depending upon the material or technological conditions of production of commodities (Marx, 1972, p. 363). In his historically relative determination, the ‘average’ interest rate, being constrained by no ‘natural’ or ‘material’ law, can be at any level. At the same time, the interaction of demand and supply determines the daily variations of the ‘market’ interest rate and makes it converge towards its ‘average’ level.

The application of the ‘long-period method’ to the analysis of the interest rate makes it clear that the essential element of the method is the reference to an ‘average’ or ‘normal’ position around which the actual values of the variable considered gravitate. Reference to the attainment of a uniform rate of profit in all sectors is not strictly necessary if the theory does not determine the variable considered on the basis of the technological conditions of production. In Marx’s analysis, since the ‘average’ interest rate is independent of the rate of profits, it is possible to separate the study of the factors determining the
The rise of neoclassical economics

The long-period method was also used by those economists (like Walras, Menger, Jevons, Böhm-Bawerk, J.B. Clark, Wicksell, et al.) who some years later introduced and developed the ‘neoclassical’ theory of value and distribution. *No question was raised by these authors as to the use of this method.* The new theory, unlike the previous one, determined prices, output and distribution simultaneously. The ‘natural’ or ‘equilibrium’ values of all these variables (including the interest rate and the level of activity in the economy, which turns out to be a full employment level) depended, among other things, upon the technological conditions of production and were thus associated with the attainment of a uniform rate of profits in the economy.

Among the earlier neoclassical economists, Marshall deserves special consideration, since he introduced the notion of short- and long-period equilibrium (see Marshall, 1890, pp. 80). In his writings, Marshall tried to show how the neoclassical principles of price determination in terms of supply and demand functions could be applied to analytical levels which were closer to actual events. He thus analysed price determination for each single market (partial equilibrium) and within this analysis he referred to three different notions of equilibrium (temporary, short-period and long-period), which differed as to the conditions determining the supply functions. In a temporary equilibrium, it was supposed, there is no time to change the supply of the commodity. The amount supplied is fixed and the equilibrium price is that which allows that quantity to be demanded.

Analyses of short-period equilibrium assume that there is time to change supply through production, but there is no time to change the structure of *fixed capital* goods existing in that industry. This assumption constrains the technological possibilities of production. As in the case of temporary equilibrium, short-period equilibrium is compatible with windfall profits or losses.

In long-period analyses, it is assumed instead that there is time to adapt the structure of fixed capital goods of the industry so that quasi-rents (that is, entrepreneurial net profits) disappear. The price then guarantees just the ‘normal rate of profits’ (that is, the ‘equilibrium’ real rate of return on capital which is uniform in the whole economy).

Marshall’s partial equilibrium analysis appears to rely on general equilibrium analysis for the determination of the ‘equilibrium’ rate of return on capital and of ‘ceteris paribus’ prices. The view that the ‘general equilibrium’ analysis was logically prior appears accepted in some major contributions of the debate on Marshall’s theory of value of the 1920s and the early 1930s (see Sraffa, 1925 and 1926,
and Pigou's reply, 1927). Marshall's starting point thus was the same as that of Walras, Wicksell, and of the other neoclassical economists mentioned above.

Long-period general equilibrium must not be confused with 'secular' equilibrium, which results from allowing enough time for factor endowments to change under the influences of demographic factors and propensity to save, so as to cause the economy to reach 'stationary' or 'steady growth' conditions (see Robbins, 1930).

**Short- and long-period in Keynes**

By the end of the 1920s, dissatisfaction with the neoclassical conclusions as to the level of activity of the economy and with the analysis of capital led some economists to new analytical developments, which affected for the first time the method used too.

J.M. Keynes criticized the neoclassical conclusion that the market economy has an inherent tendency towards full employment. In the preparatory works and in the introduction to the *General Theory* he insisted that his concern was not the analysis of the temporary and cyclical fluctuations of the level of activity, but the theory dealing with the more fundamental forces which tend to prevail in the economic system (see Keynes, 1936, pp. 4–5; 1973; pp. 405–7; and 1979, pp. 54–7). He wanted thus to replace the neoclassical long-period theory of the level of output with a new one. Yet the way he presented his new theory has raised many problems of interpretation also related to the method used.

First of all, Keynes stated in his book that he assumed as given the structure of *fixed capital goods* existing in the economy. This can lead to consider his theory as a short-period one, arguing that it would determine the level of capacity utilization in the economy. It is difficult, however, to support this interpretation also with the argument that in the *General Theory* Keynes was following Marshall's definition of short-period, which was confined to partial equilibrium analysis. Marshall knew that the time required for adjustment of the structure of fixed capital goods differed from one industry to the other, so that it would have been unreasonable to extend the hypothesis of a fixed structure from one industry to the whole economy, as Keynes did. This element of ambiguity as to the use of the concepts has raised many puzzling questions among the interpreters of Keynes.

At the same time, Keynes explicitly stated that his theory was meant to explain why the level of employment, over a specific historical period, oscillates round an intermediate or average position (often not a full-employment one), whereas in other periods it oscillates round a different one (Keynes, 1936, p. 254). This reference to 'specific historical periods' and to 'average or normal positions' can lead to consider Keynes's theory as a long-period one, in the same way as Marx's theory of the 'average' interest rate. The assumption of a fixed structure of capital goods would thus play a secondary role in Keynes's theory.

Besides, Keynes hinted towards an analysis of accumulation which emphasizes the role played by effective demand (Keynes, 1936, p. 372–80). The trend followed by a growing economy in which adjustment in the structure of fixed capital goods has occurred, is affected by the level of effective demand. The possibility of assuming in this analysis an adjusted structure of fixed capital goods (to which a uniform rate of profits corresponds) can lead to consider this as the *long-period theory* present in the *General Theory*.

Finally, the maintenance in the *General Theory* of elements belonging to the neoclassical tradition, like
the acceptance of the principle of diminishing marginal returns for capital from which the existence of a full-employment level of the rate of interest is derived (see Keynes, 1936, pp. 147–8, 178, 203, 235 and 243; Keynes, 1973, pp. 456, 615, 630) has allowed some interpreters to consider Keynes's ‘underemployment equilibrium’ as a situation in which market forces have not yet worked out their effects fully, consequently defining it as a position of ‘short-period equilibrium’ (see Patinkin, 1976, pp. 116–19; Winch, 1969, p. 167).

The presence of several lines of development of its basic principle (that of effective demand) and the lack of precision and coherence as to the concepts and the analytical elements used appear to be an endless source of discussion as to the interpretation of Keynes's work. The existing evidence does not seem to support, however, the view that the General Theory wanted to move along the same lines as Hayek, Hicks and others, who in those years were proposing the neoclassical theory of value, distribution and the level of output on the basis of a method of analysis different from the long-period one.

Post-Walrasian developments

In the same years, dissatisfaction with the neoclassical analysis of capital was leading to a shift in method, owing to the adoption of what may be called ‘post-Walrasian’ notions of general equilibrium, elaborated by Hayek and Lindahl around the 1930s, but first proposed to a wider audience in 1939 by Hicks's Value and Capital (see Garegnani, 1976; Milgate 1979). The change in method derives from the change in the treatment of the capital endowment.

In the traditional neoclassical treatment, dominant up to the 1950s, the conception of equilibrium as a centre of gravitation of time-consuming adjustments (a conception incompatible with taking as given the equilibrium endowments of the several capital goods) had been reconciled with the supply-and-demand approach to factor pricing by conceiving capital as a single factor of production, capable of changing ‘form’ (that is, of embodying itself into different vectors of heterogeneous capital goods) without changing in ‘quantity’, so that its ‘form’ (that is, composition) could be left to be determined by the equilibrium condition of a uniform rate of return on the supply price of capital goods – the distinguishing element of long-period positions. Capital so conceived had ultimately to be measured as an amount of value, because in equilibrium different capital goods earn rewards proportional to their values. Within the neoclassical framework, therefore, the reference to a homogeneous factor ‘capital’, a value magnitude, was a logical necessity, entailed by the attempt to explain distribution through the equilibrium between demand for and supply of ‘factors of production’, without abandoning the traditional method of long-period positions (Petri, 2004). With one exception, this conception of capital was in fact more or less explicitly adopted by all founders of neoclassical theory and it was the target of the Cambridge critique of the 1960s (Harcourt, 1969; Garegnani, 1970). The only exception had been Walras, who intended as well to determine a long-period equilibrium and accordingly maintained the uniform-profit-rate condition, but took as data the endowment of each kind of capital goods, with the result that his model was generally devoid of solutions.

Walras's treatment of the capital endowment as a given vector is maintained in post-Walrasian general equilibrium analyses, but the condition of uniform profit rate on supply price is dropped. Existing capital goods are treated like natural resources; commodities are dated, so prices of future commodities are
distinguished from prices of currently available commodities; and the current composition of the production of new capital goods is determined in either of two ways: by assuming the existence of complete futures markets (intertemporal equilibria, see for example Debreu, 1959), or through the introduction of expectations among the data (temporary equilibria, see for example Hicks, 1939 and Grandmont, 1977).

The difference between the notion of equilibrium entailed by such a treatment of capital and that entailed by the long-period method of analysis warrants emphasis (Garegnani, 1990). The latter attempts to represent states of the economy which have the role of centres of gravitation of observed day-to-day magnitudes: chance movements away from such a state set off forces tending to bring the economy back to it. Changes in the economy can then be studied by comparing the long-period positions corresponding to the situation before and after the change. Post-Walrasian equilibria cannot have such a role, because they rely on data some of which (the endowments of capital goods and, where futures markets are not complete, expectations) would be altered by any chance deviation from the equilibrium: thus the forces set off by this deviation would not tend to bring the economy back to the same equilibrium. For the same reason, stability questions relative to post-Walrasian equilibria can only be asked for imaginary atemporal adjustment processes which exclude the implementation of disequilibrium production decisions before the equilibrium is reached.

A variety of usages

The introduction of new equilibrium concepts, together with the tendency to overlook the existence of differences with previous ones and to use the same terminology for the former and for the latter, has been a source of confusion and misunderstandings in recent debates on theoretical and applied work. The term ‘short-period equilibria’ has been sometimes applied to post-Walrasian equilibria (including ‘fix price’ equilibria with quantity adjustments, which share the same impermanence of data). On other occasions, Keynes's notion of equilibrium has been identified with temporary equilibrium. In both cases, the very great difference between Marshall's and Keynes's analyses on one side and post-Walrasian analyses on the other side has been neglected: in post-Walrasian models, all capital goods, including circulating capital goods, are given, while in Marshall's short-period analyses only the fixed plant of a single industry is a datum, and in Keynes's work only the fixed capital goods of the whole economy are given.

At the same time, the term ‘long-period equilibrium’ has been used in recent years to refer (a) to post-Walrasian intertemporal equilibria with futures markets extending far into the future; (b) to sequences of temporary equilibria; (c) to stationary or steady-growth equilibria. In all these cases, an incomplete grasp of the changes introduced in the notion of equilibrium appears to emerge. Finally, modern neoclassical economists sometimes develop applied analyses using the traditional method of long-period positions, although rejecting, as their theoretical foundations, the traditional versions of neoclassical theory in favour of the post-Walrasian ones, which are not compatible with that method.

How to cite this article

Longfield was born at Desertserges, Country Cork, Ireland, in 1802. Although he graduated from Trinity College, Dublin, in 1823 with first class honours in natural sciences, he was elected a Fellow of his college in 1825 as ‘jurist’. His subsequent career was primarily in real property law, but when Archbishop Whately founded the professorship of political economy at Trinity College, Dublin, in 1832, Longfield was the successful candidate and became the first holder of the chair, from 1832 until 1836. In 1834 he was appointed Regius Professor of Feudal and English Law and in 1849 became one of the first Commissioners of the newly established Irish Incumbered Estates Commission. When this was transmuted into the Landed Estates Court in 1858, Longfield was appointed a Judge of that court, retiring in 1867. He died in Dublin in 1884.

In 1847 he was one of the founder members of the Dublin Statistical Society (later re-named the Statistical and Social Inquiry Society of Ireland) and followed Whately as its President in 1863, but his many other public services derived primarily from his positions as advocate and judge. In his later years Longfield never returned to political economy but continued to write on questions of Irish land tenure and social reform.

The three volumes of lectures which Longfield published during his tenure of the Whately chair attracted little attention at the time, but have since been recognized as containing contributions to economic theory of outstanding originality. In his Lectures on Political Economy (1834a) Longfield dealt with the central issues of classical theory, those of value and distribution, in a manner which displayed a very clear grasp of the structure of Ricardian theory, but which in content diverged fundamentally from Ricardo’s approach. He laid stress on the determination of market rather than natural values and presented remarkably complete demand-and-supply theory supplemented by elements of utility analysis. Perhaps his most original contribution was made in the area of distribution, where he formulated a theory of profits as determined by the marginal productivity of physical capital and a theory of wages as determined by the specific productivity of the labourer.

Longfield rejected the idea that the ‘natural price’ of labour was determined by subsistence, arguing that the ‘wages of the labourer depend upon the value of his labour and not upon his wants’ (1834a, p. 206). Although, like Ricardo, Longfield predicted a rise in rents, a fall in profits and a rise in wages in the progress of society, his view of the long-term prospects for economic growth was optimistic. He
expected the effects of increased population to be offset by technical progress in agriculture, and foresaw many benefits from the increased accumulations of capital which would lower profits, not least among them the increased productivity of labour, which would raise wages. Longfield’s two other published courses of lectures are more concerned with current economic problems, but his Lectures on Commerce (1835) contained several anticipations of later developments in international trade theory. His analysis of the causes of international specialization extended to all variations in factor endowments and he specifically treated the case of trade in more than two commodities, showing that each country would tend to export those commodities in which the productivity of its labour was above average and import those in which it was below average.

In his Lectures on Poor Laws (1834b) Longfield endorsed Senior’s stern principle that assistance to the able-bodied should be confined to the barest subsistence – perhaps, ironically, because of the very optimism of his views about the likely trends of profits and wages. On the other hand, he favoured generous public assistance to those unable, through age or disability, to fend for themselves – even to the extent of advocating non-contributory old-age pensions. Longfield repeated this proposal in 1872, when he specifically considered state interference with the distribution of wealth; unlike most of his contemporaries he was then prepared also to advocate public dispensaries and hospitals to which access would not be means-tested, improved sanitary regulation of housing standards, free public education and improved public recreation facilities.

Longfield’s economic writings appear to have had little influence on his contemporaries, but since his rediscovery by Seligman (1903) the originality of his contributions has come to be generally recognized.

Article

1 Why panel data?

‘Longitudinal data’ (or ‘panel data’) refers to data-sets that contain time series observations of a number of individuals. In other words, it provides multiple observations for each individual in the sample. Compared with cross-sectional data, in which observations for a number of individuals are available only for a given time, or time-series data, in which a single entity is observed over time, panel data have the obvious advantages of more degrees of freedom and less collinearity among explanatory variables, and so provide the possibility of obtaining more accurate parameter estimates. More importantly, by blending inter-individual differences with intra-individual dynamics, panel data allow the investigation of more complicated behavioural hypotheses than those that can be addressed using cross-sectional or time-series data.

For instance, suppose a cross-sectional sample yields an average labour-participation rate of 50 per cent for married women. Given that the standard assumption for the analysis of cross-sectional data is that, conditional on certain variables, each woman is a random draw from a homogeneous population, this would imply that each woman has a 50 per cent chance of being in the labour force at any given time. Hence, a married woman would be expected to spend half of her married life in the labour force and half...
out of it. The job turnover would be frequent, and the expected average job duration would be just two years (Ben-Porath, 1973). However, the cross-sectional data could be drawn from a heterogeneous population in which 50 per cent of the sample was drawn from the population that always works and 50 per cent from the population that never works. In this situation, there is no turnover and a woman's current work status is a perfect predictor of her future work status. To discriminate between these two possibilities, we need information on individual labour-force histories in different sub-intervals of the life cycle, which can be provided only if information is available on the intertemporal dynamics of individual entities. On the other hand, although time series data provide information on dynamic adjustment, variables over time tend to move collinearly, hence making it difficult to identify micro-dynamic or macro-dynamic effects. Often, estimation of distributed lag models has to rely on strong prior restrictions like the Koyck or Almon lag, with very little empirical justification (for example, Griliches, 1967). With panel data, the inter-individual differences can often lessen the problem of multicollinearity and provide the possibility of estimating unrestricted time adjustment patterns (for example, Pakes and Griliches, 1984).

By utilizing information on both the intertemporal dynamics and the individuality of the entities, panel data may also allow an investigator to control the effects of missing or unobserved variables. For instance, MaCurdy's (1981) life-cycle labour supply of prime-age males with perfect foresight model assumes that the logarithm of hours worked is a linear function of the real wage rate and the logarithm of the worker's marginal utility of initial wealth, which is unobserved. Since the wage rate and the marginal utility of initial wealth are correlated, any instrument that is correlated with the wage rate will be correlated with the marginal utility of initial wealth. There is no way one can obtain a consistent estimate of the coefficient of the wage rate with cross-sectional data. But, if panel data are available and since marginal utility of initial wealth stays constant over time, one can take the difference of the labour supply model over time to get rid of the marginal utility of initial wealth as an explanatory variable. Regressing change in hour on change in wage rate and other socio-demographic variables can yield consistent estimates of the coefficient of the wage rate and other explanatory variables.

Panel data may also provide microfoundations for aggregate data analysis. Aggregate data analysis often invokes the ‘representative agent’ assumption. If micro units are heterogeneous, the time series properties of aggregate data may be very different from those of disaggregate data (for example, Granger, 1990; Lewbel, 1994) and policy evaluation based on aggregate data could also be grossly misleading (for example, Hsiao, Shen and Fujiki, 2005). By providing time series observations for a number of individuals, panel data are ideal for the investigation of the homogeneity issue.

Panel data involve observations of two or more dimensions. In normal circumstances, one would expect the computation and inference of panel data models to be more complicated than those of cross-section or time series data. However, in certain situations the availability of panel data actually simplifies inference. For instance, statistical inference for non-stationary panel data can be complicated (for example, Phillips, 1986). But, if observations are independently distributed across cross-sectional units, central limit theorems applied across cross-sectional units lead to asymptotically normally distributed statistics (for example, Levin, Lin and Chu, 2002; Im, Pesaran and Shin, 2003).

2 Issues of panel data analysis
Standard statistical methodology is based on the assumption that the outcomes, say $y$, conditional on certain variables, say $\sim$, are random outcomes from a probability distribution that is characterized by a fixed dimensional parameter vector, $\theta$, $f(y|x; \theta)$. For instance, the standard linear regression model $f(y|x; \theta)$ assumes that $y$ takes the form that $E(y|x) = \alpha + \beta' x$, and $\text{Var}(y|x) = \sigma^2$, where $\theta' = (\alpha, \beta', \sigma^2)$. Panel data, by their nature, focus on individual outcomes. Factors affecting individual outcomes are numerous. It is rare to be able to assume a common conditional probability density function of $y$ conditional on $\sim$ for all cross-sectional units, $i$, at all time, $t$. If the conditional density of $y$ given $\sim$ varies across $i$ and over $t$, the fundamental theorems for statistical inference, the laws of large numbers and central limit theorems, will be difficult to implement. Ignoring the heterogeneity across $i$ and over $t$ that are not captured by $\sim$ can lead to severely biased inference. For instance, suppose that the data is generated by

$$y_{it} = \alpha_i + \beta' x_{it} + \nu_{it}, \quad i = 1, \ldots, N, \quad t = 1, \ldots, T.$$  

(2.1)

as depicted by Figure 1 in which the broken-time ellipses represent the point scatter of individual observation around the mean, represented by the broken straight lines. If an investigator ignores the presence of unobserved individual-specific effects, $\alpha_i$, and mistakenly estimates a model of the form

$$y_{it} = \alpha + \beta' x_{it} + \nu_{it},$$  

(2.2)

the following equation solid line in Figure 1 would depict the pooled least squares regression result which could completely contradict the individual relation between $y$ and $\sim$.

Figure 1
Scatter diagram of $(y_{it}, x_{it})$
However, the dimension of $Z$ can be large. A model is a simplification of reality, not an exact representation of reality. The inclusion of $Z$ may confuse the fundamental relationship between $y$ and $x$, in particular when there is a shortage of degrees of freedom or multicollinearity, and so on. Moreover, $X$ may not be observable. If an investigator is interested only in the relationship between $y$ and $Z$, one approach to characterize the heterogeneity not captured by $Z$ is to assume that the parameter vector varies across $i$ and over $t$, $\theta$, so that the conditional density of $y$ given $X$ takes the form $f(y_{it}|X_{it}; \theta)$. However, without a structure being imposed on $\theta$, such a model has only descriptive value; it is not possible to draw any inference on $\theta$ from observed data.

One primary focus of methodological panel data literature is to suggest possible structures for $\theta$. One way to impose some structure on $\theta$ is to decompose $\theta$ into $\beta$, referred to as structural parameters, and $\gamma_{it}$ as incidental parameters because when observations in cross-sectional units and/or time series units increase, there are rising numbers of $\gamma_{it}$ to be estimated. The focus then will be on how to make valid inference on $\beta$ after controlling the impact of $\gamma_{it}$. Without imposing structure for $\gamma_{it}$, again it is not possible to make any inference on $\gamma_{it}$ because the unknown $\gamma_{it}$ will exhaust all available sample information. On the assumption that the impacts of observable variables, $\gamma_{it}$, are the same across $i$ and over $t$, represented by the structure parameters, $\beta$, the incidental parameters $\gamma_{it}$ represent the heterogeneity across $i$ and over $t$ that are not captured by $\gamma_{it}$. They can be considered as composed of the effects of omitted individual time-invariant, $\alpha_i$, period individual-invariant, $\lambda_t$, and individual time-varying variables, $\delta_{it}$. The individual time-invariant variables are variables that are the same for a given cross-sectional unit through time but that vary across cross-sectional units, such as individual-firm management, ability, gender, and socio-economic background. The period individual-invariant variables are variables that are the same for all cross-sectional units at a given time but that vary through time, such as prices, interest rates, and widespread optimism or pessimism. The individual time-varying variables are variables that vary across cross-sectional units at a given point in time and also exhibit variations through time, such as firm profits, sales and capital stock. The unobserved heterogeneity as represented by the individual-specific effects, $\alpha_i$ and time specific effects, $\lambda_t$, or individual time-varying effects, $\delta_{it}$ can be assumed to be either random variables (referred to as the random effects model) or fixed parameters (referred to as the fixed effects model).
3 Linear static models

A widely used panel data model assumes that the effects of observed explanatory variables, $x$, are identical across cross-sectional units, $i$, and over time, $t$, while the effects of omitted variables can be decomposed into the individual-specific effects, $\alpha_i$, time-specific effects, $\lambda_t$, and individual time-varying effects, $\delta_{it} = u_{it}$, as follows:

$$y_{it} = \beta' x_{it} + \alpha_i + \lambda_t + u_{it}, \quad i = 1, \ldots, N,$$

$$t = 1, \ldots, T.$$  

(3.1)

In a single equation framework, individual time effects, $u_i$, are assumed random and uncorrelated with $x$, while $\alpha_i$ and $\lambda_t$ may or may not be correlated with $x$. When $\alpha_i$ and $\lambda_t$ are treated as fixed constants, they are parameters to be estimated, so whether they are correlated with $x$ is not an issue. On the other hand, when $\alpha_i$ and $\lambda_t$ are treated as random, they are typically assumed to be uncorrelated with $x$.

For ease of exposition, we assume that there are no time-specific effects, that is, $\lambda_t = 0$ for all $t$ and $u_{it}$ are independently, identically distributed (i.i.d) across $i$ and over $t$. Stack an individual's $T$ time series observations of $(y_{it}, x_{it})$ into a vector and a matrix, (3.1) may alternatively be written as

$$y = X_i \beta + \varepsilon_{\alpha_i} + u_{\sim i}, \quad i = 1, \ldots, N,$$

(3.2)

where $\sim i = \{1, \ldots, T\}$, $X_i = (x_{\sim i1}, \ldots, x_{\sim iT})'$, $u = (u_{\sim i1}, \ldots, u_{\sim iT})'$, and $\varepsilon$ is a $T \times 1$ vector of 1's.

Let $Q$ be a $T \times T$ matrix satisfying the condition that $Q \varepsilon = 0$. Pre-multiplying (3.2) by $Q$ yields

$$Q y = Q X_i \beta + Q u, \quad i = 1, \ldots, N.$$

(3.3)
Equation (3.3) no longer involves $\alpha_i$. The issue of whether $\alpha_i$ is correlated with $\sim it$ or whether $\alpha_i$ should be treated as fixed or random is no longer relevant for (3.3). Moreover, since $X_i$ is exogenous,

$$E(QX_iu_i'Q') = EQ(X_iu_i'Q') = 0 \quad \text{and} \quad EQu_i'Q' = \sigma^2 QQ'$$

An efficient estimator of $\sim$ is the generalized least squares estimator (GLS),

$$\hat{\beta} = \left[ \sum_{i=1}^{N} X_i'Q'(QQ')^{-1}QX_i \right]^{-1} \left[ \sum_{i=1}^{N} X_i'Q'(QQ')^{-1}QY_i \right].$$

(3.4)

where $(Q'Q)^{-1}$ denotes the Moore–Penrose generalized inverse (for example, Rao, 1973).

When $Q = I - \frac{1}{T} \bar{e} \bar{e}'$, $Q$ is idempotent. The Moore–Penrose generalized inverse of $(Q'Q)^{-1}$ is just $Q = I - \frac{1}{T} \bar{e} \bar{e}'$ itself. Pre-multiplying (3.3) by $Q$ is equivalent to transforming (3.1) into a model

$$(Y_{it} - \bar{Y}_i) = (X_i - \bar{X}_i) (\beta_{\sim} - \bar{\beta}) \sim_{\sim} + (u_{it} - \bar{u}_i), \quad t = 1, \ldots, T, \quad i = 1, \ldots, N,$$

(3.5)

where $\bar{Y}_i = \frac{1}{T} \sum_{t=1}^{T} Y_{it}$, $\bar{X}_i = \frac{1}{T} \sum_{t=1}^{T} X_{it}$ and $\bar{u}_i = \frac{1}{T} \sum_{t=1}^{T} u_{it}$. The transformation is called covariance transformation. The least squares estimator (LS) (or a generalized least squares estimator, GLS) of (3.5),

$$\hat{\beta} = \left[ \sum_{i=1=1}^{N} \sum_{t=1}^{T} (X_{it} - \bar{X}_i) (X_{it} - \bar{X}_i)' \right]^{-1} \left[ \sum_{i=1}^{N} \sum_{t=1}^{T} (X_{it} - \bar{X}_i) (Y_{it} - \bar{Y}_i) \right],$$

(3.6)

is called covariance estimator or within estimator because the estimation of $\sim$ only makes use of within (group) variation of $y_{it}$ and $\sim X_i$ only. The covariance estimator of $\sim$ turns out to be also the least squares
estimator of (3.1) when $\lambda_t = 0$. It is the best linear unbiased estimator of $\beta$ if $\alpha_i$ is treated as fixed and $u_{it}$ is i.i.d.

If $\alpha_i$ is random, transforming (3.2) into (3.3) transforms $T$ independent equations (or observations) into $(T - 1)$ independent equations, hence the covariance estimator is not as efficient as the efficient generalized least squares estimator if $\text{cov}(u_{it}, u_{jt}) = 0$. When $\alpha_i$ is independent of $u_{it}$ and is independently, identically distributed across $i$ with mean $\mu$ and variance $\sigma^2$, the best linear unbiased estimator (BLUE) of $\beta$ is GLS,

$$
\hat{\beta} = \left[ \sum_{i=1}^{N} x_i' V^{-1} x_i \right]^{-1} \left[ \sum_{i=1}^{N} x_i' V^{-1} y_i \right],
$$

(3.7)

where

$$
V = \sigma^2_{it} I_T + \sigma^2_{\alpha} e e', \quad V^{-1} = \frac{1}{\sigma^2} \left[ I_T - \frac{\sigma^2_{\alpha}}{\sigma^2 + \tau \sigma^2_{\alpha}} e e' \right],
$$

$$
\psi = \frac{\sigma^2_{\alpha}}{\sigma^2 + \tau \sigma^2_{\alpha}},
$$

Let the GLS is equivalent to first transforming the data by subtracting a fraction $(1 - \psi^{1/2})$ of individual means $\bar{y}_i$ and $\bar{x}_i$ from their corresponding $y_{it}$ and $x_{it}$, then regressing $[y_{it} - (1 - \psi^{1/2})\bar{y}_i]$ on $[x_{it} - (1 - \psi^{1/2})\bar{x}_i]$ (for detail, see Baltagi, 2001; Hsiao, 2003).

When $\alpha_i$ is treated as fixed, the covariance estimator is equivalent to applying LS to the transformed model (3.5). If a variable is time-invariant, like a gender dummy, $x_{kit} = x_{kis} = \bar{x}_k$, the transformation eliminates the corresponding variable from the specification. Hence, the coefficients of time-invariant variables cannot be estimated. On the other hand, if $\alpha_i$ is random and uncorrelated with $u_{it}$, the GLS can still estimate the coefficients of those time-invariant variables.

### 4 Dynamic models

When the regressors of a linear model contains lagged dependent variables, say, of the form (for example, Balestra and Nerlove, 1966)

$$
\gamma = \gamma_i^{\prime} \theta + e_{\gamma_i} + u = Z_i \theta + e_{\alpha_i} + u, \quad i = 1, \ldots, N.
$$

(4.1)
longitudinal data analysis: The New Palgrave Dictionary of Economics

where \( y_{i-1} \), \( y_{i-1} \), \( z_{i} \), \( \theta \), and \( e \). For ease of notation, we assume that \( y_{i0} \) are observable. Technically, we can still eliminate the individual-specific effects by pre-multiplying (4.1) by the transformation matrix

\[
Q y \sim y, \quad Q \equiv Q Z \theta + Q u.
\]

(4.2)

However, because of the presence of lagged dependent variables, \( \text{EQ} Z \text{u} \neq 0 \) even with the assumption that \( u_{it} \) is independently, identically distributed across \( i \) and over \( t \). For instance, the covariance transformation matrix transforms (4.1) into the form

\[
(y_{it} - \bar{y}_{it}) = (y_{i,t-1} - \bar{y}_{i,t-1}) \gamma + (x_{i} - \bar{x}) \beta + (u_{it} - \bar{u}_{it}), \quad i = 1, \ldots, N, \quad t = 1, \ldots, T.
\]

(4.3)

where \( \bar{y}_{i} = \frac{1}{T} \sum_{t=1}^{T} y_{it}, \bar{y}_{i,t-1} = \frac{1}{T} \sum_{t=1}^{T} y_{i,t-1} \) and \( \bar{u}_{i} = \frac{1}{T} \sum_{t=1}^{T} u_{it} \). Although, \( y_{i,t-1} \) and \( u_{it} \) are uncorrelated under the assumption of serial independence of \( u_{it} \), the covariance between \( y_{i,t-1} \) and \( u_{it} \) or \( y_{i,t-1} \) and \( u_{it} \) is of order \( (1/T) \) if \( |\gamma| < 1 \). Therefore, the covariance estimator of \( \gamma \) creates a bias of order \( (1/T) \) when \( N \to \infty \) (Anderson and Hsiao, 1981; 1982; Nickell, 1981). Since most panel data contain large \( N \) but small \( T \), the magnitude of the bias can not be ignored (for example, with \( T = 10 \) and \( \gamma = 0.5 \), the asymptotic bias is \( -0.167 \)).

When \( \text{EQ} Z \text{u} \neq 0 \), one way to obtain a consistent estimator for \( \gamma \) is to find instruments \( W_{i} \) that satisfy

\[
\text{EW}_{i} Z \text{u} \sim 0,
\]

(4.4)
and

\[
\text{rank}(W_i Q Z_i) = k, \tag{4.5}
\]

where \( k \) denotes the dimension of \((Y, \beta')'\), then apply the generalized instrumental variable or generalized method of moments (GMM) estimator by minimizing the objective function

\[
\left[ \sum_{i=1}^{N} W_i (Q_Y - Q Z_i \theta) \right]' \left[ \sum_{i=1}^{N} (W_i Q u_t u_t' Q W_i) \right]^{-1} \left[ \sum_{i=1}^{N} W_i (Q_Y - Q Z_i' \theta) \right], \tag{4.6}
\]

with respect to \( \theta \) (for example, Arellano, 2003; Ahn and Schmidt, 1995; Arellano and Bond, 1991; Arellano and Bover, 1995). For instance, one may let \( Q \) be a \((T - 1) \times T\) matrix of the form

\[
D = \begin{bmatrix}
-1 & 1 & 0 & \ldots \\
0 & -1 & 1 & \ldots \\
0 & \ldots & \ldots & \ldots \\
\ldots & \ldots & \ldots & -1 & 1
\end{bmatrix}, \tag{4.7}
\]

then the transformation (4.2) is equivalent to taking the first difference of (4.1) over time to eliminate \( \alpha_i \) for \( t = 2, \ldots, T \),

\[
\Delta Y_{it} = \Delta Y_{i,t-1} Y + \Delta X_{it} \beta + \Delta u_{it}, \quad i = 1, \ldots, N, \quad t = 2, \ldots, T, \tag{4.8}
\]
where $\Delta = (1 - L)$ and $L$ denotes the lag operator, $LY_t = Y_{t-1}$. Since $\Delta u_{it} = (u_{it} - u_{i,t-1})$ is uncorrelated with $V_{i,t-j}$ for $j \geq 2$ and $\sim_{it}$, for all $s$, when $u_{it}$ is independently distributed over time and $\sim_{it}$ is exogenous, one can let $W_i$ be a $T(T - 1) (K + \frac{1}{2}) \times (T - 1)$ matrix of the form

$$
W_i = \begin{bmatrix}
q & 0 & \cdots \\
\sim_{i2} & q & \cdots \\
0 & \sim_{i3} & q & \cdots \\
\cdots & \cdots & \cdots & \cdots & \cdots \\
\cdots & \cdots & \cdots & \cdots & \cdots \\
\sim_{iT} & \cdots & \cdots & \cdots & q
\end{bmatrix},
$$

where $q = (\sim_{i0}, \sim_{i1}, \cdots, \sim_{i,t-2}, \sim_{iT})$, $X = (x_{i,1}, \cdots, x_{iT})'$, and $K = K - 1$. Under the assumption that $\sim_{it}$ are independently, identically distributed across $i$, the Arellano–Bover (1995) GMM estimator takes the form

$$
\hat{\theta}_{GMM} = \left\{ \left[ \frac{1}{N} \sum_{i=1}^{N} Z_i'D_iW_i' \right] \left[ \frac{1}{N} \sum_{i=1}^{N} W_iAW_i' \right]^{-1} \left[ \frac{1}{N} \sum_{i=1}^{N} W_iDZ_i \right] \right\}^{-1} \left\{ \left[ \frac{1}{N} \sum_{i=1}^{N} Z_i'D_iW_i' \right] \left[ \frac{1}{N} \sum_{i=1}^{N} W_iAW_i' \right]^{-1} \left[ \frac{1}{N} \sum_{i=1}^{N} W_iDy_{i0} \right] \right\},
$$

(4.10)

where $A$ is a $(T - 1) \times (T - 1)$ matrix with 2 on the diagonal elements, −1 on the elements above and below the diagonal elements, and 0 elsewhere.

The GMM estimator has the advantage that it is consistent and asymptotically normally distributed whether $\alpha_i$ is treated as fixed or random because it eliminates $\alpha_i$ from the specification. However, the number of moment conditions increases at the order of $T^2$, which can create severe downward bias in finite sample (Zilak, 1997). An alternative is to use a (quasi-) likelihood approach which has the advantage of having a fixed number of orthogonality conditions independent of the sample size. It also has the advantage of making use of all the available samples, hence can yield a more efficient estimator than (4.10) (for example, Hsieh, Pesaran and Tahmiscioglu, 2002; Binder, Hsieh and Pesaran, 2005).

Since there is no reason to assume the data-generating process of initial observations, $y_{i0}$, to be different
from the rest of \( y_{it} \), the likelihood approach has to formulate the joint likelihood function of \( \{ y_{i0}, y_{i1}, \ldots, y_{iT} \} \) (or the conditional likelihood function \( \{ y_{i1}, \ldots, y_{iT|y_{i0}} \} \)). However, \( y_{i0} \) depends on previous values of \( \sim \), \( i \), and \( \alpha_i \), which are unavailable. Bhargava and Sargan (1983) suggest circumscribing this missing data problem by conditioning \( y_{i0} \) on \( \sim \) and \( \alpha_i \) if \( \alpha_i \) is treated as random, while Hsiao, Pesaran and Tahmiscioglu (2002) propose conditioning \( \{ y_{i1} - y_{i0} \} \) on the first difference of \( \sim \) if \( \alpha_i \) is treated as a fixed constant.

5 Random vs. fixed effects specification

The advantages of random effects (RE) specifications are as follows:

1. The number of parameters stays constant when sample size increases.
2. It allows the derivation of efficient estimators that make use of both within- and between-(group) variation.
3. It allows the estimation of the impact of time-invariant variables.

The disadvantages of RE specification are that it typically assumes that the individual- and/or time-specific effects are randomly distributed with a common mean and are independent of \( \sim \). If the effects are correlated with \( \sim \) or if there is a fundamental difference among individual units, that is, conditional on \( \sim \), \( \{ y_{it} \} \) cannot be viewed as a random draw from a common distribution, the common RE model is mis-specified and the resulting estimator is biased.

The advantages of fixed effects (FE) specification are that it allows the individual-and/or time-specific effects to be correlated with explanatory variables \( \sim \). Neither does it require an investigator to model their correlation patterns.

The disadvantages of the FE specification are as follows:

1. The number of unknown parameters increases with the number of sample observations. In the case when \( T \) (or \( N \) for \( \lambda_t \)) is finite, it introduces the classical incidental parameter problem (for example, Neyman and Scott, 1948).
2. The FE estimator does not allow the estimation of the coefficients that are time-invariant.

In other words, the advantages of RE specification are the disadvantages of FE specification, and the disadvantages of RE specification are the advantages of FE specification. To choose between the two specifications, Hausman (1978) notes that the FE estimator (or GMM), \( \sim FE \), is consistent whether \( \alpha_i \) is fixed or random. On the other hand, the commonly used RE estimator (or GLS), \( \sim RE \), is consistent and efficient only when \( \alpha_i \) is indeed uncorrelated with \( \sim \). If \( \alpha_i \) is correlated with \( \sim \), the RE estimator is
inconsistent. Therefore, Hausman (1978) suggests using the statistic

$$\left( \hat{\theta}_{FE} - \hat{\theta}_{RE} \right) \left[ \text{cov}(\hat{\theta}_{FE}) - \text{cov}(\hat{\theta}_{RE}) \right]^{-1} \left( \hat{\theta}_{FE} - \hat{\theta}_{RE} \right)$$

(5.1)

to test RE vs FE specification. The statistic (5.1) is asymptotically chi-square distributed with degrees of freedom equal to the rank of $\text{cov}(\hat{\theta}_{FE}) - \text{cov}(\hat{\theta}_{RE})$.

6 Nonlinear models

The introduction of individual-specific effects, $\alpha_i$, and/or time-specific effects, $\lambda_t$, provides a simple way to capture the unobserved heterogeneity across $i$ and over $t$. However, the likelihood functions are in terms of observables, therefore, we will have either to treat $\alpha_i$ as unknown parameters (fixed effects) and consider the conditional likelihood,

$$f(y_{it} | x_{it}, \beta, \alpha_i), i = 1, \ldots, N$$

(6.1)

or to treat $\alpha_i$ as random and consider the marginal likelihood

$$f(y_{it} | x_{it}, \beta) = \int f(y_{it} | x_{it}, \beta, \alpha_i) f(\alpha_i | x_{it}) d\alpha_i, i = 1, \ldots, N$$

(6.2)

where $f(\alpha_i | x_{it})$ denotes the conditional density of $\alpha_i$ given $x_{it}$.

When the unobserved individual specific effects, $\alpha_i$, (and or time-specific effects, $\lambda_t$) affect the outcome, $y_{it}$, linearly, one can avoid the consideration of random versus fixed effects specification by eliminating them from the specification through some linear transformation such as the covariance transformation (3.3) or first difference transformation (4.8). However, if $\alpha_i$ affects $y_{it}$ nonlinearly, it is
not easy to find a transformation that can eliminate $\alpha_i$. For instance, consider the following binary choice model where the observed $y_{it}$ takes the value of either 1 or 0 depending on the latent response function

$$
\nu_{it}^* = \beta' x + \alpha_i + u_{it},
$$

(6.3)

and

$$
y_{it} = \begin{cases} 
1, & \text{if } \nu_{it}^* > 0, \\
0, & \text{if } \nu_{it}^* \leq 0,
\end{cases}
$$

(6.4)

where $u_{it}$ is independently, identically distributed with density function $f(u_{it})$. Let

$$
y_{it} = E(y_{it}|x, \alpha_i) + \epsilon_{it},
$$

(6.5)

then

$$
E(y_{it}|x, \alpha_i) = \int_{-\infty}^{\infty} (\beta' x + \alpha_i) f(u) du = [1 - F(-\beta' x - \alpha_i)].
$$

(6.6)

Since $\alpha_i$ affects $y_{it}$ nonlinearly, $\alpha_i$ remains after taking successive difference of $y_{it}$,

$$
y_{it} - y_{i,t-1} = [1 - F(-\beta' x - \alpha_i)] - [1 - F(-\beta' x_{i,t-1} - \alpha_i)] + (\epsilon_{it} - \epsilon_{i,t-1}).
$$
The likelihood function conditional on $X_i$ and $\alpha_i$ takes the form,

$$
\prod_{i=1}^N \prod_{t=1}^T \left[ F\left( \frac{-\beta'X_i - \alpha_i}{\sim \sim_{it}} \right) \right]^{1-Y_{it}} \left[ 1 - F\left( \frac{-\beta'X_i - \alpha_i}{\sim \sim_{it}} \right) \right]^{Y_{it}}.
$$

(6.8)

If $T$ is large, a consistent estimator of $\beta$ and $\alpha_i$ can be obtained by maximizing (6.8). If $T$ is finite, there is only limited information about $\alpha_i$ no matter how large $N$ is. The presence of incidental parameters, $\alpha_i$, violates the regularity conditions for the consistency of the maximum likelihood estimator of $\beta$.

If $f(\alpha_i | X_i)$ is known, and is characterized by a fixed dimensional parameter vector, a consistent estimator of $\beta$ can be obtained by maximizing the marginal likelihood function,

$$
\prod_{i=1}^N \int \prod_{t=1}^T \left[ F\left( \frac{-\beta'X_i - \alpha_i}{\sim \sim_{it}} \right) \right]^{1-Y_{it}} \left[ 1 - F\left( \frac{-\beta'X_i - \alpha_i}{\sim \sim_{it}} \right) \right]^{Y_{it}} f(\alpha_i | X_i) d\alpha_i.
$$

(6.9)

However, maximizing (6.9) involves $T$-dimensional integration. Butler and Moffitt (1982), Chamberlain (1984), Heckman (1981), and others have suggested methods to simplify the computation.

The advantage of RE specification is that there is no incidental parameter problem. The problem is that $f(\alpha_i | X_i)$ is in general unknown. If a wrong $f(\alpha_i | X_i)$ is postulated, maximizing the wrong likelihood function will not yield a consistent estimator of $\beta$. Moreover, the derivation of marginal likelihood through multiple integration may be computationally infeasible. The advantage of FE specification is that there is no need to specify $f(\alpha_i | X_i)$. The likelihood function will be the product of individual likelihood (for example, (6.8)) if the errors are assumed i.i.d. The disadvantage is that it introduces incidental parameters.

A general approach to estimating a model involving incidental parameters is to find transformations to transform the original model into a model that does not involve incidental parameters. Unfortunately, there is no general rule available for nonlinear models. One has to explore the specific structure of a nonlinear model to find such a transformation. For instance, if $f(u)$ in (6.3) is logistic, then
longitudinal data analysis: The New Palgrave Dictionary of Economics

Since, in a logit model, the denominators of \( \Pr(y_{it} = 1|x_{it}, \alpha_i) \) and \( \Pr(y_{it} = 0|x_{it}, \alpha_i) \) are identical and the numerator of any sequence \( \{Y_{i1}, \ldots, Y_{iT}\} \) with \( \sum_{t=1}^{T} Y_{it} = s \) always equal to

\[
\exp(\alpha_i s) \cdot \exp\left(\sum_{t=1}^{T} (\beta'x_{it}) Y_{it}\right),
\]

the conditional likelihood function conditional on \( \sum_{t=1}^{T} Y_{it} = s \) will not involve the incidental parameters \( \alpha_i \). For instance, consider the simple case that \( T = 2 \), then

\[
\Pr(Y_{i1} = 1, Y_{i2} = 0|Y_{i1} + Y_{i2} = 1) = \frac{\beta'x_{i1}}{\exp(\beta'x_{i1} + \beta'x_{i2})} = \frac{1}{1 + \exp(\beta'x_{i2})}
\]

(6.11)

and

\[
\Pr(Y_{i1} = 0, Y_{i2} = 1|Y_{i1} + Y_{i2} = 1) = \frac{\beta'x_{i2}}{\exp(\beta'x_{i1} + \beta'x_{i2})},
\]

(6.12)

(Chamberlain, 1980; Hsiao, 2003).

This approach works because of the logit structure. In the case when \( f(u) \) is unknown, Manski (1987) exploits the latent linear structure of (6.3) by noting that, for given \( i \),

and suggests maximizing the objective function

\[
H_N(b) = \frac{1}{N} \sum_{i=1}^{N} \sum_{t=2}^{T} sgn(b' \Delta x_i) \Delta y_{it},
\]

(6.14)

where \( sgn(w) = 1 \) if \( w > 0 \), \( = 0 \) if \( w = 0 \), and \( -1 \) if \( w < 0 \). The advantage of the Manski (1987) maximum score estimator is that it is consistent without the knowledge of \( f(u) \). The disadvantage is that (6.13) holds for any \( \sim \) where \( \sim > 0 \). Only the relative magnitude of the coefficients can be estimated with some normalization rule, say \( \sim \). Moreover, the speed of convergence is considerably slower \( (N^{1/3}) \) and the limiting distribution is quite complicated. Horowitz (1992) and Lee (1999) have proposed modified estimators that improve the speed of convergence and are asymptotically normally distributed.

Other examples of exploiting specific structure of nonlinear models to eliminate the effects of incidental parameters \( \alpha_i \) include dynamic discrete choice models (Chamberlain, 1993; Honoré and Kyriazidou, 2000; Hsiao et al., 2005), symmetrically trimmed least squares estimator for truncated and censored data (tobit models) (Honoré, 1992), sample selection models (or type II tobit models) (Kyriazidou, 1997), and so on. However, often they impose very severe restrictions on the data such that not much of it can be utilized to obtain parameter estimates. Moreover, there are models that do not appear to yield consistent estimator when \( T \) is finite.

An alternative to consistent estimators is to consider bias-reduced estimators. The advantage of such an approach is that the bias-reduced estimators may still allow the use of all the sample information so that, from a mean square error point of view, the bias-reduced estimator may still dominate consistent estimators because the latter often have to throw away a lot of the sample, and thus tend to have large variances.

Following the ideas of Cox and Reid (1987), Arellano (2001) and Carro (2006) propose to derive the modified MLE by maximizing the modified log-likelihood function

\[
\beta' x_{it} > \beta' x_{it-1} \Leftrightarrow E(y_{it} | x_{it}, \alpha_i) > E(y_{i,t-1} | x_{i,t-1}, \alpha_i),
\]

\[
\beta' x_{it} = \beta' x_{it-1} \Leftrightarrow E(y_{it} | x_{it}, \alpha_i) = E(y_{i,t-1} | x_{i,t-1}, \alpha_i),
\]

\[
\beta' x_{it} < \beta' x_{it-1} \Leftrightarrow E(y_{it} | x_{it}, \alpha_i) < E(y_{i,t-1} | x_{i,t-1}, \alpha_i),
\]

(6.13)
longitudinal data analysis: The New Palgrave Dictionary of Economics

\[
L^* (\beta) = \sum_{i=1}^{N} \left[ L_i^* (\beta, \hat{\alpha}_i(\beta)) - \frac{1}{2} \log E_i^* (\beta, \hat{\alpha}_i(\beta)) \right]
\]

(6.15)

where \( L_i^* (\beta, \hat{\alpha}_i(\beta)) \) denotes the concentrated log-likelihood function of \( \sim_i \) after substituting the MLE of \( \alpha_i \) in terms of \( \sim_i \) (that is, the solution of \( \frac{\partial \log L}{\partial \alpha_i} = 0 \) in terms of \( \sim_i \), \( i = 1, \ldots, N \)) into the log-likelihood function and \( E_i^* (\beta, \hat{\alpha}_i(\beta)) \) denotes the second derivative of \( L_i^* \) with respect to \( \alpha_i \). The bias correction term is derived by noting that to the order of \((1/T)\) the first derivative of \( \beta \) converges to a scalar. By subtracting the order \((1/T)\) bias from the likelihood function, the modified MLE is biased only to the order of \((1/T^2)\), without increasing the asymptotic variance.

Monte Carlo experiments conducted by Carro (2006) have shown that, when \( T = 8 \), the bias of modified MLE for dynamic probit and logit models is negligible. Another advantage of the Arellano–Carro approach is its generality. For instance, a dynamic logit model with time dummy explanatory variable does not meet the Honoré and Kyriazidou (2000) conditions for generating consistent estimators, but will not affect the asymptotic properties of the modified MLE.

7 Modelling cross-sectional dependence

Most panel studies assume that, apart from the possible presence of individual invariant but period-varying time-specific effects, \( \lambda \), the effects of omitted variables are independently distributed across cross-sectional units. However, often economic theory predicts that agents take actions that lead to interdependence among themselves. For example, the prediction that risk-averse agents will make insurance contracts allowing them to smooth idiosyncratic shocks implies dependence in consumption across individuals. Ignoring cross-sectional dependence can lead to inconsistent estimators, in particular when \( T \) is finite (for example, Hsiao and Tahmiscioglu, 2005). Unfortunately, contrary to the time series data in which the time label gives a natural ordering and structure, general forms of dependence for cross-sectional dimension are difficult to formulate. Therefore, econometricians have relied on strong parametric assumptions to model cross-sectional dependence. Two approaches have been proposed to model cross-sectional dependence: economic distance (or a spatial approach) and a factor approach.

In regional science, correlation across cross-section units is assumed to follow a certain spatial ordering, that is, dependence among cross-sectional units is related to location and distance, in a geographic or more general economic or social network space (for example, Anselin, 1988; Anselin and Griffith, 1988; Anselin, Le Gallo and Jayet, 2006). A known spatial weights matrix, \( W = (w_{ij}) \), an \( N \times N \) positive matrix in which the rows and columns correspond to the cross-sectional units, is specified to express the prior
longitudinal data analysis: The New Palgrave Dictionary of Economics

strength of the interaction between individual (location) \(i\) (in the row of the matrix) and individual (location) \(j\) (column), \(w_{ij}\). By convention, the diagonal elements, \(w_{ii} = 0\). The weights are often standardized so that the sum of each row, \(\sum_{j=1}^{N} w_{ij} = 1\).

The spatial weight matrix, \(W\), is often included into a model specification to the dependent variable, to the explanatory variables, or to the error term. For instance, a *spatial lag* model for the \(NT \times 1\) variable

\[
\mathbf{y} \sim (\mathbf{y}^\prime, \ldots, \mathbf{y}^\prime) \sim N(\mathbf{0}, \mathbf{I}_T) \sim i
\]

may take the form

\[
\mathbf{y} = \rho (W \otimes 1_T) \mathbf{y} + \mathbf{X} \mathbf{\beta} + \mathbf{u}
\]

(7.1)

where \(X\) and \(u\) denote the \(NT \times 1\) explanatory variables and \(NT \times 1\) vector of error terms, respectively, and \(\otimes\) denotes the Kronecker product. A *spatial error* model may take the form

\[
\mathbf{y} \sim \mathbf{X} \mathbf{\beta} + \mathbf{\nu}
\]

(7.2)

where \(\mathbf{\nu}\) may be specified as in a *spatial autoregressive* form,

\[
\mathbf{\nu} \sim \theta (W \otimes 1_T) \mathbf{\nu} + \mathbf{u},
\]

(7.3)

or a spatial moving average form,

\[
\mathbf{\nu} \sim \gamma (W \otimes 1_T) \mathbf{u} + \mathbf{u},
\]

(7.4)

The spatial model can be estimated by the instrumental variables (GMM estimator) or the maximum
longitudinal data analysis: The New Palgrave Dictionary of Economics

likelihood method. However, the approach of defining cross-sectional dependence in terms of ‘economic distance’ measure requires that the econometricians have information regarding this ‘economic distance’. Another approach to model cross-sectional dependence is to assume that the error of a model, say model (7.3), follows a linear factor model,

$$v_{it} = \sum_{j=1}^{r} b_{ij} f_{jt} + u_{it},$$

(7.5)

where $\sim_t f = (f_{1t}, \ldots, f_{rt})'$ is a $r \times 1$ vector of random factors, $\sim_i b' = (b_{i1}, \ldots, b_{ir})'$, is $r \times 1$ non-random factor loading coefficients, $u_{it}$, represents the effects of idiosyncratic shocks which is independent of $\sim_t$ and is independently distributed across $i$. (for example, Bai and Ng, 2002; Moon and Perron, 2004; Pesaran, 2006). The conventional time-specific effects model is a special case of (7.5) when $r = 1$ and $b_{i} = b_{i\ell}$ for all $i$ and $\ell$.

The factor approach requires considerably less prior information than the economic distance approach. Moreover, the number of time-varying factors, $r$, and factor load matrix $B = (b_{ij})$ can be empirically identified if both $N$ and $T$ are large. However, when $T$ is large, one can estimate the covariance between $i$ and $j$, $\sigma_{ij}$, by

$$\frac{1}{T} \sum_{t=1}^{T} \hat{v}_{it} \hat{v}_{jt}$$

directly, then apply the generalized least squares method, where $\hat{v}_{it}$ is some preliminary estimate of $v_{it}$.

8 Large-N and large-T panels

Our discussion has been mostly focusing on panels with large $N$ and finite $T$. There are panel data sets, like the Penn-World tables, covering different individuals, industries and countries over long periods. In general, if an estimator is consistent in the fixed-$T$, large-$N$ case, it will remain consistent if both $N$ and $T$ tend to infinity. Moreover, even in the case that an estimator is inconsistent for fixed $T$ and large $N$ (say, the MLE of dynamic model (4.1) or fixed effects probit or logit models (6.6)), it can become consistent if $T$ also tends to infinity. The probability limit of an estimator, in general, is identical irrespective of how $N$ and $T$ tend to infinity. However, the properly scaled limiting distribution may depend on how the two indexes, $N$ and $T$, tend to infinity.

There are several approaches for deriving the limits of large-$N$, large-$T$ panels:

1. Sequential limits. First, fix one index, say $N$, and allow the other, say $T$, to go to infinity, giving an intermediate limit, then let $N$ go to infinity.

2. Diagonal-path limits. Let the two indexes, $N$ and $T$, pass to infinity along a specific diagonal path, say $T = T(N)$ as $N \to \infty$. 

3. **Joint limits.** Let $N$ and $T$ pass to infinity simultaneously without placing specific diagonal path restrictions on the divergence.

In many applications, sequential limits are easy to derive. However, sometimes sequential limits can give misleading asymptotic results. A joint limit will give a more robust result than either a sequential limit or a diagonal-path limit, but will also be substantially more difficult to derive and will apply only under stronger conditions, such as the existence of higher moments. Phillips and Moon (1999) have given a set of sufficient conditions that ensures that sequential limits are equivalent to joint limits.

When $T$ is large, there is a need to consider serial correlations more generally, including both short-memory and persistent components. For instance, if unit roots are present in $y$ and $x$ (that is, both are integrated of order 1) but are not cointegrated, Phillips and Moon (1999) show that, if $N$ is fixed but $T \to \infty$, the least squares regression of $y$ on $x$ is a non-degenerate random variable that is a functional of Brownian motion that does not converge to the long-run average relation between $y$ and $x$, but it does if $N$ also tends to infinity. In other words, the issue of spurious regression will not arise in a panel with large $N$ (for example, Kao, 1999).

Both theoretical and applied researchers have paid a great deal of attention to the unit root and spurious regression properties of variables. When $N$ is finite and $T$ is large, standard time-series techniques can be used to derive the statistical properties of panel data estimators. When $N$ is large and cross-sectional units are independently distributed across $i$, central limit theorems can be invoked along the cross-sectional dimension. Asymptotically normal estimators and test statistics (with suitably adjustment for finite $T$ bias) for unit roots and cointegration have been proposed (for example, Baltagi and Kao, 2000; Im, Pesaran and Shin, 2003; Levin, Lin and Chu, 2002). They, in general, gain statistical power over their standard time series counterpart (for example, Choi, 2001).

When both $N$ and $T$ are large and cross-sectional units are not independent, a factor analytic framework of the form (7.5) has been proposed to model cross-sectional dependency and variants of unit root tests are proposed (for example, Moon and Perron, 2004). However, the implementation of those panel unit root tests is quite complicated. When $N \to \infty$, $\frac{1}{N} \sum_{i=1}^{N} u_{it} \to 0$, (7.5) implies that $\bar{v}_t = \bar{b}' f \sim \sim_t$, where $\sim$ is the cross-sectional average of $\sim_i (b'_{il}, \ldots, b'_{ir})$. Approximating $\sim_i$ by its cross-sectional mean function, Pesaran (2005; 2006) suggests a simple approach to filter out the cross-sectional dependency by augmenting the cross-sectional means, $\bar{V}_t$ and $\sim_t$ to the regression model (7.2),

$$ v_{it} = x' \beta + \alpha_i + \bar{V}_t \xi_i + \bar{x}' d \sim_t + e_{it}, $$

(8.1)

or $\bar{V}_t \sim \bar{V}_t - j$ to the Dickey–Fuller (1979) type regression model,

---

\[ \Delta y_{it} = \alpha + \delta i + \psi_i \Delta y_{i,t-1} + \sum_{q=1}^{P_i} \varphi_{iq} \Delta y_{i,t-q} + c_i \bar{y}_{t-1} + \sum_{q=1}^{P_i} \delta_i \Delta \bar{y}_{t-q} + \varepsilon_{it} \]

(8.2)

for testing of unit root, where \[ \bar{y}_t = \frac{1}{N} \sum_{i=1}^{N} y_{it}, \bar{x}_t = \frac{1}{N} \sum_{i=1}^{N} x_{it}, \Delta \bar{y}_{t-j} = \frac{1}{N} \sum_{i=1}^{N} \Delta y_{i,t-j} \]
and \[ \Delta = (1 - L), L \] denotes the lag operator. The resulting pooled estimator will again be asymptotically normally distributed.

When cross-sectional dependency is of unknown form, Chang (2002) suggests using nonlinear transformations of the lagged level variable, \( y_{i,t-1} \), as instrumental variables (IV) for the usual augmented Dickey–Fuller (1979) type regression. The test statistic for the unit root hypothesis is simply defined as a standardized sum of individual IV \( t \)-ratios. As long as \( F(\cdot) \) is regularly integrable, say \( F(y_{i,t-1}) = y_{i,t-1} e^{-c_i y_{i,t-1}^2} \), where \( c_i \) is a positive constant, the product of the nonlinear instruments \( F(y_{i,t-1}) \) and \( F(y_{j,t-1}) \) from different cross-sectional units \( i \) and \( j \) are asymptotically uncorrelated, even if the variables \( y_{i,t-1} \) and \( y_{j,t-1} \) generating the instruments are correlated. Hence, the usual central limit theorems can be invoked and the standardized sum of individual IV \( t \)-ratios is asymptotically normally distributed.

For further review of the literature on unit roots and cointegration in panels, see Breitung and Pesaran (2006) and Choi (2006).

9 Concluding remarks

In this paper we have tried to provide a summary of the advantages of using panel data and the fundamental issues of panel data analysis. Assuming that the heterogeneity across cross-sectional units and over time that is not captured by the observed variables can be captured by period-invariant individual specific and/or individual-invariant time-specific effects, we surveyed the fundamental methods for the analysis of linear static and dynamic models. We have also discussed difficulties in analysing nonlinear models and modelling cross-sectional dependence. There are many important issues, such as the modelling of joint dependence or simultaneous equations models, time-varying parameter models (for example, Hsiao, 1996; 2003; Hsiao and Pesaran, 2006), unbalanced panel, measurement errors (Griliches and Hausman, 1986; Wansbeek and Koning, 1989), and so on, that were not discussed, but can be found in Arellano (2003), Baltagi (2001) or Hsiao (2003).

Although panel data offer many advantages, they are no panacea. The power of panel data to isolate the effects of specific actions, treatments or more general policies depends critically on the compatibility of the assumptions of statistical tools with the data-generating process. In choosing the proper method for exploiting the richness and unique properties of the panel, it might be helpful to keep the following questions in mind. First, in investigating economic issues what advantages do panel data offer us over data-sets consisting of a single cross section or time series? Second, what are the limitations of panel data
and the econometric methods that have been proposed for analysing such data? Third, when using panel
data, how can we increase the efficiency of parameter estimates? Fourth, are the assumptions underlying
the statistical inference procedures and the data-generating process compatible?
I would like to thank Steven Durlauf for helpful comments.

1. Why Panel Data?

Panel data, or longitudinal data, refers to data set that contains observations of a number of individuals over time. In other words, it provides multiple observations for each individual in the sample. Compared to the cross-sectional data in which observations for a number of individuals are available only for a given time, or the time series data, in which a single entity is observed over time, panel data has the obvious advantages of having more degrees of freedom and less collinearity among explanatory variables, hence provides the possibility of obtaining more accurate parameter estimates. More importantly, panel data by blending inter-individual differences with intra-individual dynamics, allows the investigation of more complicated behavioral hypotheses than those that can be addressed using cross-sectional or time series data. For instance, standard assumption for the analysis of cross-sectional data is that conditional on certain variables, each woman is a random sample from a homogeneous population. Therefore, if a cross-sectional sample yields an average labor-participation rate of 50 percent for married women, it would imply that each woman has a 50 percent chance of being in the labor force at any given time, hence a married woman would be expected to spend half of her married life in the labor force and half out of the labor force. The job turnover would be frequent, and the average job duration would be expected just two years (Ben-Porath (1973)). However, the cross-sectional data could be drawn from a heterogeneous population in which 50 percent of the sample coming from the population that always work and 50 percent from the population that never work. In this situation, there is no turnover and current work status about a woman is a perfect predictor of her future work status. To discriminate between these two possibilities, we need information on individual labor-force histories in different subintervals of the life cycle, which can only be provided if information on intertemporal dynamics of individual entities are available. On the other hand, although time series data provide information on dynamic adjustment, variables over time tend to move collinearly, hence makes it difficult to identify microdynamic or macrodynamic effects. Often estimation of
distributed lag models has to rely on strong prior restrictions like Koyck or Almon lag with very little empirical justification. With panel data, the interindividual differences often can reduce or lessen the problem of multicollinearity and provide the possibility of estimating unrestricted time adjustment patterns (e.g. Pakes and Griliches (1984)).

By utilizing information on both the intertemporal dynamics and the individuality of the entities, panel data may also allow an investigator to control the effects of missing or unobserved variables. For instance, MaCurdy’s (1981) life cycle labor supply of prime-age males under certainty model assumes that the logarithm of hours worked is a linear function of the real wage rate and the logarithm of the worker’s marginal utility of initial wealth, which is unobserved. Since wage rate and marginal utility of initial wealth are correlated, any instrument that is correlated with the wage rate will be correlated with the marginal utility of initial wealth. There is no way one can obtain consistent estimate of the coefficient of the wage rate with cross-sectional data. But if panel data are available, one can transform the labor supply model by taking first difference to get rid of the marginal utility of initial wealth as an explanatory variable. The resulting regression can yeild consistent estimates of the coefficient of wage rate and other explanatory variables.

Panel data may also provide micro foundations for aggregate data analysis. Aggregate data analysis often invokes the “representative agent” assumption. If micro units are heterogeneous, the time series properties of aggregate data may be very different from those of disaggregate data (e.g. Granger (1990), Lewbel (1992, 94), Pesaran (1999)) and policy evaluation based on aggregate data could also be grossly misleading (e.g. Hsiao, Shen and Fujiki (2004)). Panel data by providing time series observations for a number of individuals is ideal for the investigation of homogeneity issue.

Panel data involve observations of two or more dimensions. In normal circumstance, one would expect that the computation and inference of panel data models be more complicated than cross-section or time series data. However, in certain situations, the availability of panel data actually simplify inference. For instance, statistical inference for nonstation-
ary panel data can be complicated (e.g. Phillips (1986)). But, if observations are independently distributed across cross-sectional units, central limit theorems applied across cross-sectional units lead to asymptotically normally distributed statistics (e.g. Levin, Lin and Chu (2002), Pesaran, Shin and Smith (2002)).

2. Issues of Panel Data Analysis

Standard statistical methodology is based on the assumption that the outcomes, say $y$, conditional on certain variables, say $x$, are random outcomes from a probability distribution that is characterized by a fixed dimensional parameter vector, $\theta$, $f(y \mid x; \theta)$. For instance, the standard linear regression model assumes that $f(y \mid x; \theta)$ takes the form that

$$E(y \mid x) = \alpha + \beta' x. \tag{2.1}$$

and

$$\text{Var}(y \mid x) = \sigma^2, \tag{2.2}$$

where $\theta' = (\alpha, \beta', \sigma^2)$. Panel data, by its nature, focus on individual outcomes. Factors affecting individual outcomes are numerous. It is rare to be able to assume a common conditional probability density function of $y$ conditional on $x$ for all cross-sectional units, $i$, at all time, $t$. If the conditional density of $y$ given $x$ varies across $i$ and over $t$, the fundamental theorems for statistical inference, the laws of large numbers and central limit theorems, will be difficult to implement. Blindly imposing a homogeneity assumption of $f(y \mid x; \theta)$ across $i$ and over $t$ can lead to severely biased inference. For instance, suppose that the data is generated by

$$y_{it} = \alpha_i + \beta_i' x_{it} + v_{it}, \quad i = 1, \ldots, N, \quad t = 1, \ldots, T, \tag{2.3}$$

as depicted by Figure 1 in which the broken-time ellipses represent the point scatter of individual observation around the mean, represented by the broken straight line. If an investigator mistakenly estimate a model of the form

$$y_{it} = \alpha + \beta' x + v_{it}^*, \tag{2.4}$$
The solid line in Figure 1 would depict the pooled least squares regression result which could be completely contradict the individual relation between \( y \) and \( x \).

One way to restore homogeneity across \( i \) and/or over \( t \) is to add more conditional variables, say \( z \),

\[
f(y_{it} \mid x_{it}, z_{it}; \theta).
\]  

However, the dimension of \( z \) can be large. A model is a simplification of reality, not a mimic of reality. The inclusion of \( z \) may confuse the fundamental relationship between \( y \) and \( x \), in particular, when there is a shortage of degrees of freedom or multicollinearity, etc. Moreover, \( z \) may not be observable. If an investigator is only interested in the relationship between \( y \) and \( x \), a common approach to characterize the heterogeneity not captured by \( x \) is to assume that the parameter vector varies across \( i \) and over \( t \), \( \theta_{it} \), so that the conditional density of \( y \) given \( x \) takes the form \( f(y_{it} \mid x_{it}; \theta_{it}) \). However, without a structure being imposed on \( \theta_{it} \), such a model only has descriptive value, it is not possible to draw any inference.

One way to impose some structure on \( \theta_{it} \) is to decompose \( \theta_{it} \) into \( (\beta, \gamma_{it}) \), where \( \beta \) is the same across \( i \) and over \( t \), referred to as structural parameters, and \( \gamma_{it} \) as incidental parameters because when cross-units, \( N \) and/or time series observations, \( T \) increases, so is the dimension of \( \gamma_{it} \). The focus of panel data literature is to make inference on \( \beta \) after controlling the impact of \( \gamma_{it} \).

Without imposing structure for \( \gamma_{it} \), again it is not possible to make any inference on \( \beta \) because the unknown \( \gamma_{it} \) will exhaust all available sample information. Assuming that the impacts of observable variables, \( x \), are the same across \( i \) and over \( t \), represented by the structure parameters, \( \beta \), the incidental parameters \( \gamma_{it} \) represent the heterogeneity across \( i \) and over \( t \) that are not captured by \( x_{it} \). They can be considered as composed of the effects of omitted individual time-invariant, \( \alpha_i \), period individual-invariant, \( \lambda_t \), and individual time-varying variables, \( u_{it} \). The individuals time-invariant variables are variables that are the same for a given cross-sectional unit through time but that vary across cross-sectional
units such as individual-firm management, ability, gender, and socio-economic background variables. The period individual-invariant variables are variables that are the same for all cross-sectional units at a given time but that vary though time such as prices, interest rates, and wide spread optimism or pessimism. The individual time-varying variables are variables that vary across cross-sectional units at a given point in time and also exhibit variations through time such as firm profits, sales and capital stock. In a single equation framework, it is a common practice to assume that the effects of omitted individual time-varying variables, $u_{it}$ as random and uncorrelated with $\tilde{x}$. The individual-specific effects, $\alpha_i$ and time specific effects, $\lambda_t$ can either be assumed as random variables-referred to as the random effects model, or fixed parameters-referred to as the fixed effects model.

3. Linear Static Models

A widely used panel data model is to assume that the effects of observed explanatory variables, $\tilde{x}$, are identical across cross-sectional units, $i$, and over time, $t$, while the effects of omitted variables can be decomposed into the individual-specific effects, $\alpha_i$, time-specific effects, $\lambda_t$, and individual time-varying effects, $u_{it}$, as follows:

$$y_{it} = \beta' \tilde{x}_{it} + \alpha_i + \lambda_t + u_{it}, \quad i = 1, \ldots, N, \quad t = 1, \ldots, T. \quad (3.1)$$

In a single equation framework, individual time effects, $u$, are assumed to be uncorrelated with $\tilde{x}$, while $\alpha_i$ and $\lambda_t$ may or may not correlated with $\tilde{x}$. When $\alpha_i$ and $\lambda_t$ are treated as fixed constants, they are parameters to be estimated so whether they are correlated with $\tilde{x}$ is not an issue. On the other hand, when $\alpha_i$ and $\lambda_t$ are treated as random, they are typically assumed to be uncorrelated with $\tilde{x}_{it}$.

For ease of exposition, we shall assume that there are no time specific effects, i.e., $\lambda_t = 0$ for all $t$ and $u_{it}$ are independently, identically distributed (i.i.d) across $i$ and over $t$. Stack an individuals $T$ time series observations of $(y_{it}, \tilde{x}_{it}')$ into a vector and a matrix, (3.1) may alternatively be written as

$$y_i = X_i \beta + \varepsilon \alpha_i + \varepsilon_i, \quad i = 1, \ldots, N, \quad (3.2)$$
where $y_i = (y_{i1}, \ldots, y_{iT})'$, $X_i = (x_{i1}, \ldots, x_{iT})'$, $u_i = (u_{i1}, \ldots, u_{iT})'$, and $\epsilon$ is a $T \times 1$ vector of $1$'s.

Let $Q$ be a $T \times T$ matrix satisfying the condition that $Q\epsilon = 0$. Premultiplying (3.2) by $Q$ yields

$$Qy_i = QX_i\beta + Qu_i, \quad i = 1, \ldots, N. \quad (3.3)$$

Equation (3.3) no longer involves $\alpha_i$. The issue of whether $\alpha_i$ is correlated with $x_{it}$ or whether $\alpha_i$ should be treated as fixed or random is no longer relevant for (3.3). Moreover, since $X_i$ is exogenous, $E(QX_iu_i'Q') = QE(X_iu_i')Q' = 0$ and $EQy_iu_i'Q' = \sigma_u^2 QQ'$. An efficient estimator of $\hat{\beta}$ is the generalized least squares estimator (GLS),

$$\hat{\beta} = \left[ \sum_{i=1}^{N} X_i'(Q'Q)^{-1}X_i \right]^{-1} \left[ \sum_{i=1}^{N} X_i'(Q'Q)^{-1}y_i \right], \quad (3.4)$$

where $(Q'Q)^{-1}$ denotes the Moore-Penrose generalized inverse (e.g. Rao (1973)).

When $Q = I_T - \frac{1}{T}T\epsilon\epsilon'$, $Q$ is idempotent. The Moore-Penrose generalized inverse of $(Q'Q)^{-1}$ is just $Q = I_T - \frac{1}{T}T\epsilon\epsilon'$ itself. Premultiplying (3.3) by $Q$ is equivalent to transforming (3.1) into a model

$$(y_{it} - \bar{y}_i) = \beta'(x_{it} - \bar{x}_i) + (u_{it} - \bar{u}_i), \quad i = 1, \ldots, N, \quad t = 1, \ldots, T, \quad (3.5)$$

where $\bar{y}_i = \frac{1}{T} \sum_{t=1}^{T} y_{it}$, $\bar{x}_i = \frac{1}{T} \sum_{t=1}^{T} x_{it}$ and $\bar{u}_i = \frac{1}{T} \sum_{t=1}^{T} u_{it}$. The transformation is called covariance transformation. The least squares estimator (LS) (or a generalized least squares estimator (GLS)) of (3.5),

$$\hat{\beta}_{cv} = \left[ \sum_{i=1}^{N} \sum_{t=1}^{T} (x_{it} - \bar{x}_i)(x_{it} - \bar{x}_i)' \right]^{-1} \left[ \sum_{i=1}^{N} \sum_{t=1}^{T} (x_{it} - \bar{x}_i)(y_{it} - \bar{y}_i) \right], \quad (3.6)$$

is called covariance estimator or within estimator because the estimation of $\hat{\beta}$ only makes use of within (group) variation of $y_{it}$ and $x_{it}$ only. The covariance estimator of $\hat{\beta}$ turns out to be also the least squares estimator of (3.1) when $\lambda_t = 0$. It is the best linear unbiased estimator of $\hat{\beta}$ if $\alpha_i$ is treated as fixed and $u_{it}$ is i.i.d.
If $\alpha_i$ is random, transforming (3.2) into (3.3) transforms $T$ independent equations (or observations) into $(T-1)$ independent equations, hence the covariance estimator is not as efficient as the efficient generalized least squares estimator if $E\alpha_i\bar{x}_{it} = 0$. When $\alpha_i$ is independent of $\bar{x}_{it}$ and is independently, identically distributed across $i$ with mean $0$ and variance $\sigma^2_\alpha$, the best linear unbiased estimator (BLUE) of $\beta$ is GLS,

$$\hat{\beta} = \left( \sum_{i=1}^{N} X_i' V^{-1} X_i \right)^{-1} \left( \sum_{i=1}^{N} X_i' V^{-1} y_i \right).$$

where $V = \sigma^2_u I_T + \sigma^2_\alpha \epsilon \epsilon'$, $V^{-1} = \frac{1}{\sigma_u} \left[ I_T - \frac{\sigma^2_\alpha}{\sigma_u^2 + T \sigma^2_\alpha} \epsilon \epsilon' \right]$. The GLS is equivalent to first transforming the data by subtracting a fraction $(1 - \psi^{1/2})$ of individual means $\bar{y}_i$ and $\bar{x}_i$ from their corresponding $y_{it}$ and $\bar{x}_{it}$, then regressing $[y_{it} - (1 - \psi^{1/2}) \bar{y}_i]$ on $[\bar{x}_{it} - (1 - \psi^{1/2}) \bar{x}_i]$, where $\psi = \frac{\sigma^2_\alpha}{\sigma_u^2 + T \sigma^2_\alpha}$. (for detail, see Baltagi (2001), Hsiao (2003)).

When $\alpha_i$ is treated as fixed, the covariance estimator is equivalent to applying LS to the transformed model (3.5). If a variable is time-invariant, like gender dummy, $x_{kit} = x_{kis} = \bar{x}_{ki}$, the transformation eliminates the corresponding variable from the specification. Hence, the coefficients of time-invariant variables cannot be estimated. On the other hand, if $\alpha_i$ is random and uncorrelated with $\bar{x}_i, \psi \neq 0$, the GLS can still estimate the coefficients of those time-invariant variables.

4. Dynamic Models

When the regressors of a linear model contains lagged dependent variables, say, of the form

$$y_i = y_{i,-1} \gamma + X_i \beta + \epsilon \alpha_i + u_i = Z_i \theta + \epsilon \alpha_i + u_i, \quad i = 1, \ldots, N. \quad (4.1)$$

where $y_{i,-1} = (y_{i0}, \ldots, y_{i,T-1})'$, $Z_i = (y_{i,-1}, X_i)$ and $\theta = (\gamma, \beta')'$. For ease of notation, we assume that $y_{i0}$ are observable. Technically, we can still eliminate the individual-specific effects by premultiplying (4.1) by the transformation matrix $Q$ ($Q\epsilon = 0$),

$$Q y_i = QZ_i \theta + Q u_i. \quad (4.2)$$
However, because of the presence of lagged dependent variables, \( EQZ_i u_i' Q' \neq 0 \) even with the assumption that \( u_{it} \) is independently, identically distributed across \( i \) and over \( t \). For instance, the covariance transformation matrix \( Q = I_T - \frac{1}{T} e e' \) transforms (4.1) into the form

\[
(y_{it} - \bar{y}_i) = (y_{i,t-1} - \bar{y}_{i,-1})\gamma + (\bar{x}_{it} - \bar{x}_i)'\beta + (u_{it} - \bar{u}_i), \quad i = 1, \ldots, N, \quad t = 1, \ldots, T, \tag{4.3}
\]

where \( \bar{y}_i = \frac{1}{T} \sum_{t=1}^{T} y_{it}, \bar{y}_{i,-1} = \frac{1}{T} \sum_{t=1}^{T} y_{i,t-1} \) and \( \bar{u}_i = \frac{1}{T} \sum_{t=1}^{T} u_{it} \). Although, \( y_{i,t-1} \) and \( u_{it} \) are uncorrelated under the assumption of serial independence of \( u_{it} \), the covariance between \( \bar{y}_{i,-1} \) and \( u_{it} \) or \( y_{i,t-1} \) and \( \bar{u}_i \) is of order \( (1/T) \) if \( |\gamma| < 1 \). Therefore, the covariance estimator of \( \theta \) creates a bias of order \( (1/T) \) when \( N \to \infty \) (Anderson and Hsiao (1981, 1982), Nickell (1981)). Since most panel data contain large \( N \) but small \( T \), the magnitude of the bias cannot be ignored (e.g. with \( T=10 \) and \( \gamma=0.5 \), the asymptotic bias is -0.167).

When \( EQZ_i u_i' Q' \neq 0 \), one way to obtain a consistent estimator for \( \theta \) is to find instruments \( W_i \) that satisfy

\[
EW_i u_i' Q' = 0, \tag{4.4}
\]

and

\[
\text{rank} (W_i Q Z_i) = k, \tag{4.5}
\]

where \( k \) denotes the dimension of \( (\gamma, \beta')' \), then apply the generalized instrumental variable or generalized method of moments estimator (GMM) by minimizing the objective function

\[
\left[ \sum_{i=1}^{N} W_i (Q y_i - Q Z_i \theta)' \right] \left[ \sum_{i=1}^{N} W_i Q u_i u_i' Q' W_i' \right]^{-1} \left[ \sum_{i=1}^{N} W_i (Q y_i - Q Z_i \theta) \right], \tag{4.6}
\]

with respect to \( \theta \). (e.g. Ahn and Honoré (2003), Ahn and Schmidt (1995), Arellano and Bond (1991), Arellano and Bover (1995)). For instance, one may let \( Q \) be a \((T - 1) \times T\) matrix of the form

\[
D = \begin{bmatrix}
-1 & 1 & 0 & \cdots \\
0 & -1 & 1 & \cdots \\
0 & \cdots & \cdots & -1 & 1
\end{bmatrix}, \tag{4.7}
\]
then the transformation (4.2) is equivalent to taking the first difference of (4.1) over time to eliminate $\alpha_i$ for $t = 2, \ldots, T$,

$$\Delta y_{it} = \Delta y_{i,t-1} \gamma + \Delta \tilde{x}_{it}' \beta + \Delta u_{it}, \quad i = 1, \ldots, N; \quad t = 2, \ldots, T, \quad (4.8)$$

where $\Delta = (1 - L)$ and $L$ denotes the lag operator, $L y_t = y_{t-1}$. Since $\Delta u_{it} = (u_{it} - u_{i,t-1})$ is uncorrelated with $y_{i,t-j}$ for $j \geq 2$ and $\tilde{x}_{is}$, for all $s$, when $u_{it}$ is independently distributed over time and $\tilde{x}_{it}$ is exogenous, one can let $W_i$ be a $T(T-1)[K + \frac{1}{2}] \times (T-1)$ matrix of the form

$$W_i = \begin{bmatrix} q_{i2} & 0 & \cdots & \cdots & \cdots & \cdots & 0 \\ \vdots & \ddots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & \ddots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & \cdots & \cdots & \cdots & \cdots & q_{iT} \end{bmatrix}, \quad (4.9)$$

where $q_{it} = (y_{i0}, y_{i1}, \ldots, y_{i,t-2}, \tilde{x}_{i1}', \tilde{x}_{iT}')', \tilde{x}_i = (\tilde{x}_{i1}', \ldots, \tilde{x}_{iT}')'$, and $K = k - 1$. Under the assumption that $(y_{i}'', \tilde{x}_i')$ are independently, identically distributed across $i$, the Arellano-Bover (1991) GMM estimator takes the form

$$\hat{\theta}_{AB,GMM} = \left\{ \begin{bmatrix} \sum_{i=1}^{N} Z_i'D W_i' \\ \sum_{i=1}^{N} W_i A W_i' \end{bmatrix}^{-1} \begin{bmatrix} \sum_{i=1}^{N} W_i D Z_i \\ \sum_{i=1}^{N} W_i D y_i' \end{bmatrix}^{-1} \left\}^{-1} \left\{ \begin{bmatrix} \sum_{i=1}^{N} Z_i'D W_i' \\ \sum_{i=1}^{N} W_i A W_i' \end{bmatrix}^{-1} \begin{bmatrix} \sum_{i=1}^{N} W_i D Z_i \\ \sum_{i=1}^{N} W_i D y_i' \end{bmatrix} \right\} \quad (4.10)$$

where $A$ is a $(T-1) \times (T-1)$ matrix with 2 on the diagonal elements, $-1$ on the elements above and below the diagonal elements and 0 elsewhere.

The GMM estimator has the advantage that it is consistent and asymptotically normally distributed whether $\alpha_i$ is treated as fixed or random because it eliminates $\alpha_i$ from the specification. However, the number of moment conditions increases at the order of $T^2$ which can create severe downward bias in finite sample (Ziliak (1997)). An alternative is to use a (quasi-) likelihood approach which has the advantage of having a fixed number of orthogonality conditions independent of the sample size. It also has the advantage of making use all the available sample, hence can yield more efficient estimator than (4.10) (e.g.
Hsiao, Pesaran and Tahmiscioglu (2002), Binder, Hsiao and Pesaran (2004)). Since there is no reason to assume that the data generating process of initial observations, \(y_{i0}\), to be different from the rest of \(y_{it}\), the likelihood approach has to formulate the joint likelihood function of \((y_{i0}, y_{i1}, \ldots, y_{iT})\) (or the conditional likelihood function \(\{y_{i1}, \ldots, y_{iT} \mid y_{i0}\}\)). However, \(y_{i0}\) depends on previous values of \(\bar{x}_{i,-j}\) and \(\alpha_i\) which are unavailable. Bhargava and Sargan (1983) suggest to circumscribe this missing data problem by conditioning \(y_{i0}\) on \(\bar{x}_i\) and \(\alpha_i\) if \(\alpha_i\) is treated as random while Hsiao, Pesaran and Tahmisciogulu (2002) propose conditioning \((y_{i1} - y_{i0})\) on the first difference of \(\bar{x}_i\) if \(\alpha\) is treated as fixed constants.

5. Random vs Fixed Effects Specification

The advantages of random effects (RE) specifications are:

1. The number of parameters stay constant when sample size increases.
2. It allows the derivation of efficient estimators that make use of both within and between (group) variation.
3. It allows the estimation of the impact of time-invariant variables.

The disadvantages of RE specification is that it typically assumes that the individual- and/or time-specific effects are randomly distributed with a common mean and are independent of \(\bar{x}_{it}\). If the effects are correlated with \(\bar{x}_{it}\) or if there is a fundamental difference among individual units, i.e., conditional on \(\bar{x}_{it}\), \(y_{it}\) cannot be viewed as a random draw from a common distribution, common RE model is misspecified and the resulting estimator is biased.

The advantages of fixed effects (FE) specification are that it allows the individual- and/or time specific effects to be correlated with explanatory variables \(\bar{x}_{it}\). Neither does it require an investigator to model their correlation patterns.

The disadvantages of the FE specification are:

1’. The number of unknown parameters increases with the number of sample observations. In the case when \(T\) (or \(N\) for \(\lambda_t\)) is finite, it introduces the classical
incidental parameter problem (e.g. Neyman and Scott (1948)).

2’. The FE estimator does not allow the estimation of the coefficients that are time-invariant.

In other words, the advantages of RE specification are the disadvantages of FE specification and the disadvantages of RE specification are the advantages of FE specification. To choose between the two specifications, Hausman (1978) note that the FE estimator (or GMM), \( \hat{\theta}_{FE} \), is consistent whether \( \alpha_i \) is fixed or random. On the other hand, the commonly used RE estimator (or GLS), \( \hat{\theta}_{RE} \), is consistent and efficient only when \( \alpha_i \) is indeed uncorrelated with \( x_{it} \). If \( \alpha_i \) is correlated with \( x_{it} \), the RE estimator is inconsistent. Therefore, Hausman (1978) suggests using the statistic

\[
(\hat{\theta}_{FE} - \hat{\theta}_{RE})' \left[ \text{Cov}(\hat{\theta}_{FE}) - \text{Cov}(\hat{\theta}_{RE}) \right]^{-1} (\hat{\theta}_{FE} - \hat{\theta}_{RE})
\] (5.1)

to test RE vs FE specification. The statistic (5.1) is asymptotically chi-square distributed with degrees of freedom equal to the rank of \( \left[ \text{Cov}(\hat{\theta}_{GMM}) - \text{Cov}(\hat{\theta}_{RE}) \right] \).

6. Nonlinear Models

The introduction of individual-specific effects, \( \alpha_i \), and/or time-specific effects, \( \lambda_t \), provide a simple way to capture the unobserved heterogeneity across \( i \) and over \( t \). However, the likelihood functions are in terms of observables, \( (y_{it}, x_{it}), i = 1, \ldots, N \). Therefore, we will have to either treat \( \alpha_i \) as unknown parameters (fixed effects) and consider the conditional likelihood,

\[
f(y_i \mid x_i, \beta, \alpha_i), i = 1, \ldots, N, \tag{6.1}
\]
or to treat \( \alpha_i \) as random and consider the marginal likelihood

\[
f(y_i \mid x_i; \beta) = \int f(y_i \mid x_i, \beta, \alpha_i) f(\alpha_i \mid x_i) d\alpha_i, i = 1, \ldots, N, \tag{6.2}
\]

where \( f(\alpha_i \mid x_i) \) denotes the conditional density of \( \alpha_i \) given \( x_i \).

When the unobserved individual specific effects, \( \alpha_i \), (and or time-specific effects, \( \lambda_t \)) affect the outcome, \( y_{it} \), linearly, one can avoid the consideration of random versus fixed
effects specification by eliminating them from the specification through some linear transform-
ation such as the covariance transformation (3.3) or first difference transformation (4.8). However, if $\alpha_i$ affects $y_{it}$ non-linearly, it is not easy to find transformation that can eliminate $\alpha_i$. For instance, consider the following binary choice model where the observed $y_{it}$ takes the value of either 1 or 0 depending on the latent response function

$$y_{it}^* = \beta' \tilde{x}_{it} + \alpha_i + u_{it},$$

(6.3)

and

$$y_{it} = \begin{cases} 1, & \text{if } y_{it}^* > 0, \\ 0, & \text{if } y_{it}^* \leq 0, \end{cases}$$

(6.4)

where $u_{it}$ is independently, identically distributed with density function $f(u_{it})$. Let

$$y_{it} = E(y_{it} \mid \tilde{x}_{it}, \alpha_i) + \epsilon_{it},$$

(6.5)

then

$$E(y_{it} \mid \tilde{x}_{it}, \alpha_i) = \int_{-\infty}^{\infty} f(u)du$$

$$= [1 - F(-\beta' \tilde{x}_{it} - \alpha_i)].$$

(6.6)

Since $\alpha_i$ affects $E(y_{it} \mid \tilde{x}_{it}, \alpha_i)$ non-linearly, $\alpha_i$ remains after taking successive difference of $y_{it}$,

$$y_{it} - y_{i,t-1} = [1 - F(-\beta' \tilde{x}_{it} - \alpha_i)]$$

$$- [1 - F(-\beta' \tilde{x}_{i,t-1} - \alpha_i)] + (\epsilon_{it} - \epsilon_{i,t-1}).$$

(6.7)

The likelihood function conditional on $\tilde{x}_i$ and $\alpha_i$ takes the form,

$$\Pi_{i=1}^{N} \Pi_{t=1}^{T} [F(-\beta' \tilde{x}_{it} - \alpha_i)]^{1-y_{it}} [1 - F(-\beta' \tilde{x}_{it} - \alpha_i)]^{y_{it}}.$$ 

(6.8)

If $T$ is large, consistent estimator of $\hat{\beta}$ and $\alpha_i$ can be obtained by maximizing (6.8). If $T$ is finite, there is only limited information about $\alpha_i$ no matter how large $N$ is. The presence of incidental parameters, $\alpha_i$, violates the regularity conditions for the consistency of the maximum likelihood estimator of $\beta$. 

12
If \( f(\alpha_i \mid x_{it}) \) is known, and is characterized by a fixed dimensional parameter vector, consistent estimator of \( \beta \) can be obtained by maximizing the marginal likelihood function,

\[
\Pi_{i=1}^{N} \int \Pi_{t=1}^{T} \left[ F(-\beta' x_{it} - \alpha_i) \right]^{1-y_{it}} \left[ 1 - F(-\beta' x_{it} - \alpha_i) \right]^{y_{it}} f(\alpha_i \mid x_i) d\alpha_i. \tag{6.9}
\]

However, maximizing (6.9) involves \( T \)-dimensional integration. Butler and Moffit (1982), Chamberlain (1984), Heckman (1981), etc., have suggested methods to simplify the computation.

The advantage of RE specification is that there is no incidental parameter problem. The problem is that \( f(\alpha_i \mid x_{it}) \) is in general unknown. If a wrong \( f(\alpha_i \mid x_{it}) \) is postulated, maximizing the wrong likelihood function will not yield consistent estimator of \( \beta \). Moreover, the derivation of marginal likelihood through multiple integration may be computationally infeasible. The advantage of FE specification is that there is no need to specify \( f(\alpha_i \mid x_{it}) \). The likelihood function will be the product of individual likelihood (e.g. (6.8)) if the errors are assumed i.i.d. The disadvantage is that it introduces incidental parameters.

A general approach of estimating a model involving incidental parameters is to find transformations to transform the original model into a model that does not involve incidental parameters. Unfortunately, there is no general rule available for nonlinear models. One has to explore the specific structure of a nonlinear model to find such a transformation. For instance, if \( f(u) \) in (6.3) is logistic, then

\[
\text{Prob} \left( y_{it} = 1 \mid x_{it}, \alpha_i \right) = \frac{e^{\beta' x_{it} + \alpha_i}}{1 + e^{\beta' x_{it} + \alpha_i}}. \tag{6.10}
\]

Since, in a logit model, the denominators of \( \text{Prob}(y_{it} = 1 \mid x_{it}, \alpha_i) \) and \( \text{Prob}(y_{it} = 0 \mid x_{it}, \alpha_i) \) are identical and the numerator of any sequence \( \{y_{i1}, \ldots, y_{iT}\} \) with \( \sum_{t=1}^{T} y_{it} = s \) is always equal to \( \exp(\alpha_i s) \cdot \exp\left( \sum_{t=1}^{T} (\beta' x_{it}) y_{it} \right) \), the conditional likelihood function conditional on \( \sum_{t=1}^{T} y_{it} = s \) will not involve the incidental parameters \( \alpha_i \). For instance, consider the
simple case that $T = 2$, then

$$\text{Prob}(y_{i1} = 1, y_{i2} = 0 \mid y_{i1} + y_{i2} = 1) = \frac{e^{\beta' x_{i1}}}{e^{\beta' x_{i1}} + e^{\beta' x_{i2}}} = \frac{1}{1 + e^{\beta' \Delta x_{i2}}},$$

(6.11)

and

$$\text{Prob}(y_{i1} = 0, y_{i2} = 1 \mid y_{i1} + y_{i2} = 1) = \frac{e^{\beta' \Delta x_{i2}}}{1 + e^{\beta' \Delta x_{i2}}},$$

(6.12)

(Chamberlain (1980), Hsiao (2003)).

Alternatively, Manski (1987) exploits the latent linear structure of (6.3) by noting that for given $i$,

$$\beta' x_{it} \gtrless \beta' x_{i,t-1} \iff E(y_{it} \mid x_{it}, \alpha_i) \gtrless E(y_{i,t-1} \mid x_{i,t-1}, \alpha_i),$$

(6.13)

and suggests maximizing the objective function

$$H_N(b) = \frac{1}{N} \sum_{i=1}^{N} \sum_{t=2}^{T} \text{sgn}(b' \Delta x_{it}) \Delta y_{it},$$

(6.14)

where $\text{sgn}(w) = 1$ if $w > 0$, $0$ if $w = 0$, and $-1$ if $w < 0$. The advantage of the Manski (1987) maximum score estimator is that it is consistent without the knowledge of $f(u)$. The disadvantage is that (6.13) holds for any $c\beta$ where $c > 0$. Only the relative magnitude of the coefficients can be estimated with some normalization rule, say $\| \beta \| = 1$. Moreover, the speed of convergence is considerably slower ($N^{1/3}$) and the limiting distribution is quite complicated. Horowitz (1993) and Lee (1996) have proposed modified estimators that improve the speed of convergence and are asymptotically normally distributed.

Other examples of exploiting specific structure of nonlinear models to eliminate the effects of incidental parameters $\alpha_i$ include dynamic discrete choice models (Chamberlain (1993), Honoré and Kyriazidou (2000), Hsiao, Shen, Wang and Weeks (2004)), symmetrically trimmed least squares estimator for truncated and censored data (Tobit models) (Honoré (1992)), sample selection models (or type II Tobit models) (Kyriazidou (1997)),
etc. However, often they impose very severe restrictions on the data such that not much information of the data can be utilized to obtain parameter estimates. Moreover, there are models such that there does not appear to possess consistent estimator when \( T \) is finite.

An alternative to consider consistent estimators is to consider bias reduced estimator. The advantage of such an approach is that the bias reduced estimators may still allow the use of all the sample information so that from a mean square error point of view, the bias reduced estimator may still dominate a consistent estimators because the latter often have to throw away a lot of sample, thus tend to have large variances.

Following the idea of Cox and Reid (1987), Arellano (2001) and Carro (2004) propose to derive the modified MLE by maximizing the modified log-likelihood function

\[
L^*(\beta) = \sum_{i=1}^{N} \left[ \ell_i^* (\beta, \hat{\alpha}_i(\beta)) - \frac{1}{2} \log \ell_{i,d_i,d_i}^* (\beta, \hat{\alpha}_i(\beta)) \right],
\]

where \( \ell_i^* (\beta, \hat{\alpha}_i(\beta)) \) denotes the concentrated log-likelihood function of \( y_i \) after substituting the MLE of \( \alpha_i \) in terms of \( \beta, \hat{\alpha}_i(\beta) \), (i.e., the solution of \( \frac{\partial \log L}{\partial \alpha_i} = 0 \) in terms of \( \beta, i = 1, \ldots, N \)), into the log-likelihood function and \( \ell_{i,\alpha_i,\alpha_i}^* (\beta, \hat{\alpha}_i(\beta)) \) denotes the second derivative of \( \ell_i^* \) with respect to \( \alpha_i \). The bias correction term is derived by noting that to the order of \( (1/T) \) the first derivative of \( \ell_i^* \) with respect to \( \beta \) converges to \( \frac{1}{2} \frac{E[\ell_{i,\beta,\alpha_i}^*(\beta, \alpha_i)]}{E[\ell_{i,\alpha_i,\alpha_i}^*(\beta, \alpha_i)]} \). By subtracting the order \( 1/T \) bias from the likelihood function, the modified MLE is biased only to the order of \( (1/T^2) \), without increasing the asymptotic variance.

Monte Carlo experiments conducted by Carro (2004) have shown that when \( T = 8 \), the bias of modified MLE for dynamic probit and logit models are negligible. Another advantage of the Arellano-Carro approach is its generality. For instance, a dynamic logit model with time dummy explanatory variable can not meet the Honoré and Kyriaizidou (2000) conditions for generating consistent estimator, but will not affect the asymptotic properties of the modified MLE.

7. Modeling Cross-Sectional Dependence

Most panel studies assume that apart from the possible presence of individual in-
variant but period varying time specific effects, $\lambda_t$, the effects of omitted variables are independently distributed across cross-sectional units. However, often economic theory predicts that agents take actions that lead to interdependence among themselves. For example, the prediction that risk averse agents will make insurance contracts allowing them to smooth idiosyncratic shocks implies dependence in consumption across individuals. Ignoring cross-sectional dependence can lead to inconsistent estimators, in particular when $T$ is finite (e.g. Hsiao and Tahmiscioglu (2005)). Unfortunately, contrary to the time series data in which the time label gives a natural ordering and structure, general forms of dependence for cross-sectional dimension are difficult to formulate. Therefore, econometricians have relied on strong parametric assumptions to model cross-sectional dependence. Two approaches have been proposed to model cross-sectional dependence: economic distance or spatial approach and factor approach.

In regional science, correlation across cross-section units is assumed to follow a certain spatial ordering, i.e. dependence among cross-sectional units is related to location and distance, in a geographic or more general economic or social network space (e.g. Anselin (1988), Anselin and Griffith (1988), Anselin, Le Gallo and Jayet (2005)). A known spatial weights matrix, $W = (w_{ij})$ an $N \times N$ positive matrix in which the rows and columns correspond to the cross-sectional units, is specified to express the prior strength of the interaction between individual (location) $i$ (in the row of the matrix) and individual (location) $j$ (column), $w_{ij}$. By convention, the diagonal elements, $w_{ij} = 1$. The weights are often standardized so that the sum of each row, $\sum_{j=1}^{N} w_{ij} = 1$.

The spatial weight matrix, $W$, is often included into a model specification to the dependent variable, to the explanatory variables, or to the error term. For instance, a spatial lag model for the $NT \times 1$ variable $y = (y_1', \ldots, y_N')', y_i = (y_{i1}, \ldots, y_{iT})'$, may take the form

$$ y = \rho(W \otimes I_T)y + X\beta + u $$

(7.1)

where $X$ and $u$ denote the $NT \times K$ explanatory variables and $NT \times 1$ vector of error terms,
respectively, and $\otimes$ denotes the Kronecker product. A spatial error model may take the form,

$$\tilde{y} = X\tilde{\beta} + \tilde{v},$$  \hspace{1cm} (7.2)

where $\tilde{v}$ may be specified as in a spatial autoregressive form,

$$\tilde{v} = \theta (W \otimes I_T) \tilde{v} + u,$$  \hspace{1cm} (7.3)

or a spatial moving average form,

$$\tilde{v} = \gamma (W \otimes I_T) u + u.$$  \hspace{1cm} (7.4)

The spatial model can be estimated by the instrumental variables (generalized method of moments estimator) or the maximum likelihood method. However, the approach of defining cross-sectional dependence in terms of “economic distance” measure requires that the econometricians have information regarding this “economic distance”. Another approach to model cross-sectional dependence is to assume that the error of a model, say model (7.3) follows a linear factor model,

$$v_{it} = \sum_{j=1}^{r} b_{ij} f_{jt} + u_{it},$$  \hspace{1cm} (7.5)

where $\tilde{f}_t = (f_{1t}, \ldots, f_{rt})'$ is a $r \times 1$ vector of random factors, $b_{i}' = (b_{i1}, \ldots, b_{ir})$, is a $r \times 1$ nonrandom factor loading coefficients, $u_{it}$, represents the effects of idiosyncratic shocks which is independent of $\tilde{f}_t$ and is independently distributed across $i$. (e.g. Bai and Ng (2002), Moon and Perron (2004), Pesaran (2004)). The conventional time-specific effects model is a special case of (7.5) when $r = 1$ and $b_i = b_\ell$ for all $i$ and $\ell$.

The factor approach requires considerably less prior information than the economic distance approach. Moreover, the number of time-varying factors, $r$, and factor load matrix $B = (b_{ij})$ can be empirically identified if both $N$ and $T$ are large. However, when $T$ is large, one can estimate the covariance between $i$ and $j$, $\sigma_{ij}$, by $\frac{1}{T} \sum_{t=1}^{T} \hat{v}_{it} \hat{v}_{jt}$ directly, then apply the generalized least squares method, where $\hat{v}_{it}$ is some preliminary estimate of $v_{it}$.
8. Concluding Remarks

In this paper we have tried to provide a summary of advantages of using panel data and the fundamental issues of panel data analysis. Assuming that the heterogeneity across cross-sectional units and over time that are not captured by the observed variables can be captured by period-invariant individual specific and/or individual-invariant time specific effects, we surveyed the fundamental methods for the analysis of linear static and dynamic models. We have also discussed difficulties of analyzing nonlinear models and modeling cross-sectional dependence. There are many important issues such as the modeling of joint dependence or simultaneous equations models, time-varying parameter models (e.g. Hsiao (1992, 2003), tests of unit root or cointegration (e.g., Levin, Lin and Chu (2003), Pesaran, Shin and Smith (2004), Hsiao and Pesaran (2004)), the asymptotics for panels with large N and T (e.g. Phillips and Moon (1999)), unbalanced panel, measurement errors (Griliches and Hausman (1986), Wansbeek and Konig (1989)), etc. that were not discussed, but could be found in Baltagi (2001) or Hsiao (2003).

Although panel data offer many advantages, they are not panacea. The power of panel data to isolate the effects of specific actions, treatments or more general policies depends critically on the compatibility of the assumptions of statistical tools with the data generating process. In choosing the proper method, for exploiting the richness and unique properties of the panel, it might be helpful to keep the following factors in mind: First, what advantages do panel data offer us in investigating economic issues over data sets consisting of a single cross section or time series? Second, what are the limitations of panel data and the econometric methods that have been proposed for analyzing such data? Third, when using panel data, how can we increase the efficiency of parameter estimates? Fourth, are the assumptions underlying the statistical inference procedures and the data-generating process compatible.

Lorenz curve

Nanak Kakwani
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

The Lorenz curve is the most widely used technique to represent and analyse the size distribution of income and wealth. The curve plots cumulative proportion of income units and the cumulative proportion of income received when income units are arranged in ascending order of their income. Max Otto Lorenz, a statistician (born 19 September 1876 in Burlington, USA; retired 1944), proposed this curve in 1905 in order to compare and analyse inequalities of wealth in a country during different epochs, or in different countries during the same epoch – and since then, the curve has been widely used as a convenient graphical device to summarize the information collected about the distributions of income and wealth.

The Lorenz curve may be represented by a function \( L(p) \), which is interpreted as the fraction of total income received by the lowest \( p \)th fraction of income units. It satisfies the following conditions (Kakwani, 1980):

1. (a) if \( p=0 \), \( L(p)=0 \)
2. (b) if \( p=1 \), \( L(p)=1 \)
3. (c) \( L'(p)=(x/\mu) \geq 0 \) and \( L''(p)=(1/\mu f(x))>0 \)
4. (d) \( L(p) \geq p \)

where income \( x \) of a unit (which can be negative for some units but is assumed to be non-negative here for notational convenience) is a random variable with the probability density function \( f(x) \) with mean \( \mu \) and \( L'(p) \) and \( L''(p) \) are the first and second derivatives of \( L(p) \) with respect to \( p \), respectively.

A hypothetical Lorenz curve is illustrated in Figure 1. The ordinate and abscissa of the curve are \( L(p) \) and \( p \), respectively. The slope of the Lorenz curve is positive and increases monotonically, in other words, the curve is convex to the \( p \)-axis. From this it follows that \( L(p)<p \). The straight line represented by the equation \( L(p)=p \) is called the egalitarian line.

The curve lies below this line. If, however, the curve coincides with the egalitarian line, it means that each unit receives the same income, which is the case of perfect equality of incomes. In the case of perfect inequality of incomes, the Lorenz curve coincides with \( OA \) and \( AB \), which implies that all income is received by only one unit.

Figure 1
The Lorenz curve

![Lorenz Curve Diagram](http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_L000149&goto=B&result_number=1014)
Since the Lorenz curve displays the deviation of each individual income from perfect equality, it captures, in a sense, the essence of inequality. The nearer the Lorenz curve is to the egalitarian line, the more equal the distribution of income will be. Consequently, the Lorenz curve could be used as a criterion for ranking income distributions: if the Lorenz curve for one distribution, $X$, lies everywhere above that for another distribution, $Y$, then the distribution $X$ may be said to be more equal than the distribution $Y$. However, the ranking provided by the curve is only partial – when two Lorenz curves intersect, neither distribution can be said to be more equal than the other. This partial ranking (or quasi-ordering as Sen (1973) calls it) need not, however, be considered a weakness of the Lorenz curve. In fact Sen (1973) criticizes the inequality measures that provide complete orderings on the grounds that ‘the concept of inequality has different facets which may point in different directions and sometimes a total ranking can not be expected to emerge’. According to him, the concept of inequality is essentially a question of partial ranking and the Lorenz curve is consistent with such a notion of inequality.

Is there any relation between the Lorenz curve ranking of distributions and social welfare? The answer has been provided by Atkinson (1970) who proved a theorem which shows that if social welfare is the sum of the individual utilities and every individual has an identical utility function which is concave, the ranking of distributions according to the Lorenz curve criterion is identical to the ranking implied by the social welfare function, provided the distributions have the same mean income and their Lorenz curves do not intersect. This theorem implies that one can judge between the distributions without knowing the form of the utility function except that it is increasing and concave. If the Lorenz curves do intersect, however, two utility functions that will rank the distributions differently can always be found.

Atkinson's theorem is based on the assumption that the social welfare function is equal to the sum of individual utilities and that every individual has the same utility function. These assumptions are somewhat limited and have been criticized by DasGupta, Sen and Starrett (1973) as well as by Rothschild and Stiglitz (1973), who have demonstrated that the result is, in fact, more general and would hold for any symmetric welfare function that is quasi-concave.

The Lorenz curve makes distributional judgements independently of the size of income, which as Sen (1973) points out, ‘will make sense only if the relative ordering of welfare levels of distributions were strictly neutral to the operation of multiplying everybody’s income by a given number’. This is rather an extreme requirement because social welfare depends on both size and the distribution of income.

Working independently on extensions of the Lorenz partial ordering, Shorrocks (1983) and Kakwani (1984) arrived at a criterion which would rank any two distributions with different mean incomes. The new criterion is given by $L(\mu, p)$, which is the product of the mean income $\mu$ and the Lorenz curve $L(p)$, whereas the Lorenz curve ranking is based only on $L(p)$. Ranking the distributions according to $L(\mu, p)$ will be identical to the Lorenz ranking if the distributions have the same mean income. This criterion of ranking has been justified from the welfare point of view in terms of several alternative classes of social welfare functions. Kakwani (1984) has used this criterion for international comparison of welfare using data from 72 countries.

As pointed out in the beginning, the Lorenz curve technique was devised as a convenient graphical method to represent and analyse the size distributions of income and wealth. The technique has proved to be extremely powerful and its applications in many areas of applied economics have recently been explored. In analysing data on consumer expenditures Mahalanobis (1960) developed a new technique ‘Fractile Graphical Analyses’ for comparison of socioeconomic groups at different places or points of time. In this paper, he proposed to extend and generalize the concept of the Lorenz curve to deal with problems of consumer behaviour patterns with respect to different commodities. He suggested that generalized Lorenz curves be called concentration curves, and in fact, used them as a convenient graphical device to describe consumption patterns for different commodities based on data from the National Sample Survey of India.

Kakwani (1977, 1980) provided, however, a more general and rigorous treatment of concentration curves in order to study the relationships among the distributions of different economic variables. He proved theorems which have many applications, particularly in the field of public finance where the effect of taxation and public spending of income distribution is analysed. Other areas in which concentration curves can be applied are inflation as it affects income distribution, estimation of Engel elasticities, disaggregation of total inequality by factor components, and economic growth and income distribution. In a later contribution he used concentration curves to explore how the sense of envy felt by individuals affects the optimal tax structure (Kakwani, 1985).

business cycles; distance; Great Depression; location; Lösch, A.; partial equilibrium; population cycles; regional economics; secular stagnation; transfer problem

Article

Lösch was born on 15 October 1906 in Oehringen (Württ), though he considered Heidenheim (Brenz) his home. He went to school there, studied in Freiburg with Eucken and in Bonn with Schumpeter and Spiethoff. He was twice a Rockefeller Fellow in the United States, where he did most of the theoretical and empirical work on Die räumliche Ordnung der Wirtschaft (1939a), published in the United States as the Economics of Location in 1954. His Habilitation (that is, his qualification to teach at a university) on population waves and business cycles was accepted but its unpopular conclusions and his known anti-Nazi views prevented him from getting the venia legendi, the actual permission to teach. He found refuge with the Kiel Institut für Weltwirtschaft, where he became chief of his own research group while at the same time suffering from political interference. He wrote a number of reports for the institute, one of which was published with his conclusions reversed. He kept his personal integrity at great personal cost. He died on 30 May 1945 in Ratzeburg (Holstein) of scarlet fever, which his weakened condition could not tolerate. In 1971, the City of Heidenheim honoured his memory by sponsoring biennial international conferences on location problems, establishing a prize for the best theses in the field and, a few years later, a special honour for older scholars in the field.

Although Lösch's first published paper dealt with the transfer problem, and he continued to be interested in international monetary problems, his only other publications in that field are two discussions of the transfer problem and an extensive fragment in the posthumously published ‘Theory of Foreign Exchanges’. The two major subjects of his published work were the relation of population and business cycles and, of course, his highly original Räumliche Ordnung der Wirtschaft.

The discussions of population problems anticipate many later developments. Waves of population increase were neither sufficient nor necessary for the explanation of business cycles. With detailed statistics, some going back to the 17th century, Lösch showed that any relation went from business
cycles to population waves, much as recent theory suggests. Though Lösch can claim priority there is no evidence that he actually influenced later developments.

The investigations about a declining and ageing population resulted, however, in quite different conclusions from what was then either politically or academically acceptable. The ageing of the population (the German ‘Vergreisung’ has sinister overtones absent from the English equivalent) had its economic compensations. It allowed the better training of the younger generation and increased capital accumulation and productivity. Even in military terms, fewer but better trained and better equipped people were preferable to more but less skilled individuals. In short, fewer young people allowed greater savings and investments leading to increased productivity and growth. This differed substantially from the then prevalent secular stagnation thesis and is much more in keeping with the warnings of present-day development economists of the dangers of rapid population growth. Lösch's earlier Was ist vom Geburtenrückgang zu halten? (1932) was later put on the index by the Nazis and his doctoral thesis on the same topic was effectively suppressed.

Lösch's greatest contribution dealt, in most general terms, with general equilibrium theory applied to space. Distance itself becomes the central phenomenon. Lösch's intellectual predecessors dealt with this problem essentially in two ways. They either solved a partial equilibrium system (Alfred Weber) or they substituted a series of smaller regions for one large one (Ohlin).

Going from partial to general equilibrium, and investigating the structure of the region instead of taking it as given, involved the substitution of a very general set of assumptions for the usual ceteris paribus assumptions made. In Weber (and practically everyone else) the locations of markets, raw materials and populations are assumed. In Lösch the basic assumption is a perfectly even distribution of population and of all raw materials. With these extraordinarily general and brilliantly unrealistic assumptions Lösch succeeds in showing that competitive forces alone will establish a system of locations which, in turn, can be understood either as agglomerations of productions or the intersection of fewer or more crossroads, all being simultaneously determined.

Lösch presents a Walrasian model with distance built in as a system of coordinates of location. His most famous contribution, however, is the analysis of the structure of an economic landscape on the basis of the simple generalized assumptions mentioned. The empirical work related mostly to the American Mid-West, where the assumptions are approximately realistic. One test of the genius of the model is that, unlike with most theoretical models, the introduction of more realistic assumptions simplifies rather than complicates the model.

In the ‘ideal’ Lösch landscape the basic unit is a hexagon. This follows from the condition that consumers are initially equidistant from each other, that each producer and consumer must lie within the market area of each good and that there must be no empty corners. Modifications introduced are rectangular areas on the model of, say, the layout of American counties; or the effect of different resource endowments of different areas; or of a border separating what might otherwise be one market area.

The work does not exhaust itself with equilibrium analysis or the structure of economic landscapes. There is a dynamic analytical and empirical study of how business cycles spread over the economic landscape or how transfers are made over and between areas through intra-regional adjustments in connected areas and from one sub-market to another. Thus the initial impact of a change in demand in one landscape capital might first be felt in the capital in the centre of another landscape and spread from there in declining ripples to the border. There is a study of how the Great Depression spread in time and
geographically through an area. The usual multiplier is supplemented by a spatial one.
The Lösch analyses the *Gestalt* of a region rather than defining it by such criteria as the immobility of factors of production between but not within regions: all factors are mobile at a cost which varies with distance, even land whose physical immobility is substituted for by changes in its utilization. The case of completely specific resources is investigated, though considered rare.
Lösch left a number of unfinished studies, and plans for many more. His is probably the most original book published on economics in the German language between the two world wars. Most scholars would consider themselves lucky if they had added a layer of bricks to an existing wall. Only few scholars can claim to have started a new wall, and even fewer to have started a new building. Lösch is one of those few scholars.

Article

Born on 4 March 1893 in Stuttgart, Adolph Lowe was educated at Berlin and Tübingen and received the Dr. Juris. from Tübingen in 1918. From 1919 to 1924 he was Section Head in the Ministries of Labour and Economics of the Weimar Republic, and was largely responsible for the practical planning and management of the currency reforms that brought the great hyperinflation to an end. From 1924 to 1926 he was Head of the International Division of the Federal Statistical Bureau, a politically sensitive post in the light of disputes over reparations payments. In 1926 he became Director of Research at the Institute of World Economics at the University of Kiel, where he established an important centre for research into business cycles and their control and regulation through planning. In 1931 he was appointed Professor of Political Economy at the University of Frankfurt, where he joined the leaders of a major renaissance in social and socialist thinking. But in March 1933 he became the first professor in the social sciences to be fired by Hitler. He moved immediately to England, where he held a post at Manchester until 1940, when he moved to the New School for Social Research in New York, where he was Professor of Economics, Director of Research at the Institute of World Affairs, and then Professor Emeritus, remaining active in the Department until his return to Germany, in March 1983, 50 years after his forced departure. In 1984 he was awarded the Dr. honoris causa by the University of Bremen.

Unlike many economists, Lowe considered economics inseparable from social inquiry in general. In his view, the central question of economics is the determination of the path of economic growth and its
relation to technical progress and social change. Lowe developed a strikingly simple three-sector model in which structural changes during expansion could be displayed. Growth will normally not take place in a balanced manner; more commonly the actual path will be a ‘traverse’ from one desired path to another, which is likely to shift again before it is reached. But the problem has to be understood in the light of what Lowe calls ‘instrumental analysis’. Conventional economic theory begins with knowledge of the prevailing situation and a set of well-defined behavioural laws, based on maximizing. From these two givens one can deduce/predict the future configuration of the economy. This approach worked well in the early stages of capitalism, when the pressure of poverty on labour and competition on capital ensured stable patterns of behaviour. But mass production and economies of scale undermine competition, while affluence and unionization, together with the growth of the middle class, lead both to unpredictable wage bargaining and to unstable consumer spending. Tastes become volatile, while consumption can be postponed or redirected, and businesses plan strategically, often in cooperation with their rivals, instead of maximizing on a short horizon – so the traditional approach is no longer appropriate. The historical conditions do not constrain behaviour sufficiently for maximizing models, even complex ones, to picture it accurately, so that the conventional method must be set aside. (Which means, as well, that the forces of the market cannot be relied upon; they are no longer determinate.) Instead, the givens should be the existing conditions and the desired terminal position, and the job of economic analysis then becomes to find the ‘goal-adequate’ sequences of change, together with the stimuli and/or constraints that will create the necessary behaviour patterns. Such stimuli and constraints must be imposed by government. Economic analysis becomes a form of planning, and Lowe's work in his last years analysed the relation of planning to freedom.

low-income housing policy

Edgar O. Olsen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Low-income housing assistance is an important part of the welfare system in many countries. This article discusses the rationale for this government activity, describes the most important differences between different low-income housing programmes, explains why economic theory has limited implications for the effects of these programmes, and summarizes the evidence on their most important effects. The most important finding of the empirical literature on the effects of different housing programmes from the viewpoint of housing policy is that recipient-based housing assistance has provided equally good housing at a much lower total cost than any type of unit-based assistance.

Keywords

crowding out; low-income housing policy; neighbourhood effects; public housing; recipient-based housing assistance; residential segregation; unit-based housing assistance

Article

Low-income housing assistance is an important part of the welfare system in many countries.

Rationales

The most compelling rationale for this government activity is that some taxpayers care about low-income households and think that the decision makers in some of these households spend too little of their income on housing for their own good. Another important argument is that some taxpayers are particularly concerned about the well-being of the children in low-income households and prefer housing subsidies to unrestricted cash grants in order to better target assistance to the objects of their concern. These rationales imply that a successful housing programme induces its recipients to occupy better housing and consume less of other goods than they would choose in response to an unrestricted...
cash grant in an amount equal to the housing subsidy.

Programmetypes

Governments have tried many methods of providing housing assistance. The most important distinction between rental housing programmes is whether the subsidy is attached to the dwelling unit or to the assisted household. If the subsidy is attached to a rental dwelling unit, each family must accept the particular unit offered in order to receive assistance and loses its subsidy when it moves. Each family offered recipient-based rental assistance has a choice among many units in the private market that meet the programme's standards, and the family can retain its subsidy when it moves. The analogous distinction for homeownership programmes is between programmes that require eligible families to buy from selected sellers in order to receive a subsidy and programmes that provide subsidies to eligible families that are free to buy from any seller that provides housing meeting the programme's standards. There are two broad types of unit-based rental assistance, namely, public housing and privately owned subsidized projects. Public housing projects are owned and operated by government entities. In public housing programmes, civil servants make all of the decisions made by private owners of unsubsidized housing. Governments also contract with private parties to provide unit-based assistance in subsidized housing projects. In the United States, the majority of these private parties are for-profit firms, but nonprofit organizations have a significant presence. Under most programmes, these private parties agree to provide rental housing meeting certain standards at restricted rents to households with particular characteristics for a specified number of years. The overwhelming majority of the projects were newly built under a subsidized construction programme. Almost all of the rest were substantially rehabilitated as a condition for participation in the programme. None of the programmes that subsidize privately owned projects provide subsidies to all suppliers who would like to participate.

In 2004, the United States government spent about $15 billion on its housing voucher programme, more than $15 billion to subsidize private projects for low-income households, and about $7.5 billion to subsidize public housing projects. The US Department of Housing and Urban Development's Section 8 New Construction and Substantial Rehabilitation Program and the Internal Revenue Service's Low-Income Housing Tax Credit Program are the two largest programmes that subsidize private rental projects, accounting for about 75 per cent of public expenditure on programmes of this type. In total, these rental programmes served about seven million households. During the same year, the US government spent only $4 billion to subsidize low-income homeowners. These programmes tend to provide shallower subsidies to households with substantially higher incomes than the rental programmes.

Theory

Economic theory that accounts for the most rudimentary features of real housing programmes does not have strong implications about their effects. For example, these programmes may induce households to occupy worse housing even if housing is a normal good. Such counterintuitive outcomes result from the nonlinear budget frontiers facing households offered housing assistance. For instance, a household offered a unit in a subsidized housing project is offered an all-or-nothing choice of a particular dwelling unit at a below-market rent. This unit might be worse than the household's current unit, but the household may accept the offer because the reduction in its rent enables it to consume more of other
Evidence

The remainder of this article summarizes the evidence on the effects of the major rental housing programmes in the United States. The United States has rental programmes of each broad type, and a disproportionate share of the evidence on the performance of low-income housing programmes throughout the world pertains to these programmes. Homeownership programmes are a small part of the current system, and little is known about their effects.

Different rental housing programmes have different effects. Indeed, the same programme has different effects in different circumstances. Olsen (2003) provides a more detailed account of the evidence on the performance of individual programmes, and the bibliography to this article contains references to some of the more important recent studies. This article endeavours to characterize what is typical of these programmes and the differences in the average effect of programmes of different types.

The most important finding of the empirical literature on the effects of different housing programmes from the viewpoint of housing policy is that recipient-based housing assistance has provided equally good housing at a much lower total cost than any type of unit-based assistance. The reasons for this result suggest that it would apply generally. These reasons include the absence of a financial incentive for good decisions on the part of civil servants who operate public housing, the excessive profits that inevitably result from allocating subsidies to selected developers of private subsidized projects, and the distortions in usage of inputs resulting from the subsidy formulas. Another reason for the excess cost of unit-based assistance is that this assistance is usually tied to the construction of new units. The least expensive approach to improving the housing conditions of low-income households involves heavy reliance on upgrading the existing housing stock.

Since housing programmes are intended to produce particular changes in consumption of housing services compared with consumption of other goods, knowledge of these changes is important for evaluating these programmes. The overwhelming majority of recipients of housing assistance occupy better housing than they would occupy in the absence of assistance. More importantly, they typically occupy better housing than they would occupy if they were given cash grants in amounts equal to their housing subsidies. Most recipients of rental housing assistance pay significantly less for their housing and hence have more to spend on other goods.

One aspect of the housing bundle broadly conceived that has attracted considerable attention is its neighbourhood. Recipients of tenant-based vouchers and occupants of privately owned subsidized projects typically live in somewhat better and less racially segregated neighbourhoods than in the absence of housing assistance. Occupants of public housing typically live in noticeably worse and more racially segregated neighbourhoods.

A careful theoretical analysis that accounts for a key feature of low-income housing programmes has shown that, even if the subsidy under the programme declines with increases in earnings and leisure is a normal good, the programme will not necessarily induce the recipient to work less (Schone, 1992). Nevertheless, evidence based on a controlled experiment indicates that voucher recipients reduce their earnings about 13 per cent on average (Patterson et al., 2004). Other evidence indicates that programmes of unit-based assistance have somewhat larger work disincentive effects (Olsen et al., 2005).
Low-income housing programmes differ substantially from unrestricted cash grants in their effects. The mean value of project-based housing assistance as judged by recipients is much less than 75 per cent of the mean housing subsidy (that is, the difference between the market rent of the subsidized unit and the tenant's contribution). The mean value of tenant-based housing assistance as judged by recipients is about 80 per cent of the mean housing subsidy.

Consistent with their intentions, the mean benefit to recipients in these programmes is greater for poorer and larger households among households that are the same in other respects. Mean benefit varies little with the age, race and sex of the head of the household after other household characteristics are accounted for. The variance in benefit among recipients with the same characteristics is large under construction programmes that have produced new units for many years. In these mature construction programmes, there is an enormous difference between the best and the worst units, and a tenant with specified characteristics would pay the same rent for these units.

Unit-based or recipient-based housing programmes can make the neighbourhoods into which subsidized households move better or worse places to live. Neighbourhood property values capture these effects. On average across all units in a programme, the evidence indicates that no programme has had a significant effect on neighbourhood property values.

Housing programmes affect the rents of unsubsidized units with unchanging characteristics. Evidence from the Housing Assistance Supply Experiment indicates that an entitlement housing voucher programme for which the poorest 20 per cent of the population is eligible will have small effects on market rents (Lowry, 1983). No evidence is available for construction programmes. However, economic theory suggests that, if a construction programme leads to a larger housing stock, it will result in higher market rents because it will drive up the prices of inputs used heavily in the housing industry. This effect might be small, however, because the evidence indicates that subsidized construction crowds out unsubsidized construction to a considerable extent (Malpezzi and Vandell, 2002; Sinai and Waldfogel, 2005; and references in Olsen, 2003).

An important recent literature estimates a wide range of impacts of offering portable vouchers to families living in the worst public housing projects or in public housing projects in the poorest neighbourhoods. The larger strand of this research is based on data from a controlled experiment called Moving to Opportunity, in which one experimental group was offered a housing voucher without any restriction on the neighbourhood where it could be used and another experimental group had to move for at least a year to a neighbourhood where the poverty rate was less than ten per cent prior to the experiment (Orr et al., 2003). These treatments led their recipients to live in better housing and neighbourhoods without a reduction in expenditure on other goods. However, they did not lead to some expected outcomes. After four to seven years in the experiment, the treatment groups did not increase their earnings and their children's educational performance did not improve. With a few notable exceptions such as the mental health of girls and their mothers, the treatments had minimal effects on health outcomes. The treatments generally had effects in opposite directions on the delinquency and risky behaviour of boys and girls. The effects on boys were negative, though these effects were not usually statistically significant. A smaller strand of this literature is based on data on natural experiments such as when public housing tenants must move because their project is torn down (Jacob, 2004).

Lucas critique

Lars Ljungqvist
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The ‘Lucas critique’ is a criticism of econometric policy evaluation procedures that fail to recognize that optimal decision rules of economic agents vary systematically with changes in policy. In particular, it criticizes using estimated statistical relationships from past data to forecast the effects of adopting a new policy, because the estimated regression coefficients are not invariant but will change along with agents’ decision rules in response to a new policy. A classic example of this fallacy was the erroneous inference that a regression of inflation on unemployment (the Phillips curve) represented a structural trade-off for policy to exploit.

Article

The ‘Lucas Critique’ is a criticism of econometric policy evaluation procedures that fail to recognize the following economic logic:

\[ \text{Given that the structure of an econometric model consists of optimal decision rules of economic agents, and that optimal decision rules vary systematically with changes in the structure of series relevant to the decision maker, it follows that any changes in policy will systematically alter the structure of econometric models. (Lucas, 1976, p. 41)} \]

At the time of his writing, Robert E. Lucas, Jr. (1976) was criticizing the prevailing approach to quantitative macroeconomic policy evaluation for ignoring this logic and, hence, as being fundamentally inconsistent with economic theory. To fully appreciate Lucas's critique, we first consider a general
Lucas critique: The New Palgrave Dictionary of Economics

At each date $t$ there is a vector $s_t$ of state variables summarizing all aspects of the history that are relevant to the economy's future evolution; for example, the vector might include the economy's capital stock. The economy is also described by a vector $x_t$ of government policy variables and a vector $\varepsilon_t$ of random shocks – for example, shocks to technology or to government policy. For given specifications of the processes governing $x_t$ and $\varepsilon_t$, it is common in macroeconomic theory to analyse models that yield an equilibrium law of motion in form of a difference equation,

$$s_{t+1} = f(s_t, x_t, \varepsilon_t).$$

(1)

(For many textbook examples of stochastic rational expectations models that yield such a recursive equilibrium representation; see Ljungqvist and Sargent, 2004.) Equation (1) is also the point of departure for the econometric policy evaluation procedures criticized by Lucas, who argued that their approach failed to recognize the optimization behaviour of economic agents that is implicit in eq. (1). Specifically, the criticized approach proceeds as follows. First, historical data are used to estimate the equation

$$s_{t+1} = F(\theta, s_t, x_t, \mu_t),$$

(2)

where $F$ is specified in advance, $\theta$ is a fixed parameter vector to be estimated, and $\mu_t$ is a vector of random disturbances. Second, with the use of the estimated eq. (2), policy evaluations are performed by comparing economic outcomes for different paths of government policy variables $\{x_t\}$. The policy choice that produces the most desirable economic outcome is deemed to be the best policy. But, as argued by Lucas, this approach violates the premises for economic theory because the parameter vector $\theta$ depends partly on agents’ decision rules that are not invariant to the conduct of government policy. That is, if the government changes its policy, the parameter $\theta$ will also change, so that the consequences of a new policy cannot be evaluated on the basis of the historical relationship in eq. (2).

Lucas's argument is best illustrated with an example. Consider the classic example of the so-called 'Phillips curve'. Phillips (1958) had estimated a negative relationship between wage inflation and unemployment using British data for the period 1861–1957. Samuelson and Solow (1960) and others interpreted this and related empirical findings as evidence of a structural trade-off between an economy's inflation rate and its unemployment rate. That is, the parameter $\theta$ in eq. (2), estimated with historical data, was considered to be fixed and to describe how unemployment would respond to inflation outcomes associated with different monetary policies. Friedman (1968) and Phelps (1968) argued
against the existence of such an exploitable trade-off because it was inconsistent with economic theory based on rational agents. To understand the fallacy of the Phillips curve and its extension—the fallacy of the econometric policy evaluation procedures criticized by Lucas—consider the monetary model of Lucas (1972). Exchange in the economy takes place in physically separated markets. Producers in a market base their output decisions on the local market-clearing price level without knowing the current economy-wide price level. The price in a market varies stochastically because there are exogenous random shocks both to the distribution of producers across markets and to the aggregate quantity of nominal money, none of which is directly observable to the agents. Hence, information on the current state of these real and monetary shocks is transmitted to agents only through the price in the market where each agent happens to be. In an equilibrium, producers in a market would like to increase their output in response to a high price driven by real but not nominal shocks. A high price due to a real shock means that the ratio of producers to consumers is low in that market and, therefore, profits on sales are high in real terms (when evaluated in terms of the economy-wide price level). But a high price in a market due to an expansion of the aggregate quantity of nominal money means that prices tend to be high in all markets and, therefore, profits on sales are high in nominal but not real terms. The inference and decision problems solved by the agents in this model are shown to give rise to a Phillips curve, as had been estimated with real-world data, but where the model’s apparent trade-off between inflation and output cannot be systematically exploited by the government in its choice of monetary policy.

To further convey the insights from this general equilibrium model of the Phillips curve, we adopt a version of Lucas’s (1976) simplified model that does not spell out all the details of the economic environment but instead postulates three equations that capture the forces at work in the fully articulated model. The economy-wide price level (in logs), $p_t$, is given by

$$p_t = \bar{p}_t + m_t$$  \hspace{1cm} (3)

where $\bar{p}_t$ reflects a systematic component of monetary policy that is known to all agents, and $m_t$ reflects an i.i.d. shock to monetary policy. It is assumed that the random variable $m_t$ is normally distributed with mean zero and variance $\sigma_m^2$. The price (in logs) in market $i$ at time $t$, $p_{it}$, is given by

$$p_{it} = p_t + z_{it}$$  \hspace{1cm} (4)

where $z_{it}$ is a deviation from the economy-wide price level because of shocks to the distribution of producers across markets. The real shock $z_{it}$ is assumed to be a normal, i.i.d. random variable with mean
zero and variance $\sigma^2_T$. Finally, let $y_{it}$ denote the log-deviation of output from its ‘natural rate’ in market $i$ at time $t$ which varies with the perceived, relative price:

$$ y_{it} = \alpha [ p_{it} - E(p_t | I_{it}) ], $$

(5)

where $\alpha > 0$ reflects intertemporal substitution possibilities in supply (determined by technological factors and tastes for substituting labour over time), and $E(\cdot | I_{it})$ denotes the mathematical expectation conditioned upon information $I_{it}$ available in market $i$ at time $t$. The agents’ prediction problem in eq. (5) is straightforward to solve (see, for example, Ljungqvist and Sargent, 2004, ch. 5):

$$ E(p_t | I_{it}) = E(p_t | p_{it}, \bar{p}_t) = (1 - \Omega) p_{it} + \Omega \bar{p}_t, $$

(6)

where $\Omega = \sigma^2_T / (\sigma^2_M + \sigma^2_T)$. The substitution of eqs. (3), (4) and (6) into eq. (5) yields

$$ y_{it} = \alpha \Omega (m_t + z_{it}). $$

(7)

Thus, output in market $i$ varies with the sum of nominal and real shocks, $(m_t + z_{it})$, because producers cannot perfectly disentangle these shocks but must make inferences based on the observed price $p_{it}$. Producers’ willingness to vary output from its natural rate depends on how likely observed price variations are due to real rather than nominal shocks, as captured by the magnitude of $\Omega \in [0, 1]$. Under the assumption of a large number $N$ of markets, the real shocks, $\{z_{it}\}$, cancel each other out when averaged over markets, and the economy’s deviation from its natural rate of output, $y_t$, becomes

$$ y_t = \frac{1}{N} \sum_{i=1}^{N} y_{it} = \alpha \Omega m_t = \alpha \Omega (p_t - \bar{p}_t), $$

(8)
where the last equality invokes eq. (3) and, hence, the economy exhibits a positive relationship between unanticipated inflation and output.

If estimations were performed using data on output and inflation from the described economy, we would find a Phillips curve along which increases in inflation are associated with higher output realizations. However, any attempts by the government to exploit that relationship would fail. For example, a government that permanently increases the growth rate of the money supply to generate higher inflation in order to stimulate output will ultimately see no real effects from that change in policy. The reason for this is that, after agents have become aware of the higher underlying inflation rate in the economy, they will change their expectations when making predictions about relative price movements due to real disturbances. Formally, the change in monetary policy represents an increase in the component \( \bar{P}_t \) and, when that systematic change becomes known to the agents, it will not affect unanticipated inflation, \((p_t - \bar{P}_t) = m_t\), so output is left unaffected in eq. (8).

This example illustrates Lucas's general criticism of econometric policy evaluation procedures that fail to recognize that the estimated eq. (2) depends partly on agents’ decision rules and is therefore not invariant to changes in government policy. For a proper policy evaluation procedure, we need to revise the econometric formulation in eq. (2) so that it becomes consistent with equilibrium outcomes as represented by eq. (1). Recall that the latter equation is derived for given specifications of the processes governing \( x_t \) and \( \varepsilon_t \). In particular, to analyse agents’ optimization behaviour, we need to specify the environment in which they live, including their perceptions about future government policy. As Lucas (1976, p. 40) remarked, ‘one cannot meaningfully discuss optimal decisions of agents under arbitrary sequences \( \{x_t\} \) of future shocks’. Instead, Lucas suggested that one proceeds by viewing government policy as a function of the state of the economy,

\[
x_t = C(\lambda, s_t, \eta_t),
\]

(9)

where \( \lambda \) is a parameter vector that characterizes government policy, and \( \eta_t \) is a vector of random disturbances. Then the new version of eq. (2) becomes

\[
s_{t+1} = F(\theta(\lambda), s_t, x_t, \mu_t),
\]

(10)

and the econometric problem is that of estimating the function \( \theta(\lambda) \). A change in government policy is viewed as a change in the parameter \( \lambda \) affecting the behaviour of the system in two ways: first, by altering the time series behaviour of \( \{x_t\} \), and second, by leading to modification of the parameter \( \theta \).
governing the rest of the system, which reflects changes in agents’ decision rules in response to the new policy.

A constructive response to the Lucas critique has been the development of rational expectations econometrics. A goal of that approach has been to estimate the ‘primitives’ of dynamic rational expectations models, in the form of parameters describing tastes and technologies. If historical data can be used to obtain such estimates, the economic model can in principle be used to evaluate alternative government policies that could be without precedent, as explained by Lucas and Sargent (1981). That is, knowledge about the primitives of a model enables us to derive agents’ decision rules and equilibrium outcomes for any specified policy process. In terms of eq. (10), this explains how the function $\theta(\lambda)$ could conceivably be estimated even if the historical data have been generated under a single government policy $\lambda$.

Though one of the key contributors to the methodology of rational expectations econometrics, Sargent (1984) has raised a philosophical conundrum with this approach to policy evaluation (as earlier discussed by Sargent and Wallace, 1976). Suppose that the primitives of an economic model have been estimated during an estimation period in which government policy was specified to be $\lambda$, and then the estimated model is used to compare alternative policies in order to find the best future policy $\lambda^*$. But such a procedure leads to an internal contradiction under the assumption of rational expectations, because, if the procedure were in fact likely to be persuasive in having the policy recommendation actually adopted soon, it would mean that the original econometric model with it specified policy $\lambda$ had been mis-specified. As pointed out by Sargent (1984, p. 413): ‘A rational expectations model during the estimation period ought to reflect the procedure by which policy is thought later to be influenced, for agents are posited to be speculating about government decisions into the indefinite future.’

Given its fundamental impact on questions of economic policy both in practice and in theory, the Lucas critique figured prominently in the list of contributions when the Royal Swedish Academy of Sciences (1995) awarded Robert E. Lucas, Jr. the Nobel Prize in economics ‘for having developed and applied the hypothesis of rational expectations, and thereby having transformed macroeconomic analysis and deepened our understanding of economic policy.’

Abstract

Robert E. Lucas, Jr is one of the most influential economists of our time. His work on rational expectations offered a truly new way of thinking about economics and policy that led to most of the recent successes in macroeconomics. Lucas’s path breaking research on so many issues of vital importance has advanced the frontier of science and set the stage for new exciting discoveries.

Article

In 1995, Robert E. Lucas, Jr received the Nobel Prize in Economic Sciences ‘for having developed and applied the hypothesis of rational expectations, and thereby having transformed macroeconomic analysis and deepened our understanding of economic policy’ (Press Release announcing the Nobel Prize, 1995; repr. in Svensson, 1996, p. 1).

Robert Lucas was born in Yakima, Washington on 15 September 1937. He received his BA in History in 1959, and his Ph.D. in Economics in 1964, both from the University of Chicago. He began his career as an assistant professor at Carnegie Mellon University, where he became an associate professor in 1967 and a full professor in 1970. He joined the Department of Economics at the University of Chicago as a full professor in 1975, and since 1980 has served as John Dewey Distinguished Service Professor of Economics there. He is a fellow of the Econometric Society, the American Academy of Arts and Sciences, and the American Finance Association; a member of the National Academy of Sciences and
Lucas, Robert (born 1937) : The New Palgrave Dictionary of Economics

the American Philosophical Society and a titular member of the European Academy of Arts, Sciences and Humanities. Lucas served as the President of the Econometric Society in 1997 and as the President of the American Economic Association in 2002.

Robert Lucas's seminal contributions in the early 1970s led to a paradigm shift in macroeconomics: the rational expectations revolution. By the late 1970s–early 1980s, due to the efforts of Robert Lucas and others (including Robert Barro, William Brock, Edward Prescott, Thomas Sargent and Neil Wallace) the frontier of macroeconomic research had moved away from models with static or adaptive expectations towards models in which agents act in their best interest, utilizing all available information about past, present and future. As a result, dynamic stochastic general equilibrium models with rigorous microfoundations have been developed to understand economic fluctuations and growth and to analyse the effects of monetary and fiscal policies. While these models have become increasingly complex in an effort to better understand the economy, almost all of them are built on the principles set forth by Robert Lucas.

The beginning of the rational expectations revolution: expectations and the neutrality of money

Robert Lucas's ‘Expectations and Neutrality of Money’, published in 1972 in the *Journal of Economic Theory*, was the first paper to incorporate the idea of rational expectations into a dynamic general equilibrium model. (rational expectations were introduced by Muth, 1961. In their ground-breaking study of investment under uncertainty, Lucas and Prescott, 1971 applied the notion of rational expectations in a dynamic partial equilibrium model of a competitive industry facing stochastic demand.) The agents in Lucas's (1972b) model are fully rational: based on the available information, they form expectations about future prices and quantities, and based on these expectations they act to maximize their expected lifetime utility. This paper also was the first to provide sound theoretical underpinnings to Milton Friedman's (1968) and Edmund Phelps's (1968) view of the long-run neutrality of money, and at the same time to provide an explanation of the observed positive correlation between output and inflation, famously depicted by the Phillips curve.

Lucas's model is built on Paul Samuelson's (1958) overlapping generations model. Agents live for two periods. In each period the young generation works, consumes and saves. The old generation consumes its savings. Goods are perishable and there is only one savings instrument in the economy, money. The population in the economy is allocated into two distinct markets (islands) across which no communication is possible. The old generation is equally divided between the islands. The allocation of the young generation across the islands is a random variable. The amount of money holdings by the old generation is also a random variable, because it depends on the realization of a random shock in the money growth rate: each dollar carried from one period to another is multiplied by the realized money growth rate between these two periods. Agents do not observe the current allocation of young across islands and the money growth rate, but know their underlying probability distributions. To solve for the optimal amount of labour supply and savings, the young must form expectations about the future value of money, that is, the future price level. How does one form such expectations? Lucas's answer is, rationally. He defined and explicitly solved for the rational expectations equilibrium, in which agents correctly predict how the price level depends on the state of the economy. Of course, to do so each agent also must correctly understand the actions of all other agents in the current and future generations and
how these actions affect prices (and quantities).

In the model, the positive correlation between the money growth rate and output arises because the young, when faced with a high demand for their goods, are unable to distinguish its source: the demand could be high because of a higher money growth rate, or because of a lower fraction of the young workers on the island. Due to their inability to infer exactly the source of the high demand, the young find it optimal to produce whenever they face a high demand. Consequently, a positive money growth shock leads to an economic expansion on both islands. Without uncertainty about the money growth rate, the neutrality of money is immediately attained. Any pre-announced proportional money growth rule – for example, the $k\%$ rule advocated by Milton Friedman – results in the same real outcomes. Lucas showed that invariance of real outcomes to the pre-announced part of the money growth rule holds also when there are shocks to money growth. This finding is often characterized as a ‘policy ineffectiveness’ result, because it implies that, although there is a positive correlation between output and money growth, this correlation cannot be exploited by the monetary authority to influence real economic activity.

Prior to Lucas's (1972b) work, economists often emphasized that a distinction should be drawn between the long-run and the short-run effects of monetary shocks. An important corollary of Lucas's work is that this distinction often is misleading. The true distinction must be made between anticipated and unanticipated monetary disturbances, because their effects on real economic activity are likely to be very different. Most of the subsequent monetary business cycle literature embraces this distinction.

**Econometric policy evaluation: the Lucas Critique**

Lucas (1976), known as the Lucas critique, marked the turning point in how economists approached econometric policy evaluation. Thomas Sargent's (1996) account of the events following the Lucas critique gives a sense of its tremendous impact:

[W]e didn't understand what was going on until, upon reading Lucas's 'Econometric Policy Evaluation' in Spring of 1973, we were stunned into terminating our long standing Minneapolis Fed research project to design, estimate and optimally control a Keynesian macroeconometric model. We realized that Kareken, Muench, and Wallace's (1973) defense of the ‘look-at-everything’ feedback rule for policy – which was thoroughly based on ‘best responses’ for the monetary authority exploiting a ‘no response’ private sector – could not be the foundation of a sensible research program, but was better viewed as a memorial plaque to the Keynesian tradition in which we had been trained to work.

(Sargent, 1996, p. 539)

The essence of the Lucas critique stems naturally from the concept of rational expectations. Indeed, rationality of the private sector implies that it cannot be modelled as a ‘no response’ entity. Rather, any observed or anticipated change in monetary policy, including the ‘best response’ of the monetary authority, will induce the ‘best responses’ from the agents in the private sector. This, in turn, implies that the effects of a new policy cannot be assessed according to econometric estimation of the private sector's behaviour under the old policy.
Robert Lucas has made several other major contributions in different areas of economics. A small subset of them is presented below, in chronological order.

Lucas (1978a) elegantly introduced the first general equilibrium model of asset pricing. In the model economy, physical assets are represented by what nowadays typically is referred to as ‘Lucas trees’: infinitely lived objects that generate stochastic dividends (fruits). Lucas explicitly derived asset prices as functions of the economy's state variables. The logic of Lucas's asset pricing equation forms the foundation of many models in macro and financial economics.

Lucas (1980b) and Lucas and Stokey (1987) helped to lay the foundations of monetary economics. The ideas and the methodology developed in these papers continue to guide monetary economists, particularly in applied research. Lucas (1980b) is the first general equilibrium study of the determination of prices in an economy in which the use of money arises from a cash-in-advance constraint. The model in Lucas and Stokey (1987), which is the prototype for a number of widely used dynamic stochastic general equilibrium monetary models, features both real and nominal shocks. Methods developed by Lucas and Stokey for establishing the existence of, characterizing and solving for the equilibrium of such models have proven to be powerful tools in applied and theoretical research.

Lucas (1982) extended the logic of his earlier contributions, Lucas (1978a) and Lucas (1980b), to a two-country stochastic general equilibrium model with infinitely lived agents, in which he explicitly derived formulas for pricing real assets and nominal bonds as well as for determining exchange rates. The framework developed in this paper serves as a point of departure for many models in international economics.

Lucas and Stokey (1983) is a major contribution to modern public finance. Lucas and Stokey studied the Ramsey (1927) problem – the problem of optimal taxation when non-distortionary tax instruments are unavailable – in dynamic stochastic economies without physical capital. Their paper provided a number of important insights about the structure and time consistency of optimal fiscal and monetary policies. Lucas and Stokey showed that a sufficiently rich debt maturity structure could allow for time consistency of the optimal fiscal policy.

Lucas (1988) is a seminal contribution in the economic development and growth literature (see also the 1991 Fisher and Shultz Lecture at the European Meetings of Econometric Society, published as Lucas, 1993). Lucas (1988) and an earlier paper by Paul Romer (1986) heralded the birth of endogenous growth theory and the resurgence of research on economic growth in the late 1980s and the 1990s. These papers offered an escape from ‘the straightjacket of the neoclassical growth model, in which the long term per capita (output) growth is pegged by the rate of exogenous technological progress’ (Barro and Sala-i-Martin, 2004, p. 19), by showing that factor accumulation does not need to run into diminishing returns to scale and, therefore, could lead to perpetual growth. In particular, Lucas emphasized the role of human capital, and externalities generated by it, as important sources of long-run economic growth.

Robert Lucas has written a number of seminal books. Among them are Models of Business Cycles (1987) and, with N. Stokey and E. Prescott, Recursive Methods in Economic Dynamics (1989). The former presents a critical assessment of the business cycle literature of the 1970s and the early 1980s and offers novel insights about economic fluctuations. This monograph contains Lucas's famous calculation of the cost of business cycles, which he argued to be insignificant. (In a similar spirit, Lucas, 2000a...
provided a quantitative assessment of the welfare cost of inflation. In this paper, he found that the gains from reducing inflation could be non-negligible. Subsequent research often has taken his calculations of the cost of business cycles and of the cost of inflation as benchmarks.) Another indispensable volume, *Recursive Methods in Economic Dynamics* (1989), deals with stochastic dynamic programming. It has been widely used as a textbook in graduate macroeconomics courses and as a guide for formulating and solving dynamic stochastic general equilibrium models.

A lump sum tax is fixed in amount and of such a nature that no action by the victim (short of emigration or suicide) can alter his or her liability. An example would be a poll tax, perhaps differentiated on the basis of sex and age. It is difficult to find other examples. Differentiation on the basis of ability, wealth, income or expenditure would clearly lead to taxes that were not lump sum. Ability can be disguised. Wealth can be consumed. Leisure can be substituted for income, and saving for spending. All such actions would reduce tax. This implies that the principal criteria one might like to use as a basis for redistributive taxation are ruled out if one is confined to lump sum taxes. It also implies that it may be difficult to relate lump sum taxes to ability to pay. A feature of lump sum taxation is that what taxpayers bear is exactly balanced (in monetary terms) by what the fisc gains. That is because there is no tax at the margin. (If there were tax at the margin, taxpayers could vary their liabilities by varying their activities, and the tax would not be lump sum.) The absence of tax at the margin means that no transaction is killed off by the driving of a wedge between what one party pays and the other receives. When there is such a wedge (caused by a tax that is not lump sum) transactions are not entered into which, but for the tax, would have been mutually advantageous to the parties; and the loss to the parties is not balanced by any gain to the fisc. This is the ‘excess burden’ of taxation. It can never occur when taxes are lump sum. In general equilibrium analysis the imposition of a set of lump sum taxes and bounties is equivalent to an adjustment of initial endowments. The attainment of equilibrium is not impaired, but its position will usually be altered. In welfare economics the conditions are investigated under which such an equilibrium may also represent a general optimum of production and exchange (in the sense of Pareto). If these conditions are met, it will not be possible to make one person better off without making someone else worse off. But the distribution of wealth may be very unequal: in an extreme case one person could end
up with everything, the others with nothing. Lump sum taxes can, in theory, correct this situation without impairing the general optimum. In this sense, they are an ideal form of taxation. Lump sum taxes are thus of some importance in theoretical work. But in the real world, poll taxes being their only viable form, they are rarely encountered precisely because they cannot in practice be matched to ability to pay or used to achieve a redistribution of income of wealth without ceasing to be lump sum. At most they are a benchmark against which the less than perfect taxes we normally encounter can be measured.

Article

Lundberg was born in Stockholm and obtained a Ph.D. in economics in 1937 at the Stockholms Högskola. From 1937 to 1955 he was director of the Government Economic Research Institute (Konjunkturinstitutet), and from 1946 to 1965 he was professor of economics at the University of Stockholm; he held the same post at the Stockholm School of Economics from 1965 to 1970. He was president of the Royal Swedish Academy of Science from 1973 to 1976, and chairman of the Nobel Prize Committee for Economics from 1975 to 1980. He held numerous visiting professorships throughout the world.

Lundberg’s main contributions to economic theory are his models of macroeconomic fluctuations and his analysis of the problems of economic policy, in particular the conflicts between stabilization policy and policies for the allocation of resources and the distribution of income.

His Studies in The Theory of Economic Expansion (1937) is an early work of high originality about the instability of growth, the main analytical technique being systems of difference equations of multiplier and accelerator mechanisms (with some consideration to the possibilities of flexible coefficients), embedded in a simple macroeconomic framework. Lags between inputs, output, income formation and spending play strategic roles (the lag between output and income-formation is often referred to as ‘the Lundberg lag’). Rather than providing reduced-form solutions to the system, Lundberg presented numerical sequences of various macroeconomic variables and their relations, so-called ‘sequence analysis’.

The part of the book which had the strongest immediate influence on other theorists is perhaps the inventory model. Non-anticipated increases in sales, while first resulting in a fall in inventories, later on, due to attempts by firms to restore the initial relation of inventory stocks to production levels, result in various kinds of inventory cycles. Lundberg's inventory analysis inspired, for instance, Lloyd Metzler's
Lundberg was also a pioneer in analysing the role of taxation for ‘cost inflation’, a point formalized by an equation expressing how much nominal wage rates would have to rise to guarantee a one per cent increase in after-tax real wage rates, after considering both the marginal tax rates and the price effects of wage increases (the Lundberg wage-multiplier). When analysing long-term growth problems, Lundberg also discovered the so-called ‘Horndal effect’, expressing how labour productivity can go on rising over long periods of time without new investment, hence providing an indication of disembodied productivity growth (1961). Lundberg also made interesting comparative studies of growth, fluctuations and economic policy in various countries, for instance in Instability and Economic Growth (1968). He also participated frequently in Swedish economic policy discussion, emphasizing the importance of avoiding overvalued exchange rates. His own policy recommendations, in addition, built on combining general, market-orientated stabilization policies with rather selective social policies to achieve economic security and desired income redistributions.

Selected works

Within twelve years, from Poincaré's *Mémoire sur les courbes définies par une équation différentielle* (1881–6) to Lyapunov's thesis *Obsh•aya zada•a ob unstoi•ivosti dvîženiya* (1892), the qualitative theory of differential equations emerged almost from scratch as the core of a new field in mathematics; both Poincaré and Lyapunov were motivated by problems in mechanics, celestial mechanics above all. Even if he did not match Poincaré's prodigious creativity between 1880 and 1883, Lyapunov developed from 1888 to 1892 a theory of dynamical stability which makes his 1892 thesis both a pioneering piece of work and a classic; in particular he developed a general stability criterion which now bears his name: the Lyapunov function.

Consider a system of ordinary differential equations

$$\begin{align*}
\dot{x} &= f(x, t) \\
\end{align*}$$

Where $x$ is a vector in $\mathbb{R}^n$ and depends on $t$ ($t$ is in general interpreted as time), where $\dot{x} = \frac{dx}{dt}$ is the derivative of $x$ with respect to $t$ and where $f$ is a function from $\mathbb{R}^{n+1}$ to $\mathbb{R}^n$. A trajectory of the system is a function $x$ from an interval $T$ in $\mathbb{R}$ to $\mathbb{R}^n$

$$x: T \rightarrow \mathbb{R}^n; t \rightarrow x(t)$$

which is a solution of the system, i.e. such that $\dot{x}(t)$ and $f(x(t), t)$ are identical on $T$; $T$ is often of the form $[t_0, +\infty]$. In what follows we shall limit ourselves to autonomous systems, i.e. systems of the form $\dot{x} = f(x)$, where $f$ is dependent on $t$ only through $x$. However, our whole presentation is easily generalized to non-autonomous systems, as is done in Rouche et al. (1977) and Rouche and Mawhin (1980).

It would appear at first sight that the system $\dot{x} = f(x)$ suffers from another restriction: it is a first-order system, in the sense that its equations include first-order derivatives only.
might be seen a serious restriction indeed; think for example of the system formalizing the dynamics of the simple frictionless pendulum

\[ \dot{x}_1 + \sin x_1 = 0 \]

where \( x_1 \) is the angular distance from the vertical line. However, it is always possible to transform a system including derivatives of order higher than one into a first-order system with a higher number of equations. For example, the former system consisting of one second-order equation is equivalent to the following system of two first-order equations:

\[ \begin{align*}
\dot{x}_1 &= x_2 \\
\dot{x}_2 &= -\sin x_1
\end{align*} \]

To investigate the stability properties of the pendulum, it is thus immediately possible to make use of the general concepts and methods available for first-order systems. In order to introduce these concepts and methods in the spirit of Lyapunov, and then to see how they operate in economic models, we first have to be slightly more precise in defining an autonomous differential system as a system of first-order differential equations

\[
(DS) \quad \dot{x} = f(x)
\]

where \( f \) is a continuous Lipschitzian function from an open subset \( \Omega \) of \( \mathbb{R}^n \) to \( \mathbb{R}^n \), i.e.

\[ f : \Omega \to \mathbb{R}^n; x \to f(x). \]

‘Lipschitzian’ means that there exists a constant \( \alpha \) such that

\[ \forall x_1^1, x_2^1 \in \Omega, \quad \| f(x_1^1) - f(x_2^1) \| \leq \alpha \| x_1^1 - x_2^1 \| ; \]

this assumption is very convenient because it ensures (see Coddington and Levinson, 1955) that through any point in \( \Omega \) there passes one and only one trajectory of (DS); hence trajectories do not cross. However this assumption is not strictly necessary for what follows (see Aubin and Cellina, 1984 and Rouche et al. 1977).

We may now introduce the basic concepts of stability and attractivity for equilibria of dynamic systems. A point \( x^e \) in \( \Omega \) is an equilibrium of (DS) if \( f(x^e) = 0 \); in other words, \( x^e \) is an equilibrium if for any \( t_0 \) in \( \mathbb{R} \) the function

\[ x^e: [t_0, +\infty) \to \mathbb{R}^n; t \to x^e \]
is a trajectory.

*Stability:* an equilibrium $x^e$ is stable if a trajectory which comes sufficiently close to $x^e$ never after recedes too far from $x^e$.

More precisely an equilibrium $x^e$ is stable if, for any neighbourhood $B_\delta$ of $x^e$ included in $\Omega$, there exists a neighbourhood $B_\eta \subset B_\epsilon$ such that any trajectory passing through $B_\eta$ remains in $B_\epsilon$ ever after (see Figure 1).

*Local attractivity:* an equilibrium $x^e$ is a local attractor if a trajectory which comes sufficiently close to $x^e$ later on tends to $x^e$. 

![Figure 1](http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_L000165&goto=B&result_number=1022(第 3/12 页)2009-1-2 16:50:23)
More precisely an equilibrium $x^e$ is a local attractor if there exists a neighbourhood $B_\delta$ of $x^e$ included in $\Omega$ such that any trajectory which passes through $B_\delta$ tends to $x^e$ as $t \to + \infty$; this does not mean that the trajectory always remains in $B_\delta$ (see Figure 2).

Figure 2

An equilibrium may be stable without being a local attractor, as in the case of the frictionless pendulum. It is also true that an equilibrium may be a local attractor, without being stable, but this is much more difficult to illustrate (see section 40 in Hahn, 1967). An equilibrium which is both stable and a local attractor is often called asymptotically stable.
Lyapunov functions: The New Palgrave Dictionary of Economics

Global attractivity: given a subset \( \Omega_s \) of \( \Omega \), an equilibrium \( x^e \) in \( \Omega_s \) is a global attractor with respect to \( \Omega_s \) if any trajectory which passes through \( \Omega_s \) tends to \( x^e \) as \( t \to + \infty \). An equilibrium which is both stable and a global attractor with respect to some \( \Omega_s \) is often called globally asymptotically stable (globally with respect to \( \Omega_s \)).

The convenient way, often the sole way, to deal with stability and attractivity as defined above, is in general to find a suitable Lyapunov function.

Lyapunov function: consider a subset \( \Delta \) of \( \Omega \) and a function of class \( C^1 \) (i.e. continuous and having continuous first-order partial derivatives)

\[
W : \Delta \to \mathbb{R} : x \to W(x).
\]

\( W \) is a Lyapunov function if it satisfies the following requirements:

1. (i) it is bounded below on \( \Delta \), i.e.

\[
\exists \ a \in \mathbb{R} \text{ such that, } \forall x \in \Delta, W(x) \geq a.
\]

(ii) it tends to infinity as \( x \) does, i.e.

\[
\text{if } ||x|| \to + \infty, \text{ then } W(x) \to + \infty.
\]

(iii) its time derivative \( \dot{W}(x) \) is nonpositive on \( \Delta \), i.e.

\[
\forall x \in \Delta, \dot{W}(x) \leq 0
\]

where the time derivative is defined as

\[
\dot{W} : \Delta \to \mathbb{R} : x \to \dot{W}(x) = \sum_{k-1}^{X} \frac{\partial W(x)}{\partial x_k} f_k(x).
\]

The name ‘time derivative’ is warranted as
Lyapunov functions: The New Palgrave Dictionary of Economics

\[ \dot{W}(x(t)) = \sum_{k=1}^{n} \frac{\partial W(x(t))}{\partial x_k} \dot{x}_k(t) = \frac{dW(x(t))}{dt} \]

along any trajectory in \( \Delta \).

It is possible for \( n=2 \) to draw level curves of \( W \) in the subset \( \Delta \) of the plane \((x_1, x_2)\). On Figure 3 two level curves are drawn, with \( k' < k'' \), as well as a trajectory. \( W \) is non-increasing along any trajectory in \( \Delta \); hence, as soon as a trajectory reaches a level curve, say \( k' \), it never again comes back to points on level curves \( k > k' \), for example \( k = k'' \). This suggests deriving properties of stability and attractivity from the existence of a Lyapunov function; we indeed have:

**Figure 3**

**Proposition 1**: if there exists on some neighbourhood \( B \) of the equilibrium \( x^e \) a Lyapunov function \( W \) and if \( x^e \) is an isolated minimum of \( W \) on \( B \), then \( x^e \) is a stable equilibrium. If moreover \( x^e \) is the only point in \( B \) where \( \dot{W} = 0 \), then \( x^e \) is also a local attractor.

These are sufficient conditions for stability and local attractivity. It turns out that the existence of a Lyapunov function is also a necessary condition (for a general exposition and complete proofs which are valid even for nonautonomous systems, see Rouche et al. (1977) and Rouche and Mawhin (1980)).
The first part of Proposition 1, but not the second part, applies to the frictionless pendulum, the Lyapunov function being here the total energy $\frac{1}{2}x^2 - \cos x + 1$. Both parts of Proposition 1 apply to the tâtonnement process in a competitive economy where all goods are gross substitutes for all prices. Let $n$ be the number of goods; let $p$ be the price vector normalized in such a way that it is in the $n-1$ dimensional unit simplex $\Sigma$ defined by $\sum_{j=1}^{n} p_j = 1$; and let $z_j(p)$ be the aggregate excess demand function for good $j$. Let $\Sigma$ be the interior of $\Sigma$. Gross substitutability implies that there exists one and only one general competitive equilibrium price vector $p^e$ and that $p^e$ is in $\Sigma$, i.e. $p^e_j$ is strictly positive for all goods $j$ (for more details see Arrow and Hahn, 1971).

Consider then the well-known tâtonnement process

$$\dot{p} = z(p).$$

It is a (DS) system, with $\Omega = \Sigma$; being the unique general competitive equilibrium price vector, $p^e$ is also the unique equilibrium of the differential system (TP). Consider on $\Sigma$ the function

$$W(p) = \| p - p^e \|^2.$$

Its time derivative is

$$\dot{W}(p) = \sum_{j=1}^{n} \frac{\partial W(p)}{\partial p_j} z_j(p) = 2 \sum_{j=1}^{n} (p_j - p^e_j) z_j(p) = -2 p^e \cdot z(p),$$

because of Walras's law. On the other hand, it is a consequence of gross substitutability that

$$\forall p \neq p^e, p^e \cdot z(p) > 0.$$

It is thus clear that $W$ is a Lyapunov function, that $p^e$ is its unique minimum on $\Sigma$ and that $\dot{W}$ is zero only at $p^e$; hence $p^e$ is stable and is a local attractor for the tâtonnement process. Is it a global attractor with respect to $\Sigma$? The answer is not within the range of proposition 1. Something more is needed.

**Proposition 2**: consider a system (DS) and a bounded subset $\Delta$ of $\Omega$ which is such that there exists a Lyapunov function $W$

$$W: \Delta \to \mathbb{R}; x \to W(x)$$
satisfying the additional requirement that $\dot{W}$ is zero only at equilibria of the system, i.e.

$$\dot{W}(x) = 0 \Rightarrow f(x) = 0.$$  

Then, if all the limit points of a trajectory are in $\Delta$, they are equilibria of the system; if moreover all the equilibria of the system are isolated, this trajectory tends to one of them as $t \to + \infty$.

**Corollary**: if the system has a unique equilibrium, if $\Delta$ is open and if any trajectory which passes through $\Delta$ has all its limit points in $\Delta$, then the equilibrium is a global attractor with respect to $\Delta$ and it is stable.

This corollary has no general counterpart when there are several isolated equilibria, because a trajectory starting in the neighbourhood of one equilibrium may tend to another one. However, if an equilibrium is an isolated minimum of $W$, prpt 1 ensures that it is stable and is a local attractor.

Proposition 2 and its corollary allow us to answer the qst, left unanswered above, about the tâtonnement process: as $\Sigma$ is bounded and as gross substitutability prevents any trajectory from having a limit point on the boundary of $\Sigma$, all conditions in prpt 2 and in the corollary are met; so $p^e$ is a global attractor with respect to $\Sigma$.

Another well-known application of Lyapunov functions is in the theory of public goods. Consider an economy with $N$ consumers ($i=1,\ldots,N$), $m$ public goods ($k=1,\ldots,m$) and one private good used as numeraire. Let $x \in R^m_+$ denote the bundle of public goods made available to the consumers, and let $y^i$ denote the amount of numeraire consumed by $i=1,\ldots,N$; this means that $(x, y^i) \in R^{m+1}_+$ describe the total consumption of $i$. His preferences are formalized by a utility function

$$u^i: R^{m+1}_+ \to \mathbb{R}: (x, y^i) \to u^i(x, y^i);$$

this function is of class $C^1$, quasi-concave, nondecreasing with respect to each of its arguments, and is strictly increasing with respect to the consumption of the numeraire, i.e.

$$\frac{\partial u^i}{\partial y^i} > 0 \text{ on } R^{m+1}_+.$$

Let $Z$ be the set of feasible allocations, i.e. the set of all $z = (x, y^1, \ldots, y^N)$ in $R^{m+N}_+$ which can be made available for consumption, given the technical possibilities and the initial resources of the economy. $Z$ is of course bounded; it is reasonable to consider that it is closed and convex; hence it is a compact convex subset of $R^{m+N}_+$.

How to reach a Pareto-optimal feasible allocation? The MDP (for Malinvaud–Drèze–Poussin, see Champsaur et al., 1977) planning procedure gives the following answer: starting from any feasible allocation, revise $z$ continuously according to the following differential system, which is a (DS) system:

$$(\text{MDP}) \quad \frac{dx_k}{dt} = -\sum_{i=1}^{N} \pi_k^i(z) - \gamma_k(z), \quad k = 1, \ldots, m; \quad \frac{dy^i}{dt} = -\sum_{k=1}^{m} \pi_k^i(z) \frac{dx_k}{dt} + \sum_{k=1}^{m} \frac{dy_k}{dt} \left[ \sum_{j=1}^{N} \pi_k^i(z) - \gamma_k(z) \right], \quad i = 1, \ldots, N.$$
where \( \pi_k^i(z) \) is the marginal willingness to pay of consumer \( i \) for public good \( k \), and \( \gamma_k(z) \) is the marginal cost of public good \( k \). The \( \delta_i, i = 1, \ldots, N \), are non-negative weights summing up to 1: \( \sum_{i=1}^{N} \delta_i = 1 \). These differential equations mean that the quantity made available of each public good is revised according to the difference between the total marginal willingness to pay for that public good and its marginal cost; simultaneously every consumer pays an amount of numéraire equal to his willingness to pay for this set of revisions, and receives a fraction of the total surplus that the revisions generate.

Consider the function

\[
W: Z \rightarrow R: z \mapsto W(z) = - u^i(x, y)
\]

where \( i \) is chosen among those \( i \) for which \( \delta_i > 0 \). Straightforward calculations lead to

\[
\dot{W}(z) = - \delta_i \sum_{k=1}^{m} \frac{\partial u^i}{\partial y^j} \left( \pi_k^i(z) - \gamma_k(z) \right)^2
\]

which is nonpositive everywhere on \( Z \) and is zero if and only if \( z \) is an equilibrium of (MDP). \( W \) is a Lyapunov function and Proposition 2 applies with \( \Delta = Z \). As \( Z \) is compact it is even possible to conclude that any limit point of any trajectory which is included in \( Z \) is an equilibrium of (MDP). If all the utility functions \( u^i, i = 1, \ldots, N \), are strictly quasi-concave, the result is sharpened in the sense that any trajectory which is included in \( Z \) tends to an equilibrium as \( t \rightarrow +\infty \). The economic significance of these results proceeds from the fact that all the equilibria of (MDP) are Pareto optima.

However, it is not guaranteed that all trajectories of (MDP) starting in \( Z \) are included in \( Z \), as the revisions generated by the equations

\[
\frac{d}{dt} x_k = \sum_{i=1}^{N} \delta_i \left( \pi_k^i(z) - \gamma_k(z) \right), \quad k = 1, \ldots, m
\]

may lead to negative values of the public goods. We would then have a meaningless procedure. In order to avoid this possibility the above equations must be replaced in (MDP) by:

\[
\frac{d}{dt} x_k = \begin{cases} 
\sum_{i=1}^{N} \delta_i \left( \pi_k^i(z) - \gamma_k(z) \right) & \text{for } x_k > 0 \\
\max \left[ \sum_{i=1}^{N} \delta_i \left( \pi_k^i(z) - \gamma_k(z) \right), 0 \right] & \text{for } x_k = 0.
\end{cases}
\]

It is then immediate that any trajectory of (MDP) starting in \( Z \) is included in \( Z \). But do trajectories still exist? and if they exist, do they actually tend to equilibria of (MDP)? The
Lyapunov functions: The New Palgrave Dictionary of Economics

Lyapunov functions have been defined with the same purposes as for ordinary systems (see Champsaur et al., 1977; Aubin and Cellina, 1984). Lyapunov functions are used in many other economic models, to prove the convergence of non-tâtonnements processes for example (see Arrow and Hahn, 1971) or to investigate the stability properties of a process of free entry and exit of firms, facing random demand and guided by expected profits (see Drèze and Sheshinski, 1984). Of particular interest is the use of a Lyapunov function of the form \((Q - q^0) \cdot (k - k^0)\), where \(k\) is the vector of capital stocks in the economy and \(Q\) is the vector of current prices for investment goods, to show that any optimal growth path tends to the (suitably modified) golden rule capital stock \(k^*\) when the discount rate is not too large (see Brock and Scheinkman, 1976; Cass and Shell, 1976).

Till now we have dealt only with dynamical stability, i.e. with qsts typically like the following one: two trajectories happen to pass through two neighbouring points; does it imply that they will ever after remain close to each other? Around 1970, G. Debreu and S. Smale introduced structural stability into economic theory, i.e. stability with respect to parameters of the system; a typical question is here: is the configuration of competitive equilibria of an economy (for example the fact that they are isolated) stable when the initial endowments of the agents in the economy change? Almost a century before, Poincaré introduced and systematically explored the concept of bifurcation in mathematics (see Poincaré, 1881); the word came to him as a natural comparison with daily experience:

On voit que les deux catégories d'ellipsoïdes forment deux séries continues de figures d'équilibre. Mais il y a une figure qui est commune aux deux séries et qui est, si l'on veut me permettre cette comparaison, un point de bifurcation. (Poincaré, 1892, p. 810)

Bifurcation is a basic concept for the study of structural stability; even if the latter expression was to come much later, the essence of the approach is in Poincaré's works. In the introduction (Poincaré, 1882), Poincaré refers to 'les recherches ultérieures parmi lesquelles les plus importantes sont, sans contredit, celles de M. Liapounoff'. It seems indeed that no other mathematician of the time saw better than Lyapunov did the significance of Poincaré's new concepts and methods. In the three volumes (Lyapunov, 1906–1912), Lyapunov explored in great detail the bifurcation of the equilibrium configurations of a rotating homogeneous mass of liquid. The ultimate goal was to explain the evolution of stars. As long as the angular velocity \(\Omega\) of the rotating mass is less than or equal to a critical value \(\omega\), there is one and only one equilibrium configuration for each velocity \(\omega\), and it is an ellipsoid. But at \(\omega^c\) a bifurcation appears: at \(\omega^c\) the equilibrium configuration is still unique and is an ellipsoid but, in Lyapunov's own words, 'C'est l'ellipsoïde, par lequel on entre dans la série des figures d'équilibre que M. Poincaré a appelé pyriformes' (Lyapunov, 1906–1912, vol. 3, p. 6). It is indeed shown (Lyapunov, 1906–1912, vol. 1, pp. 216–17 and vol. 3, p. 106) that there exists an interval \([\omega^c, \overline{\omega}]\) such that, for every \(\omega\) in this interval there are two equilibrium configurations: the usual ellipsoid and a pear-shaped configuration, whose symmetry and stability properties were systematically investigated by Lyapunov. This is a study in structural stability, the last one to appear before 1937, at which time Andronov and Pontrjagin (1937) picked up the subject, which has been exploding since then.

It has recently been shown that in (strictly deterministic) economic growth models, bifurcation phenomena can take place which are strikingly similar to those explored by Lyapunov: \(\omega\) is replaced by the discount rate \(r\), the ellipsoids by steady states and the pear-shaped configurations by closed cycles that bifurcate from the steady state for some value \(r_o\) of \(r\) (see Benhabib and Nishimura, 1979). Bifurcations even appear in stationary competitive monetary economies: at critical values of some parameters of the economy – for example the degree of concavity of utility functions – a stationary equilibrium bifurcates towards a line (a 'série', in Poincaré's words) of stationary equilibria on one hand, and a simultaneous line of closed cycles; the latter are the business cycles of the model, and their stability under suitable assumptions has been shown using Poincaré–Lyapunov methods (see Grandmont, 1985).

Economists tend to know Lyapunov for his celebrated functions, it appears that there is even more to interest them in the various approaches to stability that Lyapunov has developed during his lifelong study of dynamical systems.

\[
\frac{dz}{dt} = F(z)
\]

where \(F\) is an upper hemicontinuous correspondence such that the image \(F(z)\), of any point \(z\) in an open subset \(\Omega\) of \(R^n\), is a compact convex subset of \(R^n\). For such systems, answers are not trivial, as there are significant discontinuities in the right-hand sides of the new equations. These answers nevertheless turn out to be positive; this is a by-product of the extension of existence and stability theorems to multivalued dynamical systems.

Alec Macfie was born in Partick on 29 May 1898. He went first to school at Hillhead but later joined his brother at the High School of Glasgow where he had a distinguished career. When he left school, Macfie, too young to enlist, worked in a munitions factory for a few months. But in 1916 he joined the Second Battalion, the Gordon Highlanders, and was commissioned as a lieutenant. He saw action at Passchendaele, and was badly wounded during an action on the Asiego Plateau in the early summer of 1918. After recovering to some extent from his wounds, Macfie entered Glasgow University where he graduated with first class honours in philosophy and English literature in 1922. Thereafter he entered a law office and took his LL.B. But having opted for an academic career, he returned to the university and took a first in economics and politics in 1927. In the years that followed Macfie held temporary teaching posts in Nottingham and St Andrews (where he deputized for the professor of moral philosophy) before returning to Glasgow in 1932 as lecturer in the Department of Political Economy under W.R. Scott. Scott (the ‘chief’) died in 1940 and Macfie was invited to take the Adam Smith Chair in 1945.

Side by side with his teaching, Macfie produced three books in the period up to 1945, all of which reflect his interest in philosophy and psychology as well as in economics: *Theories of the Trade Cycle* (1934), *An Essay on Economy and Value* (1936) and *Economic Efficiency and Social Welfare* (1943). It was not until the mid-1950s, only a few years before retiring, that he embarked on a serious study of Adam Smith with special reference to the *Theory of Moral Sentiments*. Following the acquisition of the manuscripts, discovered by J.M. Lothian in 1958, Macfie became one of the driving forces behind the Glasgow edition of the Works and Correspondence of Adam Smith, and acted as co-editor (with D.D. Raphael) of the *Theory of Moral Sentiments* (1976). He also produced a little book which has exerted an enormous influence in this field, *The Individual in Society: Papers on Adam Smith* (1967).

Few modern scholars have been better equipped for the study of Smith. Macfie was a qualified lawyer, with degrees in philosophy, literature, and economics, while Smith was writing at a time when it was possible to think in terms of a global system of thought which might embrace these separate disciplines.

Article

That machinery is of benefit to the manufacturer who introduces it has never been a point of discussion in the history of economics and the machinery question is solely a dispute over whether society benefits from the introduction of machinery, the most pressing social issue being the displacement of labour by machinery and the consequent threat of widespread unemployment. In general terms, the social benefits of machinery were well appreciated by the middle of the 18th century. However, the greatly increased use of machinery at the end of the 18th century gave a new intensity to the debate at the beginning of the 19th century. The analytical tools used by classical economists to tackle this general equilibrium problem were however quite inadequate and it is doubtful whether a deeper understanding of the issue was achieved by the heroic abstractions of the 19th century.

The earliest explicit discussions of machinery appear to be in the pamphlets of John Cary (1695), *A Discourse on Trade*. It was a time when the competitiveness of English industry was being much discussed and John Cary pointed out that England retained her business advantage because of the ability of English manufacturers to invent.

Tobacco is cut by Engines: Books are printed; Deal Boards are sawn with Mills; Lead is smelted by Wind-Furnaces; all which save the Labour of many Hands, so the Wages of those employed need not be fallen. …

New Projections are every Day set on Foot to render the making our Woollen Manufactures easy, which should be rendered cheaper by the Contrivance of the Manufacturers, not by falling the Price of Labour: Cheapness creates Expence, and gives fresh Employments, whereby the Poor will be still kept at Work. (Cary, 1695, pp. 99–100)
A few years later, in his *Considerations of the East-India Trade* (1701), Henry Martin advocated the import of cheaper cloth from the East Indies by comparing it with the effects of machinery:

> Arts, and Mills, and Engines, which save the labour of Hands, are ways of doing things with less labour, and consequently with labour of less price, tho’ the Wages of Men imploy’d to do them shou’d not be abated. The *East-India* Trade procures things with less and cheaper labour than would be necessary to make the like in *England*; it is therefore very likely to be the cause of the invention of Arts, and Mills, and Engines, to save the labour of Hands in other Manufactures. Such things are successively invented to do a great deal of work with little labour of Hands; they are the effects of Necessity and Emulation; every Man must be still inventing himself, or be still advancing to farther perfection upon the invention of other Men … (Martin, 1701, pp. 589–90)

At this stage the effect of machinery in preserving competitiveness receives primary emphasis. There is as yet no link drawn between high wages and the incentive to create machinery. In the years that followed only the prolific Daniel Defoe paid serious attention to the role of machinery without making any substantive analytical contribution. Indeed, Defoe even wondered whether machinery were not sometimes an evil because it displaced labour. In parliamentary debates in 1738 on the making of buttons by loom instead of by hand, Henry Archer implicitly subscribed to the full employment and sustainability thesis in a speech of considerable eloquence:

> As to the honourable gentleman's other arguments, drawn from the number of hands employed in the needle-work manufacture … it is, in my humble opinion, a very good argument for dismissing this Bill; because, as the manufacture may be carried on by a much fewer number of hands, with equal advantage to our trade in general, those who are employed in the needle-work way, are so many hands taken from other arts and other manufactures, in which they might be employed to much better purpose.

Archer goes on to use an example that was repeated often by classical economists:

> There was a time, Sir, when all the learning of this kingdom, and the rest of Europe, was contained in manuscripts, the writing of which employed great numbers of hands, and took up a vast deal of time in re-copying. But, Sir, how ridiculous would it have been, if on the discovery of the art of printing, the transcribers and copyers of those manuscripts had joined in a petition to the legislature, that it would be pleased to prohibit the art of printing, for the same reason which the honourable gentleman now uses, because great numbers would thereby be deprived of bread! (Archer, 1742)

The next advance was stimulated by Montesquieu's claim in *The Spirit of the Laws* that the introduction of machinery was not necessarily beneficial. This provoked Josiah Tucker to provide one of the best statements on the effects of machinery:
What is the Consequence of this Abridgment of Labour, both regarding the Price of the Goods, and the Number of Persons employed? The Answer is very short and full, viz. That the Price of Goods is thereby prodigiously lowered from what otherwise it must have been; and that a much greater Number of Hands are employed. And the first Step is, that Cheapness, ceteris paribus is an Inducement to buy, -- and that many Buyers cause a great Demand, -- and that a great Demand brings on a great Consumption; -- which great Consumption must necessarily employ a vast Variety of Hands, whether the original Material is considered, or the Number and Repair of Machines, or the Materials out of which those Machines are made, or the Persons necessarily employed in tending upon and conducting them: Not to mention those Branches of the Manufacture, Package, Porterage, Stationary Articles, and Book-keeping, &c. &c. which must inevitably be performed by human Labour. That System of Machines, which so greatly reduces the Price of Labour, as to enable the Generality of a People to become Purchasers of the Goods, will in the End, though not immediately, employ more Hands in the Manufacture, than could possibly have found Employment, had no such machines been invented. And every manufacturing Place, when duly considered, is an Evidence in this Point. (Tucker, 1757, pp. 241–2)

The subject received little further impetus in the half-century that followed. The tangential discussion of machinery by Adam Smith in the Wealth of Nations perhaps contributed to this state of affairs. The only notable treatment is in the lectures of Dugald Stewart at Edinburgh (1858–78), which were very influential as part of an oral tradition, but which were not available in print till the 1860s. Stewart's contribution lay in seeing the machinery question as part of a much larger and more fundamental policy issue – the trade-off between individual losses and social gains. He therefore links together three issues that had hitherto been separately discussed – the creation of large farms, the benefits of enclosures and the use of machinery. In each case Stewart grants that the hardships imposed on individuals were undeniable. He then continues;

In judging of the policy of such innovations … it is absolutely necessary to abstract from the individual hardships that may fall under our notice, and to fix our attention on those general principles which influence the national prosperity. (Stewart, 1856, vol. 8, p. 131)

In deciding upon the benefits of introducing machinery, Stewart observes that the material improvement of mankind and the use of machinery are practically inseparable. The policy recommendation was thus unequivocal.

It is hardly possible to introduce suddenly the smallest innovation into the Political Economy of a State, let it be ever so reasonable, nay, ever so profitable, without incurring some inconveniences. But temporary inconveniences furnish no objection to solid improvements. Those which may arise from the sudden introduction of a machine cannot possibly be of long continuance. The workmen will, in all probability, be soon able to turn their industry into some other channel; and they are certainly entitled to every assistance
the public can give them, when they are thus forced to change their professional habits. (1856, vol. 8, p. 193)

The severe post-Napoleonic depression contributed greatly to a reconsideration of the effects of machinery and John Barton should perhaps be given most credit for the new interest with his pamphlet, *Observations on the Circumstances which Influence the Condition of the Labouring Classes of Society* (1817). Commenting on the distinction, inherited from Adam Smith, between circulating and fixed capital, Barton pointed out that only the former serves to employ labour – the latter is embodied in machinery. Since it appeared empirically undeniable that progress involved a greater proportionate use of fixed capital Barton argued that the funds for employing labour, or circulating capital, must be subject to proportionate decrease and lead to greater unemployment. Barton was very clear about the role of high wages in inducing the adoption of machinery.

It is the proportion which the wages of labour at any particular time bear to the whole produce of that labour, which appears to me to determine the appropriation of capital in one way or the other. For if at any time the rate of wages should decline, while the price of goods remained the same, or if goods should rise, while wages remained the same, the profit of the employer would increase, and he would be induced to hire more hands. If, on the other hand, wages should rise, in proportion to commodities, the labour's share in the produce of his own industry would be increased at the expense of his master, who would of course keep as few hands at possible. – He would aim at performing every thing by machinery, rather than by manual labour. (Barton, 1817, pp. 17–18)

How far David Ricardo was directly influenced by Barton in reversing his initial optimistic position on the benefits of machinery is unclear, but in the third edition of his *Principles of Political Economy and Taxation* (1821, pp. 388–95) Ricardo tried to justify some of the pessimistic attitudes to machinery by means of a numerical example. To begin with, we have a farmer whose yearly activities can be summarized as follows:

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Fixed Capital</strong></td>
<td>7,000</td>
</tr>
<tr>
<td><strong>Wages (Circulating)</strong></td>
<td>13,000</td>
</tr>
<tr>
<td><strong>Profits (10 per cent)</strong></td>
<td>2,000 (used for consumption)</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td>22,000</td>
</tr>
</tbody>
</table>

The circulating capital is said to ‘replace the value of 15,000’, that is, to provide the required profit of 2,000. In year 1, the capitalist sets half his workers to construct machines. As surplus value arises from circulating capital, the profits of 2,000 arises in equal parts from the workers in farming and the workers in machines:

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>

</tr>
<tr>
<td>Profits (Machines)</td>
<td>1,000</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>22,000</strong></td>
</tr>
</tbody>
</table>

If the farmer still spends 2,000 for his own consumption, he is left with 5,500 to spend on wages the next year. In other words, the wage bill falls from 13,000 to 5,500 because of the construction of machines. The gross produce consists of profits, rent and wages, while the net produce consists of profits and rent only. In our case, there is no rent, so the gross produce falls from 15,000 to 7,500 while the net produce stays at 2,000. Ricardo concludes as follows:

In this case, then, although the net produce will not be diminished in value, although its power of purchasing commodities may be greatly increased, the gross produce will have fallen from a value of 15,000\(\text{\pounds}\) to a value of 7,500\(\text{\pounds}\), and as the power of supporting a population, and employing labour, depends always on the gross produce of a nation, and not on its net produce, there will necessarily be a diminution in the demand for labour, population will become redundant, and the situation of the labouring classes will be that of distress and poverty.

Subsequently, Ricardo concedes that more workers can be employed in producing goods that the capitalist may wish to consume with his increased real power of consumption, but this may not be strong enough to compensate for the initial loss of employment.

All I wish to prove, is, that the discovery and use of machinery may be attended with a diminution of gross produce; and whenever that is the case, it will be injurious to the labouring class, as some of their number will be thrown out of employment, and population will become redundant, compared with the funds which are to employ it.

There are a number of curious features about Ricardo's analysis which, though based on a simple numerical example, is claimed to have some relevance. First, it is not at all clear whether Say's Law, which Ricardo adhered to so vehemently on other occasions, also operates when labour is displaced by machinery. Secondly, Ricardo simply presents the initial disruption of new machinery without saying anything about the nature of the new equilibrium or the adjustment process leading to it. This contrasts sharply with his usual emphasis upon permanent effects – indeed, in assuming that the new machines made will be able to realize 1,000 units of profit Ricardo is implicitly assuming some sort of pervasive equilibrium. Thirdly, Ricardo appears to deny the practical importance of his example at the end of the chapter when he emphasizes that his argument holds only when the new machinery is introduced suddenly.
The statements which I have made will not, I hope, lead to the inference that machinery should not be encouraged. To elucidate the principle, I have been supposing, that improved machinery is *suddenly* discovered, and extensively used; but the truth is, that these discoveries are gradual, and rather operate in determining the employment of the capital which is saved and accumulated, than in diverting capital from its actual employment.

This point gains additional force from Ricardo's insistence that the state take no action to discourage technological progress. Most subsequent economists, from Malthus onwards, took exception to the collection of assumptions necessary to produce Ricardo's result. Of the classical economists who followed, only Nassau Senior and John Stuart Mill tried to justify Ricardo's reasoning, sometimes with the same surprising pattern of argument that characterized Ricardo. For example, John Stuart Mill (1848) begins by asserting that workers suffer temporarily when circulating capital is converted to fixed capital; almost immediately however he adds that this is a case which scarcely ever occurs in practice. An attempt by J.E. Tozer to provide a mathematical formulation of the question does not go beyond the framework set of by Ricardo. Tozer (1838) grants that there is an initial deduction from the wages fund but points out that the fund is replenished over time as the additional output from the machinery is produced. There does not appear to be a serious effort at going beyond Ricardo's analytical schema until the writings of Knut Wicksell.

With his usual clarity, Wicksell begins his section on production and distribution by setting forth the technical conditions necessary for the validity of the marginal productivity theory of distribution. He recognizes that the distributive impact of machinery depends upon the manner in which machinery alters the marginal productivities of labour and capital and that simple answers to such a question are unlikely. One issue which he analyses with considerable acumen is the position of Ricardo that machinery may actually diminish the gross product. Wicksell takes issue with Ricardo's conclusion and claims that Ricardo did not follow his premises to their logical conclusion – under free competition, changes in technique cannot lead to a diminution of gross product. This is proved as follows:

Let \( x \) and \( y \) denote the number of labourers per acre using the old and new methods of cultivation, and let \( f(x) \) and \( \phi(y) \) denote the production functions of these lands. If \( m \) acres are cultivated by the old method and \( n \) acres by the new method, then the problem of maximizing total product is

\[
\text{Maximize} \quad mf(x) + n\phi(y)
\]

subject to

\[
\]
where $B$ is the total number of acres and $A$ is the total amount of labour available. The first order conditions for a maximum are,

$$m + n = Bmx + ny = \lambda$$

where the prime denotes differentiation. The first condition states that total product is maximized when the marginal product of labour is equal, under both methods and the second condition states the equality of rents per acre. Wicksell now observes that these are precisely the conditions achieved by pure competition and hence that Ricardo was wrong to claim that a diminution of gross product was possible. Modern readers will note that Wicksell assumes throughout the validity of interior maxima. Subject to this qualification, Wicksell's analysis is a considerable improvement on anything produced before him.

The problem just discussed considered labour and land as the only explicit factors of production. Even here, Wicksell feels that 'It is scarcely possible to discover a simple and intelligible criterion which will indicate whether a change in the technique of production is in itself likely to raise or lower wages'. When Wicksell goes on to add capital as a factor of production, he has to concede that inventions may reduce the marginal product and share of labour. This leads him to say that 'The capitalist saver is ... fundamentally, the friend of labour, though the technical inventor is not infrequently its enemy' (Wicksell, 1911, pp. 140, 143, 164).

A satisfactory treatment of the machinery question depends upon modelling the general equilibrium of an economy and of following its transition from an initial equilibrium to the new equilibrium after the introduction of machinery. Even today, such a treatment is by no means easily achieved. Perhaps the classical economists would have done best to accept the general benefits of machinery, subject to transitional difficulties, as expounded by economists such as Tucker and Stewart, and wait until the proper analytical tools to discuss the issue satisfactorily had been developed.

Machlup, Fritz (1902– 1983)

John S. Chipman

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

economic integration; Haberler, G.; innovation; international monetary system; invention; Machlup, F.; multiplier analysis

Article

Fritz Machlup was born in Wiener Neustadt, south of Vienna, on 15 December 1902, and died in New York on 30 January 1983. He studied economics at the University of Vienna in the 1920s under Friedrich von Wieser and Ludwig von Mises, and wrote his doctoral dissertation on the gold-exchange standard (Machlup, 1925) under the latter. In the years 1922–32 he pursued a business career in the family cardboard-manufacturing partnership while continuing his intellectual interests in economics and philosophy of science in association with von Mises, Hayek, Haberler, Morgenstern, Felix Kaufmann and Alfred Schütz. During this period he wrote two more books including one (Machlup, 1931) dealing with the role of stock-market speculation in capital formation. As business conditions deteriorated in the 1930s he took leave from his partners to accept a Rockefeller fellowship, and spent 1933–35 in the United States. Upon receiving an appointment at the University of Buffalo in 1935 he liquidated his Austrian business interests, and following a brief stay in England began an academic career in the United States. He moved to Johns Hopkins in 1947, and to Princeton in 1960 to succeed Jacob Viner. At Hopkins he had a profound influence as a graduate teacher and in building up a first-rate graduate programme that achieved national prominence; a list of his students is contained in Machlup (1963), and tributes and testimonials from many of them will be found in Dreyer (1978). At Princeton he was extremely active in his direction of the International Finance Section. Upon his retirement in 1971 he resumed his active career at New York University until his death shortly after his 80th birthday. He was president of the Southern Economic Association (1959), the American Association of University Professors (1962–64), the American Economic Association (1966), and the International Economic Association (1971–4).

Machlup's two great areas of research were international monetary economics and industrial organization, the latter with special emphasis on the ‘knowledge industry’, an activity which began with
a study of the patent system (Machlup and Penrose, 1950; Machlup, 1958), continued with the
development of a formal theory of invention, innovation, and the optimal lag of imitation behind
innovation (see Bitros, 1976, pp. 439–502), and culminated in a monograph on the subject (1962), the
multi-volumed second edition of which remained unfinished at the time of his death (Machlup, 1980b;
1982b; 1983). What was especially original in his contributions was his peculiar talent, resulting from
his business background and study of philosophy of science, of being able to formulate a theory that
took into account – in addition to the usual economic facts – the theories or rationalizations put forward
by economic agents to justify their own actions. This was used to support his contention that economic
agents engage in maximizing behaviour even though they may deny this. Such perceptions permeate his
works on industrial organization (Machlup, 1949; 1952a; 1952b) and were developed in numerous
articles collected in Machlup (1963).
Machlup's contributions to international economics were likewise characterized by a combination of
clear logical thinking and intimate knowledge of the workings of economic institutions. His two-country
extension of the theory of the multiplier (1943) was especially illuminating in bringing out the implicit
financial assumptions of Keynesian theory. His work on the theory and policy of foreign-exchange
markets and international economic adjustment (collected in Machlup, 1964) was very influential. His
classic (1939–40) article developing Haberler's concepts of demand and supply of foreign exchange was
required reading for a generation of graduate students. In his famous controversy with Sidney
Alexander, while stressing the importance of relative prices he proved himself to be always the eclectic,
ever espousing one narrow ‘approach’ to the exclusion of all others. At first countering ‘elasticity
pessimism’ and championing flexible exchange rates in his academic writings, he later became the prime
architect of plans to reform the international monetary system in his organization of the ‘Bellagio
group’ (Machlup and Malkiel, 1964). These activities have been recounted by Robert Triffin and John
Williamson in Dreyer (1978). Machlup's last contributions to international economics included a series
of penetrating analyses of the Eurodollar market (starting with Machlup, 1970) and his one foray into
‘real’ international trade, a work on the theory of economic integration (Machlup, 1977).
Machlup had a remarkable and unforgettable personality. He was brilliant and as sharp as a whistle in
his keen analysis and grasp of economic issues; he was lucid and patient as a teacher, yet tough; he was
charming and witty: he was a great music-lover and an avid sportsman to the end of his days. Above all
he was a man of extraordinary energy and passion.
Most of Machlup's important articles have been reprinted in Machlup (1963; 1964) and Bitros (1976);
the first and third of these contain bibliographies of his work. Further information concerning his life
and work will be found in Dreyer (1978), Chipman (1979), Machlup (1980a; 1982a), and Haberler

Article

Macleod warrants special mention in this Dictionary if only because in the late 1850s and early 1860s he undertook to produce single-handedly a dictionary of economics on a grand scale – and, what is more, one to which he was to be the sole contributor. In the event the task proved to be beyond him, as it would for any mortal, and all that appeared was the first volume covering the letters A–C. Macleod never held an academic appointment, though he applied unsuccessfully for chairs at Cambridge (1863), Edinburgh (1871), and Oxford (1888).

Macleod, the son of a Scottish landholder, was born in Edinburgh. After graduation from Cambridge (BA, Trinity, 1843) and admission to the Bar (1849), he wrote a report on the administration of poor relief in the nine local parishes of the district of Easter Ross in Scotland (1851). This report led directly to the establishment of a poor-house under Scotland's first Poor Law Union. In 1854, he joined the Royal British Bank and wrote a memorandum and opinion on that bank's legal position under the Joint Stock Banking Act of 1845. This first excursion into financial matters stimulated him to study the literature of economics on the subject, but he found that

for the purpose of describing the actual principles and mechanisms of commerce they [Smith, Ricardo and Mill] were absolutely worthless. … I saw that the greatest opportunity that had come to any man since Galileo had come to me, and I then determined to devote myself to the construction of a real science of Economics on the model of the already established physical sciences. (1896b, pp. 142–3)

To his credit he stuck fast to his task. His detractors, however, have passed harsh judgement on its results (see, for example, the assessment of him in Higgs's edition of Palgrave's Dictionary); his sympathetic readers have been more generous (see, for example, Hayek, 1933). Given the sheer
magnitude of his project, there would seem to be more to be said for the position of the critics. Macleod’s employment in the banking system led to what is perhaps his most important book on that subject: *The Theory and Practice of Banking* (1855–6). Its two most interesting features for the modern reader are, perhaps, the discussion of discount policy and the insistence on the proposition that ‘the distinction between capital and currency … is of the most profound delusions that ever existed’ (1855, vol. 2, p. lxxii; see also the entry on ‘Credit’ in his Dictionary). Not surprisingly, for one who kept fast to the basic position of the Bullion Report, this latter notion introduced a number of ambiguities into the argument. However, notwithstanding these peculiarities, the book was apparently quite successful, going through five editions by the 1890s and being reprinted soon after his death. Charles Rist referred to it as Macleod’s ‘great book’ (1940, p. 261).

There followed many publications on monetary matters of which two may be singled out. In *Bimetallism* (1894), he criticized the proponents of a dual standard for advocating ‘an impossibility’; a position which put him at odds with many of his contemporaries. This polemic was continued in two short tracts issued by the Gold Standard Defence Association in 1895 under the titles ‘Gresham’s Law’ and ‘Bimetallism in France’. Secondly, in 1898, he published two contributions to the debate surrounding the Fowler Commission on Indian currency arrangements: *Indian Currency* and *A Tentative Scheme for Restoring a Gold Currency to India*.

Macleod’s project of reconstructing economic science continued on more general matters with *Elements of Political Economy* (1858). The book is interesting as an example of Macleod's advocacy of a definition of economics as the ‘science of exchanges’, or catallactics, which Marshall claimed ‘anticipated much both of the form and substance of recent criticisms on the classical doctrine of value in relation to cost, by Profs. Walras and Carl Menger’ (1920, p. 821), and for the fact that in it he introduces into the vocabulary of economics the phrase ‘Gresham's Law’.

One of Macleod’s interesting habits was that of publishing the same material in different forms and under different titles. In this he reminds one of McCulloch. Thus, *Bimetallism* was itself an expanded version of the seventh chapter of his *Theory of Credit* (1889–91), his *Elements of Political Economy* (1858) appeared in successive editions under the titles *The Principles of Economic Philosophy* (1872–5) and *The Elements of Economics* (1881–6), and his *History of Economics* (1896b) seems to be made up of material from his unfinished dictionary.

Macleod died at Norwood on 16 July 1902.

The field of open economy macroeconomics deals with the macroeconomic behaviour of economies that trade with each other. International trade can have macroeconomic effects by helping the transmission of disturbances from one economy to another as well as by affecting the impact of macroeconomic policies on economic activity. This article discusses several representative open economy macro models, highlighting the role different theoretical features play in influencing the channels through which trade flows can have macro effects.
Keynesian framework

At its simplest level, international trade is linked to macroeconomic activity through the national income relation. Consider the Keynesian income–expenditure model of a small open economy, in which prices and the interest rate are given, foreign demand for exports is exogenous, and domestic output is determined by demand. With these assumptions, an exogenous increase in domestic expenditures raises domestic income and worsens the current account balance; however, income rises less than in a closed economy because of leakages from the income stream through imports and through saving. In contrast, an exogenous increase in foreign demand for domestic goods leads to an increase in both exports and domestic income. Because the increased direct demand for exports is only partially offset by the expansion of imports induced by higher income, the current account improves overall. The resulting rise in domestic output implies positive cross-country transmission of the foreign disturbance. Income multiplier effects through changes in trade also characterize open economy extensions of the Keynesian framework, such as the classic Mundell–Fleming model. This model also takes prices as given, but allows the income effects of monetary stimulus and exogenous expenditure changes to take account of interest rate changes depending on the degree of international capital mobility and of exchange rate changes, which in turn depend on the exchange rate regime. With a flexible exchange rate regime, exchange rate changes affect the relative demand for domestic and foreign goods. Thus, for example, domestic monetary stimulus that reduces the interest rate, raises income, and creates an excess demand for foreign exchange also depreciates the domestic currency. If the Marshall–Lerner–Robinson condition is satisfied, that is, the sum of price elasticities of domestic and foreign demands for imports exceeds unity, then the lower relative price of domestic goods switches demand from foreign to domestic goods and raises the current account balance, causing domestic income to increase and foreign income to decrease. Accordingly, the domestic income multiplier effect of the monetary stimulus is augmented by the expenditure-switching effect of the exchange rate; in addition, the trade transmission effect of domestic monetary shocks to foreign income is negative.

In these models crucial parameters affecting transmission effects include the marginal propensity to import and the elasticity of trade with respect to the exchange rate. Thus, for example, an increase in the marginal propensity to import out of income lessens the multiplier effects of domestic policy stimulus.

New open economy macro models

New open-economy macroeconomic models (NOEM) integrate older fixed-price Keynesian models of macroeconomic fluctuations with dynamic intertemporal analysis based on microeconomic foundations and optimizing agents. These models embed imperfect competition and short-run nominal rigidities in a general equilibrium framework and provide clear welfare criteria in the form of the utility of the representative consumer. They also assume that bond (but not equity) markets are integrated, providing a consumption-smoothing role for net trade flows via the current account. Thus, for example, a temporary productivity shock that raises domestic output induces higher saving and a temporary current account surplus (though with investment dynamics a current account deficit may result if the increase in investment exceeds the increase in saving).
In a seminal paper, Obstfeld and Rogoff (1995) use a two-country framework in which each country specializes in producing a subset of tradable goods, and domestic and foreign consumers have identical preferences over a basket of both domestic and foreign goods. They show that monetary shocks have a positive effect on domestic output and a negative transmission effect on foreign output, as in the Mundell–Fleming model. Because monetary stimulus depreciates the domestic currency, it lowers the domestic country’s terms of trade, reduces the purchasing power of domestic residents and raises the purchasing power of foreign residents. This terms-of-trade effect makes foreign residents better off and domestic residents worse off, but not by enough to offset the domestic gains from greater output. A temporary current account surplus is generated as well via the intertemporal consumption-smoothing channel.

A key parameter in NOEM models is the elasticity of substitution between goods embedded in consumer preferences. Obstfeld and Rogoff assume that the elasticity of substitution between goods produced in the same country is the same as the elasticity of substitution between goods produced in different countries. Several papers show how the international transmission of shocks is affected by relaxing this assumption. Tille (2001) shows that, if the elasticity of substitution of domestic and foreign goods exceeds unity, the Marshall–Lerner–Robinson condition holds. In this case, a currency depreciation and decline in the terms of trade results in a large demand switch towards domestic goods and a rise in export revenue. Tille also shows that, if there is less substitutability between domestic and foreign goods across countries than within countries (the empirically more relevant case), the terms-of-trade effect of domestic monetary expansion may be large enough to lower domestic welfare (termed a ‘beggar-thyself’ effect), while raising foreign welfare. In contrast, greater fiscal expenditures on domestic output raise the domestic terms of trade and domestic welfare, while reducing relative demand for foreign goods and foreign welfare (a ‘beggar-thy-neighbour’ effect), particularly when domestic and foreign goods are poor substitutes.

Corsetti and Pesenti (2001) deal with the special case in which the elasticity of substitution between domestic and foreign goods is unity, implying constant expenditure shares on domestic and foreign goods. This specification implies that the current account is always in balance. The reason is that, with unit elasticity between domestic and foreign goods, an increase in the foreign price of foreign goods results in a proportionate decrease in the quantity of foreign demand for domestic goods, leaving expenditures on exports constant and the current account unaffected.

Other extensions to NOEM models that affect the transmission of policy include consumption bias for domestic over foreign goods (Warnock, 2003), pricing-to-market behaviour (Betts and Devereux, 1998), and non-traded distribution services (Burstein, Eichenbaum and Rebele, 2006).

**International real business cycle models**

The tendency of macro aggregates, such as output, to move together in different countries is well documented (Backus, Kehoe and Kydland, 1992; Baxter, 1995). Cross-country business cycle correlations depend on the interaction of common international shocks, country-specific shocks, and the transmission of these shocks between countries. An important question in international macroeconomics is how much these comovements reflect the transmission of shocks across borders through international trade linkages. International real business cycle (IRBC) models analyse this issue within a dynamic
On theoretical grounds, the effect of international trade links on the comovement of national business cycles is ambiguous. On the one hand, greater integration can increase intra-industry specialization and production-sharing because of low elasticity of substitution between intermediate inputs produced in different countries; in addition, it may allow demand shocks to propagate more easily across national borders, which may lead to a higher correlation of business cycles when countries trade more. On the other hand, greater trade integration can increase inter-industry specialization if countries specialize more in the goods in which they have a comparative advantage in order to achieve gains from trade; this case, if industry-specific shocks are a dominant source of business cycle movements, may lead to a lower correlation of business cycles when countries trade more.

On balance, the empirical evidence suggests that the former effect dominates, and that countries with a lot of bilateral trade tend to have more synchronized business cycles (for example, Frankel and Rose, 1998; Baxter and Kouparitsas, 2005). However, since the early 1980s business cycle synchronization has not in fact increased among industrial countries despite increasing trade integration. Stock and Watson (2005) provide a partial explanation by showing that common international shocks experienced by G-7 countries have been smaller in the 1980s and 1990s than they were in the 1960s and 1970s. But they also show that cyclical comovements have increased for subgroups of countries, notably within Europe and North America. Burstein, Kurz and Tesar (2005) construct a model that is consistent with this development in which trade between core countries and their periphery (for example, the United States and Canada) involves more production sharing than does trade between core regions (for example, the United States and Europe). Consequently, one should observe higher output correlations between core and peripheral countries than between core regions. IRBC models have been less successful in explaining the quantitative magnitude of the relation between trade intensity and the cross-country correlation of business cycles; that is, a given change in bilateral trade intensity generates a much smaller change in output correlations than is apparent in the data; this is referred to as the ‘trade comovement gap puzzle’ (Kose and Yi, 2006).

The finding that greater trade intensity is associated with greater cross-country comovements in business cycles suggests that these comovements depend on policies that enhance international trade, such as lowering of trade barriers or reductions in exchange rate costs due to membership in currency unions. Frankel and Rose (2002) find that the positive effect of currency unions on trade in turn has a large effect on output in member countries. Since the main cost of joining a currency area is the cost of giving up monetary independence, this has the implication that a pair of countries with business cycles that are dissimilar ex ante (making the act of joining a currency union appear costly) might have more correlated business cycles ex post because the increase in trade stimulated by the currency union tends to synchronize business cycles.

Trade frictions and macro models

The international tradability of goods depends not just on the degree of substitutability in consumption, but also on transport costs and other trade frictions. In fact, Obstfeld and Rogoff (2000) argue that
introducing real trade costs helps explain a variety of puzzles in international economics, including the low cross-country correlation of consumption (consumption correlations puzzle), the limited magnitude of current account imbalances (Feldstein–Horioka puzzle), international price discrepancies (purchasing power parity puzzle), and home bias in trade and asset holdings. Taken to the extreme, trade frictions play a role in explaining why some goods may not be traded at all. While open economy macroeconomics by definition analyses trade across national borders, the field has long found it useful to assume that a given exogenous set of goods is non-traded. This traded/non-traded distinction is essential to many well-known results in the field, such as the Balassa–Samuelson effect, which says that, as the productivity of traded goods rises relative to that of non-traded goods, there will be tendency for the real exchange rate to appreciate.

The international trade literature has explained non-tradedness as an outcome of trade frictions. For example, Dornbusch, Fischer and Samuelson (1977) show how a range of non-traded goods can arise in the presence of cross-country trade costs within a model in which differences in labour productivity across a continuum of goods determine the range of goods a country produces as well as the pattern of trade. A growing field of international economics research tries to integrate models of trade and macroeconomics and treats the set of tradable goods not as exogenously given but rather as an endogenously determined characteristic of the analysis. Several authors (Ghironi and Melitz, 2005; Bergin, Glick, and Taylor, 2006) formulate open economy macro models with monopolistic competition and heterogeneously productive firms, in which firms face fixed costs of selling in domestic and export markets, to explain phenomena such as the Balassa–Samuelson effect. Since only relatively more productive firms are profitable enough to engage in trade, they endogenously satisfy the precondition of the Balassa–Samuelson story that productivity gains are concentrated in the traded goods sector.

Loose ends

International trade can influence macroeconomic activity through other channels. For example, as highlighted in endogenous growth models, technological progress may depend on incentives to undertake R&D and innovate, which, in turn, may depend on externalities or spillover effects from greater markets provided by international trade (Grossman and Helpman, 1991). Greater openness to trade can also complicate the optimal conduct of monetary policy because of the impact of the exchange rate on real activity and inflation. Clarida, Gali and Gertler (2001) show how more openness to international trade can influence a central bank following an optimal policy feedback rule to raise the domestic interest rate more aggressively in response to inflation pressures. Lastly, trade may serve as a transmission channel through which financial crises may spread contagiously across countries (Glick and Rose, 1999).

Macroeconomic forecasts are ‘guesses’ of the future values of important macroeconomic aggregates such as GDP, inflation, or the unemployment rate. These forecasts inform the decisions of business, policymakers, investors, and consumers. Macroeconomic forecasts are regularly constructed by government agencies and private companies. For example, every quarter the Bank of England publishes its *Inflation Report*, which contains forecasts of inflation over the next three years. Federal Reserve policymakers also rely on forecasts from the Green Book; however, unlike the Bank of England, the Fed does not release its forecasts to the public. The Federal Reserve Bank of Philadelphia summarizes private sector macroeconomic forecasts for the United States in its quarterly *Survey of Professional Forecasters*.

Macroeconomic forecasts are constructed using a variety of methods. These methods can be grouped into four categories: (1) leading indicator indexes; (2) structural econometric models; (3) time series models; and (4) judgement.

The origin of leading indicator indexes can be traced to the 1930s when, at the request of the US Secretary of the Treasury, Wesley Mitchell proposed a set of variables that historically had moved in anticipation of the business cycle. Averages of these leading indicators are an index of leading indicators. Such an index was constructed in the United States for several years by the Department of Commerce and is now maintained and published monthly by the Conference Board, which also publishes leading indicator indexes for several other countries.

Structural econometric models construct forecasts using dynamic relationships suggested by economic theory and estimated by statistical methods. Work on these models by Tinbergen, Klein and Haavelmo
resulted in Nobel prizes for these researchers in 1969, 1980 and 1989 respectively. Large-scale structural models with hundreds of equations were developed in the 1960s and early 1970s, but forecast failures in the 1970s led researchers to question both the economic theory used in the models and the statistical procedures used to fit the models’ equations. Refinements in theory (notably the importance of expectations and dynamic adjustment) and statistical methods (notably time series methods) are incorporated in the current generation of large-scale structural models. Currently, there is a significant research effort aimed at constructing small-scale structural models (‘dynamic stochastic general equilibrium’ models) for policy evaluation and forecasting.

Time series models use serial correlation (or persistence) in variables to construct forecasts. For example, a simple autoregressive model (AR) has the form $\gamma_t = \alpha + \phi \gamma_{t-1} + \epsilon_t$, where $\gamma_t$ is an economic variable of interest and $\epsilon_t$ is a zero-mean serially uncorrelated random shock. When $\phi$ is positive (negative), larger than average values of $\gamma_{t-1}$ tend to be associated with larger (smaller) than average values of $\gamma_t$. Thus, an autoregressive forecast of $\gamma_{T+1}$ using data through time $T$ is $\hat{\gamma}_{T+1} = \hat{\alpha} + \hat{\phi} \gamma_T$. Many macroeconomic variables display short-run dependence, and time series models typically produce more accurate short-run forecasts than other forecasting methods. Time series models have been developed to construct forecasts based on linear and nonlinear dependence properties in macroeconomic variables, and multivariate time series models, such as vector autoregressions (VARs), are widely used for short-horizon macroeconomic forecasting.

Professional forecasters also rely on judgement when constructing their forecasts. That is, while the macroeconomic forecasts published by the Bank of England or the Fed’s Green Book forecasts rely on econometric models, the forecasts are not identical to model-based forecasts. Professional forecasters typically use judgement to adjust model-based forecasts. These adjustments – sometimes called ‘add-factors’ – allow forecasters (so they argue) to incorporate information that is not captured in the economic model. As an empirical matter, good judgement appears to improve the accuracy of model-based forecasts.

Much of the theory of forecasting can be derived from elementary concepts in probability theory. Let $\gamma_{T+1}$ denote the variable to be forecast and $X_T$ denote a set of variables to be used for constructing the forecast. In general, $X_T$ will include $\gamma_T$, $\gamma_{T-1}$, and longer lags, as well as current and lagged values of other series. Let $g(X_T)$ denote the forecast or ‘guess’ of $\gamma_{T+1}$ constructed from $X_T$, where good choices of $g(\cdot)$ lead to more accurate forecasts. The forecast error is $\epsilon_{T+1} = \gamma_{T+1} - g(X_T)$, and accuracy can be measured by mean squared forecast error (MSFE), where the conditional $\text{MSFE} = E(\epsilon_{T+1}^2|X_T)$. A fundamental result from probability theory is that $E(\epsilon_{T+1}^2|X_T)$ is minimized using $g(X_T) = E(\gamma_{T+1}|X_T)$; that is, the regression (conditional expectation) produces the minimum mean squared forecast error.

A key implication of this theoretical result is that more information is always better – that is, it never hurts to include more variables in $X_T$, and the information in these additional variables will often reduce the MSFE. But, this result assumes that the regression function $E(\gamma_{T+1}|X_T)$ is known, and in practice this function must be estimated using sample data. Including many variables in $X_T$ means that many parameters must be estimated to characterize the regression function, and estimating a large number of
parameters leads to statistical estimation error that increases the MSFE. This trade-off between including more variables in $X_T$ to capture more information about $y_{T+1}$ and the increased statistical error associated with estimating additional parameters for the forecasting model is one of the major practical problems in forecasting.

Another major problem is the temporal stability of the forecasting model. That is, the regression $E(y_{T+1} | X_T)$ might change over time, so that a regression estimated using past data might provide poor forecasts for future values of $y_T$. These two problems – developing methods for forecasting using many past variables and problems associated with instability – are active areas of current research. The relevant chapters in Elliott, Granger and Timmerman (2006) summarize current research on these and other important topics in economic forecasting.

Abstract

Macroeconomics, the analysis of economic aggregates, became a recognized field with Keynes's *General Theory* (1936) and its mathematical and diagrammatic reformulations, and the macroeconometric modelling pioneered by Tinbergen and Frisch. Macroeconomics grew out of two long-standing traditions: business cycle analysis from Jevons and Juglar to Mitchell, and monetary theory, building on the work of Hume, Thornton, Ricardo, Wicksell, and Fisher, supplemented by the circular flow analysis of Quesnay and Marx.

Macroeconomics analyses a whole economy or economies, dealing with aggregate output and employment, the price level and interest rate, rather than with the prices or quantities of particular commodities. It became a recognized field as textbooks and course offerings responded to John Maynard Keynes's *General Theory of Employment, Interest and Money* (1936; 1971–89, vol. 7), to the mathematical and diagrammatic reformulations of Keynes by David Champernowne, Brian Reddaway, Roy Harrod, J. R. Hicks, James Meade, Oskar Lange, Mabel Timlin and Franco Modigliani (Hicks, 1937; Young, 1987), and to the first aggregate econometric models such as Tinbergen (1939). Ragnar Frisch (1933) introduced the terms ‘macrodynamics’ and ‘macroanalysis’, and his distinction between macroanalysis and microanalysis is the same as the subsequent distinction between macroeconomics and microeconomics. Michal Kalecki (1935) first used ‘macrodynamic’ in a title, and by the time that Lawrence Klein (1946) used ‘macroeconomics’ in the title of a journal article, he presumed that its meaning would be clear to his readers. But just as Molière's *bourgeois gentilhomme* spoke prose long before he knew he was doing so, economists wrote macroeconomics long before they called it by that name. Macroeconomics grew out of two long-standing traditions within economics: business cycle theory and the theory of money.

**Macroeconomic themes in pre-classical and classical political economy**

The quantity theory of money is the oldest surviving theory in economics, yet remained, in David Laidler's (1991a) phrase, ‘always and everywhere controversial’ (primarily over whether changes in the quantity of money are exogenous or endogenous). Holding that a change in the money supply will ultimately change prices in the same proportion, the quantity theory was first used in the 16th century by Martin Navarro de Azpilcueta (writing in Latin as Navarrus) and other scholastics at the University of Salamanca (Grice-Hutchinson, 1952), and then by Jean Bodin in France, to explain the ‘Price Revolution’, the inflation following the inflow of silver from the Spanish colonies in the New World.
John Locke, Richard Cantillon and Isaac Gervaise contributed to understanding the velocity of circulation and the adjustment of international payments (Vickers, 1959). The economic essays in David Hume's *Political Discourses* (see Hume, 1752) mark a high-point of pre-classical monetary economics (see Humphrey, 1993). Hume's analysis of the specie-flow mechanism of adjustment under the gold standard showed that an increase in the quantity of gold in one country would increase prices and spending in that country, causing a trade deficit and gold inflow until balance of payments of equilibrium was restored with the world's gold distributed among countries in proportion to their demand for real money balances. Hume's specie-flow mechanism provided a crushing rejoinder to mercantilist schemes for increasing the amount of gold in a country by promoting exports and restricting imports. Such tariffs, quotas and subsidies would distort resource allocation without producing a lasting trade surplus, and would raise prices rather than the real wealth of a nation. Hume recognized that an increased money supply would provide a temporary stimulus to real output, which would fade as prices and wages adjusted. While Hume linked each country's price level to that country's money stock and emphasized relative price effects on trade balances, his younger contemporary and friend Adam Smith anticipated the monetary approach to the balance of payments by assuming purchasing power parity (with the world price level set by the world gold stock and world demand for real money balances) with adjustment taking place, not through relative price changes, but through the direct effect of a nation's excess demand for or supply of money on spending, hence on the balance of payments and on the country's stock of gold.

Keynes's *General Theory* revived interest in the debate in the years after the Napoleonic Wars about the possibility of a general glut of commodities. Keynes deplored the victory of David Ricardo's sharper analysis and endorsement of Say's (or James Mill's) Law of Markets over what Keynes regarded as Thomas Robert Malthus's deeper (but fuzzier) insight that insufficient effective demand could result in an excess supply of labour without an excess demand for any good (other than money). Malthus's insight was obscured by his failure to distinguish between a decision to save and a decision to invest, and hence to see the significance of hoarding. Statements of the Law of Markets by classical economists were more varied and complex, often subtler, and sometimes confused and contradictory than Keynes suggested in short quotations from the classics, which sometimes misled when taken out of context (see Link, 1959, and Corry, 1962, on the macroeconomics of English classical economists and their critics, and Sowell, 1972, on Say's Law). John Stuart Mill and others searched for a statement of the Law of Markets that would be stronger truism that Oskar Lange later labelled as Say's Equality (if each and every commodity market is in equilibrium, then the sum of excess demand over all commodity markets much add to zero) but weaker than what Lange called Say's Identity, that excess demand for all commodity markets (that is, all markets except money) always sums to zero for any set of prices, regardless of whether any individual market is in equilibrium. Say's Identity, taken together with the adding up of budget constraints that Lange termed Walras's Law, implies that the money market always clears for any prices, leaving the absolute level of prices indeterminate. The policy implications that classical economists drew from their analysis are also more varied and pragmatic than the later textbook caricature: Jean-Baptiste Say recommended public works as a temporary response to unemployment during periods of adjustment, and criticized Ricardo for ignoring the possibility that savings might be hoarded if investment opportunities were inadequate. Ricardo, whose economic writings had begun with a pamphlet arguing that the premium on bullion demonstrated the wartime overissue and depreciation of
inconvertible banknotes, was willing after the end of the war to support restoration of gold convertibility at the depreciated parity, rather than deflation to restore the pre-war parity. Henry Thornton (1802) introduced the concept of the central bank as the lender of last resort to support solvent but illiquid banks against bank runs. The proper role, if any, of the Bank of England generated prolonged controversy among the Banking, Currency, and Free Banking Schools in the first three quarters of the 19th century, producing analyses of lasting significance for monetary economics (V. Smith, 1936; Fetter, 1965).

François Quesnay's *Tableau Economique*, the crowning achievement of Physiocratic economics in France at the time of Hume and Smith, represented the circular flow of income and spending. It was not taken up by the mainstream of British and French classical political economy, but, a century after Quesnay, the *Tableau Economique* inspired Karl Marx's schemes of simple and expanded reproduction in the second volume of *Capital* (published posthumously in 1885), relating output and reinvestment rates in Department I (capital goods) and Department II (wage goods). For decades, this pioneering two-sector growth model was used only by Marxist economists such as Rosa Luxemburg and Otto Bauer constructing models of the supposed inevitable breakdown of capitalism, and then in 1928 by G. A. Fel'd'man, proposing a growth theory for a planned economy. Fel'd'man's articles were part of a false dawn of modern growth theory, appearing in the same year as the December 1928 issue of the *Economic Journal* that contained Allyn Young on increasing returns and economic progress (inspired by Adam Smith) and Frank Ramsey's application of calculus of variations to optimal capital accumulation by a representative agent, but by 1930 Young and Ramsey were dead and Fel'd'man had vanished in Stalin's purges (see Fel'd'man, Ramsey and Young in Dimand, 2002, vol. 3, and Bauer in vol. 5). Neoclassical hostility to Marx's theory of value and exploitation led to neglect of his contribution to growth theory, just as classical rejection of the Physiocratic doctrine of the exclusive net productivity of agriculture diverted attention from the circular flow. Marx also analysed the cyclical fluctuation of the profit rate around a downward trend, with cyclical troughs in the profit rate causing layoffs that force down wages by swelling the reserve army of the unemployed and cyclical peaks in the profit rate leading to realization crises as redistribution away from wages reduces demand for output (since Marx rejected Say's Law). However, his analysis of the increasing severity of crisis (as of the downward trend of the profit rate) was conducted within the special terminology and assumptions of his labour theory of value, which limited its influence on the mainstream of economics.

**Business cycles**

Recognition of the more or less periodic recurrence of crises and prosperity goes back at least to Thomas Tooke's discussion in 1823 of 'waves' in prices (Arnon, 1991), the beginning of the vast literature on cyclical fluctuations most conveniently sampled in the multi-volume anthologies of O'Brien (1997), Hagemann (2001), and Boianovsky (2005) and in the encyclopedia of Glasner (1997). Clément Juglar (1862) and W. Stanley Jevons (1884, collecting essays written from 1862 to 1882) advanced the analysis of economic fluctuations as periodic oscillations to a higher level, surpassing earlier descriptive and classificatory works (such as Max Wirth's *Geschichte der Handelskrisen* in 1858) and displacing the perception of crises as the result of occasional events. Jevons built upon Hyde Clarke's 1847 suggestion of a meteorological cause for the recurrence of crises every ten years or so (Hyde Clarke also perceived
multiple, overlapping cycles, including a longer period of 54 years, anticipating Kondratiev). Jevons's sunspot theory of the trade cycle has so fallen out of favour that the term ‘sunspots’ is now used in the field of business cycles to refer to any intrinsically irrelevant variables (and even the term ‘business cycles’ is no longer taken to imply that fluctuations are in fact periodic cycles). This is unfair to Jevons, who was following the accepted meteorology of his era, which held that the cycle in solar activity affected weather. Cycles in weather would affect harvests, which, in a still largely agricultural world economy, would affect all economic sectors. Jevons's sunspot theory, together with his warnings about the impending exhaustion of coal, did much more than his marginal utility analysis of relative prices to persuaded the British Association for the Advancement of Science that economics was sufficiently scientific for Section F to remain in the Association. Nonetheless, as Wesley Mitchell (1927, p. 384) remarked,

Jevons had an admirably candid mind; yet in 1875, when the sun-spot cycle was supposed to last 11.1 years, he was able to get from Thorold Rogers’ *History of Agriculture and Prices in England* a period of 11 years in price fluctuations, and when the sun-spot cycle was revised to 10.45 years he was able to make the average interval between English crises 10.466 years.

Jevons was misled by the belief that an economic cycle must have a cause that is itself cyclical, but, as Knut Wicksell put it, the motion of a rocking horse does not resemble the motion of the stick that started it rocking (cited by Frisch, 1933). Jevons's sunspot theory has distracted attention from such lasting contributions as the seasonal cycle (in his essay on the annual autumnal pressure on the Bank of England) and his use of index numbers to trace the effects of the Australian and California gold discoveries.

Wesley Mitchell (1913; 1927) was the leading figure in the statistical approach to business cycle analysis. In 1920, Mitchell founded the National Bureau of Economic Research (NBER), which was the model for institutes of business cycle or conjuncture research in Berlin, Vienna (directed first by Friedrich Hayek and then by Oskar Morgenstern), Belgium, Sofia, Moscow (directed by Nikolai D. Kondratiev, the theorist of long waves), and Warsaw (where Kalecki worked), Britain's National Institute of Economic and Social Research, and the Institute of World Economics in Kiel. Although his Columbia lectures on types of economic theory were famous, Mitchell was sceptical about taking any single explicit economic theory, such as the quantity theory of money or utility maximization, as a starting point, as he felt that many of the theories surveyed in Mitchell (1927) captured something of the truth, but none the whole truth. Mitchell was influenced by his teacher at the University of Chicago, the institutionalist Thorstein Veblen (1904), who coined the term ‘neoclassical’ to describe the sort of Marshallian economics of which he disapproved. Mitchell and Arthur F. Burns (his successor directing the NBER) concentrated on investigating the statistical properties of time series, looking for patterns of leads and lags and for superimposed cycles of different periods and amplitudes. The widely reported index of leading indicators continues the original NBER approach.

Sir William Beveridge, director of the London School of Economics, used the periodogram, an early version of spectral analysis, to decompose wheat prices into 19 cycles with periods varying from 2.735 years to 68 years (Beveridge, 1921; 1922). Finding so many cycles led sceptics, such as Harvard
statistician E.B. Wilson, to wonder whether there were any truly periodic oscillations in economic time series (apart from seasonality), since with enough cycles any series could be represented as a summation of cycles. Eugen Slutsky (1937, originally published in Russian in 1927), used a moving average of the last three digits of the winning Moscow lottery numbers to show that summation of random series could produce apparent cycles. Slutsky (1937) and Frisch (1933) influenced economists to consider fluctuations as oscillatory responses to random shocks (real or monetary), turning away from the emphasis of Jevons, Juglar, Mitchell, Beveridge and Kondratiev on underlying cycles. Cowles Commission director Tjalling Koopmans (1947) denounced Burns and Mitchell's *Measuring Business Cycles* (1946) as 'Measurement without Theory', and argued instead for simultaneous equation macroeconometric models, with the equations identified by exclusionary restrictions derived from a priori economic theory. Koopmans's Chicago colleague Milton Friedman (whose Columbia dissertation had been supervised by Burns) responded by writing down a formal model representing Mitchell's business cycle analysis (Friedman, 1952, Section III and Appendix, pp. 257–82). The vector autoregressions (VAR) of Christopher Sims (1980) marks a return (with more modern statistical techniques) to the NBER approach of investigating the statistical properties of macroeconomic time series with only limited reliance on a priori restrictions drawn from theory.

1886 and all that: the dawn of modern monetary macroeconomics, 1886–1914

Around 1886, during a period of depression, analysis of cycles and crises acquired a new emphasis on fluctuation of employment as the problem and variations in the general price level as a preventable cause. Carroll Wright (1886) devoted his first annual report as US Commissioner of Labor to a statistical study, *Industrial Depressions*, finding such depressions to be largely contemporaneous across manufacturing nations and advocating profit-sharing to mitigate the severity of fluctuations (a proposal independently rediscovered nearly a century later by Martin Weitzman). In the same year, Britain had a Royal Commission on the Depression of Trade and Industry, chaired by Lord Iddesleigh (Stafford Northcote) and including Professor Bonamy Price of Oxford but most notable for the evidence of Professor Alfred Marshall of Cambridge. In his evidence to that inquiry and to the Gold and Silver Commission of 1887–8 (both reprinted in Marshall, 1926, edited by Keynes), and in a paper to the Industrial Remuneration Conference of 1885, Marshall considered how far remediable causes adversely affect continuity of employment. This led him to suggest ‘Remedies for Fluctuations of General Prices’ in the *Contemporary Review* in March 1887 (reprinted in Pigou, 1925), revising Ricardo's ingot plan to make the monetary unit a claim on a fixed weight of gold plus a fixed weight of silver, a step toward pegging the monetary unit to a basket of commodities (Irving Fisher's compensated dollar). This symmetallism proved incomprehensible to bimetallists, who persisted in plans that would require pegging the relative price of gold and silver. Also in 1886 (two years after writing the introduction to the posthumous collections of Jevons's *Investigations in Currency and Finance*), Herbert Foxwell published a lecture on *Irregularity of Employment and Fluctuations of Prices* (in Dimand, 2002, vol. 1). Like his colleague Marshall (both were fellows of St John's College, Cambridge), Foxwell emphasized fluctuations in employment as the crucial challenge posed by economic instability, and argued that the problem ‘How to secure greater industrial stability’ could be reformulated as ‘How to diminish price fluctuations’. A young Swedish student named Knut Wicksell attended Foxwell's lectures at University
College London in 1886. As Wesley Mitchell (1927, p. 7) observed, ‘Before the end of the nineteenth century there had accumulated a body of observations and speculations sufficient to justify the writing of histories of the theories of crises’: Eugen von Bergmann's Die Wirtschaftskrisen: Geschichte der nationalökonomischen Krisentheorien, published in Stuttgart in 1895, and E. D. Jones's Economic Crises, published in New York in 1900 (see also Barnett, 1941). In 1909, the year of Beatrice and Sidney Webb's Minority Report of the Poor Law Commission and of the first edition of Beveridge's Unemployment, the London School of Economics published a 71-page bibliography of unemployment and the unemployed by F. Isabel Taylor.

The cover of David Laidler's The Golden Age of the Quantity Theory (1991b) shows the three economists who dominated monetary economics before the First World War, making the case for monetary shocks and imbalances as the avoidable source of fluctuations: Alfred Marshall, Knut Wicksell and Irving Fisher.

In Interest and Prices in 1898 and then in his Lectures on Political Economy (1915), Wicksell distinguished the market rate of interest, set by the banking system, from the natural rate, the interest rate at which desired saving and investment would balance and the price level would not change. If a technical innovation raises the natural rate, or the banking system lowers the market rate, it will be profitable for entrepreneurs to borrow for new investment projects as long as the natural rate exceeds the market rate, causing (in a pure credit economy with no cash drain) a cumulative inflation. If the market rate exceeded the natural rate, a cumulative deflation would ensue. Although he considered himself a quantity theorist following in the footsteps of Ricardo, Wicksell was a pioneer in analysing a pure credit economy, not anchored by gold or other base money, which is why Michael Woodford deliberately chose Wicksell's title Interest and Prices for his 2003 treatise analysing a world in which financial innovation has greatly reduced the role of cash and bank reserves. Wicksell's economic contributions (which included using what came to be called the Cobb–Douglas production function four years before Cobb and Douglas) were continued by a Stockholm School including Dag Hammarskjold, Karin Kock (1929), Erik Lindahl (1939), Erik Lundberg (1937), Gunnar Myrdal (1939) and Bertil Ohlin – a list including three Nobel laureates (two in economics, one in peace) and four Swedish cabinet ministers. The Stockholm economists later expressed confidence that, even if Keynes had never written The General Theory, they would have discovered it themselves, but Don Patinkin (1982) expressed doubt, because the focus of Wicksell's heirs was on price dynamics, not the equilibrium level of employment and national income. Keynes's earlier Treatise on Money in 1930 (1971–89, vols 5 and 6) was much more Wicksellian than The General Theory in its emphasis on cumulative inflation or deflation when the interest rate does not equate planned investment to planned saving.

J. Bradford De Long (2000) writes:

The story of 20th century macroeconomics begins with Irving Fisher. In his books Appreciations and Interest (1896), The Rate of Interest (1907), and The Purchasing Power of Money (1911) [Fisher, 1997, vols. 1, 3, and 4], Fisher fueled the intellectual fire that much later became monetarism. To understand the determination of prices and interest rates and the course of the business cycle, monetarism holds, look first (and often last) at the stock of money – at the quantities in the economy of those assets that constitute readily spendable purchasing power. … It is true that the ideas that we see as necessarily
producing the quantity theory of money go back to David Hume, if not before. But the equation-of-exchange and the transformation of the quantity theory of money into a tool for making quantitative analyses and predictions of the price level, inflation, and interest rates was the creation of Irving Fisher.

In *Appreciation and Interest*, Fisher argued that the difference between interest rates expressed in two standards (money and commodities, gold and silver, dollars and francs) is the expected rate of appreciation of one standard in terms of the other, deriving from this uncovered interest parity between two countries, the expectations theory of the term structure of interest rates, and the Fisher relation that nominal interest is the sum of real interest and expected inflation (plus a cross-product term). In *The Rate of Interest*, Fisher introduced the Fisher diagram, showing the optimal smoothing of consumption over two periods (assuming perfect credit markets) and an individual's saving or dissaving in each period. In *The Purchasing Power of Money*, Fisher (with his former student Harry G. Brown) upheld the quantity theory both against bimetallists who predicted permanent real benefits from expanding the money supply and against hard-money opponents of bimetallism (notably J. Laurence Laughlin of the University of Chicago), who denied the path of US prices could be explained by changes in the money supply. Fisher and Brown explained economic fluctuations by the slow adjustment of nominal interest to monetary shocks during ‘transition periods’ (lasting perhaps ten years), so that fluctuations could be avoided either by educating the public against what Fisher later termed ‘the money illusion’ (so that expected inflation and hence nominal interest would adjust to monetary shocks, leaving real interest unaltered) or by a monetary policy rule of varying the exchange rate (the dollar price of gold) to hold constant a price index (for which Fisher later proposed the Fisher ideal index, the geometric mean of the Paasche and Laspeyres indexes). Fisher's 1926 article, ‘A statistical relation between unemployment and price changes’ (in Fisher, 1997, vol. 8), correlated unemployment with a distributed lag of past price level changes (as a proxy for expected inflation), and was reprinted in the *Journal of Political Economy* in 1973 under the heading ‘Lost and Found: I Discovered the Phillips Curve – Irving Fisher’. Unlike Marshall in Cambridge and Wicksell in Stockholm, Fisher did not attract a school of disciples at Yale. Through his role in establishing the Econometric Society and the Cowles Commission, Fisher advanced his preferred economic methodology of formal theorizing using mathematical and statistical techniques, but his contributions to monetary economics and economic fluctuations (like those of Hayek, Hawtrey, and many others) were long overshadowed by Keynes's *General Theory*, notwithstanding Keynes's acknowledgement of Fisher as his intellectual great-grandparent in appreciating the real effects of monetary changes.

Although Alfred Marshall's *Money, Credit and Commerce* was not published until 1923, the year before his death, parts of it were drafted as early as the 1870s, and his ideas had long circulated through his lectures, his evidence to official inquiries (gathered by Keynes in Marshall 1926), and the ‘Cambridge oral tradition’ of monetary theory (Eshag, 1963; Bridel, 1987; Laidler; 1999). Marshall, his professorial successor A. C. Pigou, Pigou's successor D.H. Robertson (1926), the young J.M. Keynes, and Cambridge economics lecturers Frederick Lavington and J.R. Bellerby used a cash balance version of the quantity theory, relating the number of units of purchasing power the public wished to hold as cash to the level of income (in contrast to Fisher's logically equivalent version, which expressed the quantity theory in terms of the velocity of circulation of money).
Departure from the gold standard during the First World War and the post-war central European hyperinflations provided the occasion for the highest achievement of Marshallian monetary economics, Keynes's *Tract on Monetary Reform* in 1923 (Keynes 1971–89, vol. 4), an innovative work but one that innovated within the tradition established by Marshall. Keynes analysed inflation as a form of taxation of real money balances, identified as a social cost the consequent reduction in desired holdings of real money balances (M/P), and introduced covered interest parity (the spread between forward and spot exchange rates equals the difference between interest rates in the two currencies). Keynes calculated that real money balances had fallen by 92 per cent during the German hyperinflation, as a result of the soaring opportunity cost of holding money. Others had mistakenly argued that since the price level (P) was rising faster than the money supply (M), monetary expansion could not be the cause of the price inflation, and the Reichsbank president Rudolf Havenstein promised that, with 38 new high-speed printing presses, the Reichsbank would be able to print enough money to catch up with the prices. Robertson (1926), then collaborating closely with Keynes, examined forced saving ('induced lacking' in Robertson's terminology) caused by inflation. Turning from inflation to deflation, Keynes wrote *The Economic Consequences of Mr. Churchill* (in Keynes 1971–89, vol. 9) to oppose Britain's return to the gold standard at the pre-war parity in 1925, arguing that restoration of the pre-war parity would require a reduction of prices and money wages that could be achieved only through prolonged unemployment (see June Flanders, 1989, on the development of international monetary economics).

**Keynesian Revolution and monetarist counter-revolution**

The Great Depression of the 1930s helped provide a receptive audience for John Maynard Keynes's *General Theory of Employment, Interest and Money* (1936; 1971–89, vol. 7), which argued that involuntary unemployment could persist unless the government intervened with appropriate management of aggregate demand (Clarke, 1988; Dimand, 1988; Backhouse, 1995). *The General Theory* challenged Lionel Robbins and Friedrich Hayek of the London School of Economics, who argued against expansionary fiscal and monetary policy and for letting the depression take its course, and William Beveridge, who held (until his conversion to Keynesianism) that the existing level of British unemployment could be fully accounted for by structural, frictional, and seasonal unemployment without invoking any deficiency of aggregate demand. To the rising generation of new economists, from Harvard students Paul Samuelson and James Tobin to LSE economists Abba Lerner and Nicholas Kaldor, Keynes offered a message of hope that depressions were curable and preventable without adopting a Soviet-style centrally planned economy. Attempts to dismiss or ignore Keynes (Burns and Mitchell, 1946, mentioned Keynes in one sentence, in a footnote) were futile. Keynes provided an agenda for economists providing public policy advice and a framework for empirical, policy-oriented modelling, at a time when depression and war greatly expanded the role of governments. Keynes's success in winning over the next generation of economists obscured the extent to which his contemporaries in economics shared his policy views rather than those of Robbins and Hayek: although Keynes used Pigou (1933) as the target of his attack on classical theory, he recognized how close they stood on practical policy. Even Ralph Hawtrey, the Treasury economist associated with the ‘Treasury view’ about crowding out and the ineffectiveness of fiscal policy, was convinced of the effectiveness of (and need for) stabilizing monetary policy (and contributed intriguing numerical examples to the
development of the Kahn–Keynes spending multiplier; see Hawtrey, 1932). Keynes’s caricature in *The General Theory* of ‘classical economists’ from Ricardo to Pigou as upholders of a rigid version of Say’s Law, denying any role to aggregate demand in explaining unemployment (in contrast to the superior insight but fuzzier analytics of mercantilists, Malthus, and the underconsumptionists Hobson and Mummery), was more widely noted than his subsequent clarification that he did not consider Fisher or Hawtrey or Robertson or Wicksell as classical. However, support for expansionary fiscal or monetary policy during the Depression did not necessarily imply anticipation of Keynesian economics: proposals circulated for emergency public works financed by cutting other government spending and for domestic monetary expansion while keeping the exchange rate fixed, and in the United States the New Deal's National Recovery Administration was an attempt to raise price toward pre-Depression levels by restricting supply, rather than by stimulating demand. Keynes provided a framework within which the implications of such policies could be analysed. Independently of Keynes, starting from Marx and Rosa Luxemburg, Michal Kalecki in Poland developed a theory very close to Keynes's income–expenditure analysis, and in 1934 published in Polish a three-equation model of goods market equilibrium, money market equilibrium and aggregate supply. Patinkin (1982) argued that Kalecki was concerned with the dynamics of cyclical fluctuations, Keynes with determining the equilibrium level of income that equates saving to desired investment, and that Kalecki's 1934 essay (which Kalecki did not choose to be translated among his selected articles in 1966 and 1971, or refer to in other works) was not part of his central message.

The analytical framework that dominated macroeconomics for at least a quarter century after the Second World War was based on Keynes's aggregate supply and aggregate demand functions (generally with more attention to aggregate demand than to aggregate supply) and the small system of simultaneous equations behind the Hicks–Hansen IS/LM diagram, which included Keynes's money demand function (liquidity preference) and later substitutes for his consumption function (De Vroey and Hoover 2004). The system of equations representing Keynes's message in a form equivalent to IS/LM was a four-equation model in Keynes's Cambridge lectures in December 1933, attended by David Champernowne and Brian Reddaway, the first economists to use such a model in print, but Keynes did not include it in *The General Theory*, perhaps following Marshall's advice to use mathematics as a tool of inquiry but to then translate the analysis into English and burn the mathematics (Rymes, 1989; Dimand, 1988). The resulting framework (extended to open economies by Robert Mundell and J. Marcus Fleming in the 1960s) did not capture all of Keynes's message (or messages), notably his distinction between fundamental uncertainty and insurable risk. Econometric estimation of macroeconomic models was pioneered, independently of Keynes, by Ragnar Frisch, Jan Tinbergen and Trygve Haavelmo (and Keynes's review of the first volume of Tinbergen, 1939, expressed severe scepticism), but it was taken up with enthusiasm by such Keynesians as Lawrence Klein. The claim in Chapter 2 of *The General Theory* that real and money wages move in opposite directions over the course of the cycle (and by implication, that real wages vary counter-cyclically) was challenged empirically by John Dunlop and Lorie Tarshis and on theoretical grounds by Michal Kalecki, leading Keynes in 1939 to acknowledge the cyclical pattern of real wages as an open question, which it remains to this day.

Milton Friedman and his students (Friedman, 1956) offered a renewed quantity theory of money as a challenge to Keynesianism, claiming to follow a Chicago oral tradition of monetary theory. Certainly it drew on such Chicago landmarks as Henry Simons's 1936 argument for rules rather than authorities in
macroeconomics, origins and history of: The New Palgrave Dictionary of Economics

monetary policy (reprinted in Simons, 1948), but the intellectual inheritance from non-Chicago quantity theorists such as Irving Fisher and Clark Warburton (and even the young Keynes of A Tract on Monetary Reform) gradually came to be recognized. As Patinkin (1981) noted, a key element of Friedman's approach, the demand for money as a function of a small number of variables, originated in Keynes's General Theory. Although others had come close (in 1930, Fisher stated the marginal opportunity cost of holding cash balances), Keynes was the first to write the demand for money as a function of income and the interest rate. A further irony was that, though the spread of Keynesianism stemmed largely from its apparent ability to explain the Great Depression, the monetary interpretation of the Great Depression by Friedman and Schwartz (1963), as the consequence of mistaken Federal Reserve policy that permitted the US money supply to contract by a third, was crucial in persuading many economists of the explanatory power of monetarism, the revived form of the quantity theory. For an overview of the development of macroeconomics from Keynes through Friedman to the New Classical and New Keynesian research programs (and the non-mainstream Post Keynesian and Austrian schools, from Keynesian fundamental uncertainty and Mises–Hayek trade cycle theory, respectively), enlivened with interviews with leading participants (see Snowdon and Vane, 2005).

Recurring themes

Certain issues reappear throughout the history of economics. Do fluctuations result from monetary disturbances, as Hawtrey (1913; 1932) and Fisher argued, or from real productivity shocks such as Schumpeterian innovations? Is unemployment best analysed as the functioning or malfunctioning of the labour market (as in Beveridge, 1930, and Hutt, 1939) or in terms of the demand for and supply of output as a whole (Keynes)? Is there a role for demand management to offset instability caused by volatile private investment reflecting the fundamental uncertainty of future profitability (Keynes) or is government itself the source of instability (von Mises, Hayek)? Should a central bank follow a rule rather than having discretion (as Henry Simons asked in 1936), or need there even be a central bank (as Hayek's student Vera Smith asked the same year)? Are recessions undesirable and preventable disequilibrium phenomena, or, as Arthur Ellis (1879) and Friedrich Hayek (1931) held, are they a normal and necessary part of the equilibrium path of the economy? Should analysis of economic fluctuations should be primarily a study of the statistical properties of the fluctuations, as in Burns and Mitchell (1946) and decades later Sims's vector autoregressions, or should the analysis be explicitly grounded in formal economic theory? As macroeconomists continue to theorize, measure, test, and argue about these issues, they stand, knowingly or not, on the ‘shoulders of giants’ who discussed these questions before. De Long (2000, p. 83) notes that ‘The New Classical research program walks in the footprints of Joseph Schumpeter's Business Cycles (1939) [and of Schumpeter, 1912, and Robertson, 1915], holding that the key to the business cycle is the stochastic nature of economic growth [so that] the “cycle” should be analyzed with the same models used to understand the “trend”’ ,while the name of the New Keynesian research program (which emphasizes frictions that prevent instantaneous adjustment to nominal shocks) indicates its historical antecedents (although, as De Long points out, it also incorporates important features of Milton Friedman's contributions, such as emphasis on policy rules and on monetary rather than fiscal policy). Insights have sometimes long preceded the ability to formalize them;
even Adam Smith's famous increasing returns through the division of labour, revived in Allyn Young's 1928 essay on economic progress, did not make its mark on the theories of international trade and endogenous growth until the last decades of the 20th century, when ways were devised to incorporate increasing returns to scale in formal models. The field has experienced major changes, as when Keynes made determining the equilibrium level of national income the central issue, or when monetarism posed inflation as the central problem instead of unemployment, or when attention shifted from fluctuations to long-term growth, but in each case the change was a transformation of a rich heritage.

**How to cite this article**

G.S. Maddala's many publications covered almost every substantive areas of econometrics – distributed lags, generalized least squares, panel data, simultaneous equations, measurement errors, switching and disequilibrium models, qualitative and limited dependent variable models, selection and self-selection models, exact small sample distributions of estimators, outliers and bootstrap methods, robust estimators and more. G.S. became a veritable textbook himself – a pre-eminent teacher in econometrics and an authority on almost every econometrics topic. G.S. was a brilliant expositor – he could cut through the technical superstructure to reveal only essential details, while retaining the nerve centre of the subject matter he sought to explain.

Article

G.S. Maddala (universally known as ‘G.S.’) was born on 21 May 1933 in the south Indian state of Andhra Pradesh, where he had his high-school education. G.S. held the University Eminent Chair at the Ohio State University when he died on 4 June 1999 due to congestive heart failure. G.S.’s father was a schoolteacher of modest means, and his mother, though having only an elementary
education, was well versed in Sanskrit and the works of the great Indian philosopher Sankara. After graduating from high school in 1947, G.S. had to drop out of college for a few years due to health and other reasons. In 1955 he graduated first in his class from Andhra University with a BA in mathematics, and went on to graduate in First Class from Bombay University with an MA in statistics in 1957. With a Fulbright Fellowship, G.S. travelled to the University of Chicago in 1960 and completed his Ph.D. in 1963 under the supervision of the late Zvi Griliches. In that year, he was offered the job of Assistant Professor of Economics at Stanford University. Before joining Ohio State in 1993, G.S. taught at the University of Rochester (1967–75) and at the University of Florida (1975–93). He also held visiting appointments at Cornell, Yale, CORE, Monash, Columbia, Caltech (as the Fairchild Distinguished Scholar), Emory and Oakridge Labs. The fascinating narration of his journey from an early college dropout in a remote Indian village in 1947 to a faculty position at Stanford in 1963 can be found in the Introduction (‘How I Became an Econometrician’) to the two-volume selected works of Maddala (1994). More detailed biographical information, his life story and philosophy can be found in Lahiri and Phillips (1999), Lahiri (1999), Griliches (1999), Rosen (2000) and Hsiao (2003).

Beginning with his first published paper (with Zvi Griliches, Robert Lucas, and Neil Wallace) in 1962, through the next four decades, G.S. published 12 books and more than 110 articles covering almost every emerging area of econometrics – distributed lags, generalized least squares, panel data, simultaneous equations, measurement errors, tests of significance, switching and disequilibrium models, qualitative and limited dependent variable models, selection and self-selection models, exact small sample distributions of estimators, outliers and bootstrap methods, robust estimators, and more. The list is practically endless. Throughout his career G.S. used sample theory and Bayesian techniques freely in his research, a rarity in the econometrics profession, and was one of the early proponents of Bayesian approach in econometrics. Through his many books and the breadth of his own research, G.S. became a veritable textbook himself – a pre-eminent teacher in econometrics and an authority on almost every econometrics topic. Not surprisingly, according to the Social Science Citation Index, G.S. was one of the top five most-cited econometricians during each of the years 1988–93, and he was cited more times in 1994 and 1996 than each of the six econometricians who won the Clark Medal during 1970–2000. During the 1960s, G.S. contributed heavily towards the formulation and estimation of production functions and technical change. His doctoral dissertation was on productivity and technical change in the US bituminous coal industry. His two papers with Jay Kadane in 1966 and 1967 considered, respectively, the importance of alternative exogeneity assumptions in the estimation of the constant elasticity of substitution production functions parameters inclusive of the share equations; and the bias in the estimation of the returns to scale parameter when the production function is incorrectly specified as a Cobb Douglas. The rigour and depth in these papers were undoubtedly ahead of their time.

The early 1970s saw a flurry of activity on efficient estimation methods of alternative distributed lag models. One of G.S.’s widely cited papers (1971a) showed why certain commonly used two-step procedures are asymptotically less efficient than the maximum likelihood estimator in the presence of lagged dependent variables as regressors. This sort of problem is encountered also in dynamic panel data models with individual heterogeneity. The key result in this paper is that in these models the information matrix of the slope parameters and the parameters embedded in the covariance matrix of residuals are not diagonal. Using this as a starting point, Pagan (1986) developed a more thorough and modern characterization of numerous two-step procedures with estimated covariance matrix in the context of various econometric models.
With Dave Grether in 1973, G.S. studied the effects of errors in variables in distributed lag models with serial correlation. They showed analytically that the estimated speed of adjustment can be severely biased, and can give the spurious appearance of a long lag in adjustment. In two influential papers with A.S. Rao in 1971 and 1973, G.S. developed maximum likelihood procedures for Solow's Pascal lag and Jorgenson's rational distributed lag models, and compared the power of tests for serial correlation in regression models with lagged dependent variables. One important conclusion that emerged from the latter study was that the nature of the autocorrelation and trend in the exogenous variable is crucial in determining the small sample behaviour of the test statistics and the estimators – hinting at much of the work on integrated variables that would come in the 1980s.

During the early 1970s G.S. also produced a number of important papers on the use and estimation of panel data models, and rightfully became one of the three ‘fathers’ (together with Yair Mundlak and Marc Nerlove) of modern panel data analysis in econometrics. In his influential *Econometrica* (1971b) paper, G.S. demonstrated – with his characteristic clarity – that the error component estimator is a weighted combination of within and between estimators, and thus the use of dummies entails substantial loss of information by ignoring the ‘between’ variation in the data. In another *Econometrica* (1971c) paper, G.S. discussed the problem of pooling cross-section and time series data, and emphasized tests for consistency between time series and cross-section information. The paper contains a very deep analysis of an alternative Bayesian approach with diffuse priors and concludes that the two approaches should be complementary. (Publishing three full-length articles in *Econometrica* in a year has to be some kind of a record for an economist!) The profession quickly saw the enduring value of these publications and elected G.S. a fellow of the Econometric Society in 1975.

During the 1970s, like many other econometrics stalwarts of the period, G.S. was also involved in the development of econometric methodology in simultaneous equations models. He worked on appropriate estimation strategies in large and medium-size econometric models (1971d), and studied the power characteristics of alternative tests of significance associated with simultaneous equation estimation (1974a). His *Econometrica* (1974b) paper showed that ‘diffuse’ and ‘non-informative’ priors might lead to sharp posterior distributions even in under-identified models. Only recently have Chao and Phillips (2002) fully solved the so-called ‘Maddala paradox’ using Jeffreys prior. They interpret the pathological result in terms of a naive use of the diffuse prior that fails to downweight sufficiently that part of the parameter space where the rank condition either fails or nearly fails. In another potent contribution to an important recent work on weak instruments, Maddala and Jeong (1992) correctly showed that the bimodal distribution of the instrumental variable estimator obtained in the literature is merely due to the illustrative model used, where the correlation between the structural and the first-stage errors is perfect. Phillips (2006) gives a complete characterization of the bimodality problem when instruments are weak.

From the mid-1970s, G.S. was primarily focused on developing estimation and test procedures for qualitative and limited dependent variable models, and produced nearly 40 articles. This line of research also dealt with models with selection, self-selection, disequilibrium and controlled prices. His work at Rochester with Forrest Nelson (1974) on disequilibrium models and with Lung-Fei Lee (1976) on recursive models with qualitative endogenous variables and generalized selection models represents a long and very fruitful period of research on this topic. His 1983 Econometric Society monograph, *Limited Dependent and Qualitative Variables in Econometrics*, was an immediate best-seller and was declared a citation classic in *Current Contents* (vol. 30, 16 July 1993). It has fuelled much of the innovative applied and theoretical research using these tools since the mid-1980s, and has served as a
bible to empirical researchers in applied microeconomics. The strength of the book lies in its comprehensiveness, expositional simplicity, and depth. As of June 2006, the Google Scholar reports a record 3,721 citations of this advanced monograph. G.S. also wrote a number of theoretical and empirical papers analysing limited dependent and qualitative variable models with panel data, and wrote widely cited expository articles for use in other disciplines such as accounting, finance, transportation, and health.

It is notable that G.S. can jointly claim a statistical distribution – the Singh–Maddala (1976) distribution – a much better name than the Burr type 12 to which it is related. Maddala and Singh’s proposed statistical distribution has triggered much research in describing the actual size distribution of incomes, and is a generalization of the Pareto distribution and the Weibull distribution used in analysis of equipment failures. As aptly noted by Sherwin Rosen (2000) while delivering the first Maddala lecture at Ohio State University on 26 April 2000, ‘Coase may have his Theorem, Stigler his Laws, Black and Scholes their Formula, and Lucas his critique, but what economist aside from Pareto (who was just as much a sociologist and political scientist and only one third economist) has half ownership of a distribution? And what an elegant economic derivation it has.’

G.S. had a deep interest in rational expectations models, in the validity of the hypothesis that can be gleaned from recorded survey data, and in how econometric disequilibrium models play out in this framework. Maddala, Fishe and Lahiri (1983) developed methods to estimate aggregate expectations when available survey data are partly qualitative and partly quantitative. He had done pioneering work (Maddala, 1983a) on the estimation for models with bounded price variation, and with Scott Shonkwiler (1985) applied the methodology to the corn market. With Steve Donald (1992), G.S. studied the disequilibrium model with upper and lower bounds on prices under rational expectations. The latter paper foreshadowed much work on exchange rate determination in a target zone in the 1990s. Undoubtedly, the full potential of this line of research initiated by G.S. is yet to be realized.

With failing health, G.S. spent much of the 1990s working primarily on bootstrap techniques and time series models with cointegration and structural breaks. During this period, he also wrote important papers on tests of unit roots in panel data models, robust inference, errors in variables problems in finance, Bayesian shrinkage estimation, outliers and influential observations, neural nets, and many others. Thus, ill health neither slowed down his research nor dampened his passion for mentoring and supervising Ph.D. students. In total G.S. supervised close to 60 doctoral students, co-authoring more than 65 published articles with them.

While testing the rationality of survey data on interest rate expectations in the context of a multiple-indicator single index model with heteroskedasticity, Maddala and Jeong in the mid-1990s used the weighted double bootstrap method to implement the Wald test in finite samples. His work with Hongyi Li in 1996 explored the use of different bootstrap techniques in cointegration regressions, financial and non-linear models. With Wu (1999) on panel data unit root test, G.S. suggested the use of a novel Fisher test that combines N individual tests with bootstrap-based critical values. Since much remains to be done to extend the Fisher approach to combining individual tests that are correlated, further generalizations of the Maddala–Wu test are certainly to come.

Much of his work on modern time series analysis has been summarized in his seminal book with In-Moo Kim (1998). This book also presents a comprehensive and lucid review of unit root and cointegration tests, and estimation with integrated variables. It discusses problems of unit root tests and cointegration under structural change, outliers, robust methods, the Markov switching model, and Harvey’s structural
time series model. The book contains a welcome chapter on the Bayesian approach to many of these problems and bootstrap methods for small-sample inference.

G.S. contributed to a number of purely policy-oriented and applied areas. Some of these topics include consumption, production and cost functions, money demand, regulation, pseudo-data, returns to college education, housing markets, energy demand, stock prices, international macro, and cross-country growth analysis. In all these papers, G.S. made serious attempts to grapple with substantive and important issues of the day. However, one common characteristic that flows through all these papers is that they unfailingly reflect the discriminating judgement of a consummate econometrician.

G.S. had the gift of a brilliant expositor – the ability to cut through the technical superstructure to reveal only essential details, while retaining the nerve centre of the subject matter he sought to explain. He loved to write econometrics in plain English. There was magic in how he could cut to the core, strip away all the irrelevant details and illuminate the essence of the issue in a quiet and unassuming way. This exceptional expository capability made him revered by applied and theoretical econometricians alike. This skill was apparent in all his writing and was a central element in his textbook expositions. His 1977 econometrics text redefined the boundaries of econometrics that could be integrated into graduate teaching, and became a new standard for subsequent econometrics textbooks. His advanced undergraduate textbook *An Introduction to Econometrics* has gone into its third edition (2000), and all his textbooks have been translated into a number of foreign languages.

G.S.’s style was to take a critical but constructive look at evolving econometric techniques – in particular those that have little practical significance. In this, G.S. had something that was close to perfect pitch in econometrics. He was one of the few econometricians who constantly asked whether the questions being answered were worth asking – always maintaining a clear perspective on a wide range of issues in econometrics and their relationship to economic problems. In doing so, he never hesitated to go against the tide of the profession. While much of his work was undoubtedly constructive, much was also critical of many current fads in econometrics. That is also a very important contribution.

Mahalanobis, Prasanta Chandra (1893–1972)

Sukhamoy Chakravarty

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

India, economics in; Mahalanobis, P. C.; optimal growth; planning; Prebisch, R.; statistical inference; two-sector models; Fel’dman, G. A.; dual development thesis

Article

Mahalanobis was born in Calcutta of a well-to-do Bengali middle-class family with a reformed outlook on Hindu religion. He was educated first at Presidency College, Calcutta, and then at Cambridge, where he graduated with a First in Natural Sciences from King’s College in 1915. He became a Fellow of the Royal Society in 1946 and received many other scientific honours. While Mahalanobis served as Professor of Physics at Presidency College for nearly three decades, his scientific work consisted chiefly of developing statistical theory and techniques that had application to a wide range of subjects, beginning with meteorology and anthropology and ending in economics. Mahalanobis established a firm international reputation on the basis of his work on the design of large-scale sample surveys (for example, 1944) and thus laid the basis for systematic collection of a large variety of data relating to socio-economic conditions. Mahalanobis's sense of realism was combined with a deep understanding of the problems of statistical inference. This led him to place stress on 'non-sampling errors' in addition to the standard preoccupation with sampling errors. He devised his system of 'interpenetrating network of sub-samples' to derive among other things, an idea of 'non-sampling errors' which are inherently associated with large-scale collection of data. Mahalanobis's work on experimental designs developed with a view to estimating crop yields (1946) was highly influential in laying down the basis for collection of agricultural statistics in India. In multivariate statistics, Mahalanobis's measure of distance between two populations (1936), usually known as Mahalanobis's $D^2$ statistic, is a major contribution that is much used in anthropometry and elsewhere. Mahalanobis maintained a keen interest in problems of national planning even before India had gained Independence. He recognized very early that such planning had to have a firm statistical base, and from the beginning of the 1950s, when the Indian Five Year Plan was launched, began to devote a very large
part of his time and attention to questions of estimating national income and the factors determining its rate of growth. His approach to planning issues, with its strong emphasis on quantification, was significantly different from the qualitative approach favoured by the Indian economists of his generation. However, Mahalanobis was no exclusive believer in narrowly conceived quantitative techniques. He developed an important blend between qualitative and quantitative considerations, which is reflected in his ‘Approach of Operational Research to Planning in India’ (1955).

The second Five Year Plan, whose analytical structure was largely the handiwork of Mahalanobis, stands out as a very distinguished document in the development of planning theory. Mahalanobis is generally regarded as one of the prominent advocates of the inward-looking strategy of industrialization, along with Raul Prebisch. But the analytical foundation of the Mahalanobis approach was derived from somewhat different premises. While Prebisch began his theoretical study from what he thought was a historical fact, that is, the secular decline in terms of the trade of primary producing countries, Mahalanobis developed a two-sector model of growth to deduce a strategy of industrial development which he thought was best suited to India. The classification of the economy into sectors resembled in some respects Marx's famous Departmental Schema, although they were not identical.

Mahalanobis's sector-schema (1953) distinguished between ‘capital goods’ and ‘consumer goods’, but the assumption of vertical integration made in the interest of simplicity made statistical implementation difficult. The essential point of the model is that the capacity of the capital goods sector determines the potential rate of expansion of the consumer goods sector, and not the other way round. Labour is not considered to be a constraint on expanding production. The model was developed initially for a closed economy but has been subsequently extended to open economies, with an exogenously given profile of export earnings. Mahalanobis used the model to illustrate the nature of the trade-off between present and future consumption, given the objective characteristics of the two sectors.

For the dynamic closure of the model he used the ratio of the output of the capital goods sector that is ploughed back into itself ('$\lambda_k$' in his notation), to deduce a ‘gradualist growth’ path of consumption. For any given value $\lambda_k$ maintained over time, the rate of growth of aggregate output tends, over a sufficiently long period, to a magnitude $\lambda_k \beta_k$, where $\beta_k$ is the output–capital ratio of the capital goods sector. The Mahalanobis model was subsequently freed from the assumption of an exogenously stipulated $\lambda_k$. Exercises carried out by Stoleru (1965), Chakravarty (1969), Dasgupta (1969) and others introduced explicit intertemporal social utility functions along with a production technology of the Mahalanobis type. They deduced the characteristics of optimal growth paths with the help of variational calculus. $\lambda_k(t)$ was deduced as a solution of the optimizing exercise. It was shown that while the assumption of ‘non-shiftability’ critical to Mahalanobis's model could in several cases give rise to a preference for capital goods sector in early stages of growth (a strategy preferred by Mahalanobis himself), one could not obtain a universal rule of priority for capital goods irrespective of initial conditions, or the nature of social utility functions over time.

In all these exercises, the coefficients pertaining to the ‘capital goods sector’, sometimes identified as the ‘machine tool sector’, turned out to be an important determinant of the growth process. Earlier literature on business cycle theory originating with Marx, Tugan Baranovsky and Adolph Lowe had placed emphasis on the ‘machine tools sector’, without linking it up with an explicit growth model. In the growth-theoretic area Fel'dman alone appears to be the true predecessor of Mahalanobis, as is evident...
from Domar's discussion (1957).
Mahalanobis extended the two-sector model to a four-sector model, to focus on issues of reduction in unemployment along with increases in income. Mahalanobis came to the ‘dual development thesis’, which consisted in assigning high weights to the capital goods sector in the interests of long-term growth, and emphasis on the highly labour-intensive consumer goods sector in the short run. In the literature on planning, this has on occasion been referred to as the strategy of ‘walking on two legs’, with authorship occasionally ascribed to Mao Tse Tung.
Towards the end of his life, Mahalanobis returned to issues of statistical methodology and concentrated on developing what he called ‘fractile graphical analysis’ (1960), which is based on a geometrical concept of error and can also provide a generalized measure of separation between two ‘different universes’ of study.
Mahalanobis’s work remains important for economists who are working on quantitative approaches to problems of plan formulation, especially in the context of large-sized economies. His work on sample surveys has generated a very valuable literature to which economic statisticians from India and elsewhere have made notable contributions.

Makower, Helen (1910–1998)

K.J. Lancaster

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

consumer theory; household production; linear methods; Makower, H.

Article

Helen Makower was educated at Cambridge and obtained her doctorate from London University. From 1938 until her retirement in 1973 she taught at the London School of Economics and Political Science. In collaboration with Jacob Marschak she made a pioneering contribution to modern asset portfolio theory and to the study of labour mobility. After the Second World War her analytical insights and interest in work then being performed at the Cowles Commission in Chicago led to her being one of the important links through which such techniques as activity analysis entered the academic scene in Britain. Her 1957 book and other papers made original contributions to the application of linear methods in economic analysis. One of her important insights was into the analogy between production and consumption, a precursor of later work on the household production and characteristics approaches to consumer theory.

Selected works

Malthus, Thomas Robert (1766–1834)

J.M. Pullen

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A brief biographical sketch precedes a discussion of important methodological features of Malthus's work, especially his 'doctrine of proportions' and the need for moderation and balance in economic principles and policies. His principle of laissez-faire admitted exceptions; and, although his principle of population warned of over-population, he acknowledged the potential advantages of population growth. His ideas on the Poor Laws, the Corn Laws, Say's Law, and the relation between saving and investment are discussed; and the roles given to effective demand and to distribution as a factor of production, especially the distribution of landed property, are emphasized.

H.; Mill, J.; Old Poor Law; optimum; perfectibilism; population growth; protectionism; redistribution of wealth; saving–investment equality; Say, J.-B.; Say's Law; unproductive consumption

Article

Malthus has the unusual distinction not only of being a founder of classical economics – mainly because of his principle of population – but also of being instrumental in attempts to overthrow classical economics, mainly because of his principle of effective demand and its influence on John Maynard Keynes.

The most comprehensive and authoritative source of biographical information on Malthus is James (1979), from which the following brief details have been largely derived. Additional information can be found in the first edition of The New Palgrave: A Dictionary of Economics (Pullen, 1987), Malthus (1989b, pp. xv–lxix), and the Oxford Dictionary of National Biography (Pullen, 2004). Malthus was
born on 13 February 1766, near Wotton, in the county of Surrey, England, and died on 29 December 1834, at Bath. He was buried in Bath Abbey where there is a commemorative plaque. Although he was baptized Thomas Robert, he used his full name only in formal situations; in less formal correspondence he signed himself T. Robert Malthus or Robert Malthus, and was known to family and close friends as Robert or Bob.

He was the son of Henrietta (née Graham) (1733–1800) and Daniel Malthus (1730–1800). The latter, having inherited independent means, cultivated literary, artistic, scientific and theatrical interests. He was an admirer and correspondent of Rousseau, who once visited the family home soon after Malthus's birth. The extensive library of Daniel Malthus was eventually passed on to Malthus and, supplemented by acquisitions of his own and other family members, is now held in Jesus College, Cambridge.

Malthus graduated in 1788, and in 1789 was ordained deacon with title to a stipendiary curacy at the small chapel at Okewood in the parish of Wotton. He was ordained priest in 1791, was appointed non-resident Rector of Walesby in Lincolnshire in 1803, and succeeded to the perpetual curacy of Okewood in 1824. He married in 1804 and had three children, but no grandchildren. In 1805 he was appointed to the East India College as ‘Professor of General History, Politics, Commerce and Finance’, a title later altered to ‘Professor of History and Political Economy’. He held the post for the rest of his life, residing in the College at Haileybury, near Hertford. As well as performing his teaching duties, he preached regularly in the college chapel. The important collection of Malthus manuscripts held at Kanto Gakuen University in Japan (Malthus, 1997; 2004) contains four of his sermons. They corroborate the statement of his colleague William Empson: ‘Mr. Malthus was a clergyman – a most conscientious one, pure and pious. We never knew one of this description so entirely free of the vices of his caste’ (Empson, 1837, p. 481). His main publications were *An Essay on the Principle of Population*, first published in 1798, with five further editions in 1803, 1806, 1807, 1817 and 1826, and *Principles of Political Economy*, first published in 1820 with a posthumous second edition in 1836. He also published at least 20 smaller works – his authorship of a 21st is disputed – and evidence he gave at two public enquiries can be found in the published reports. There is a full list of his publications in *The New Palgrave* (Pullen, 1987) or in Malthus (1986, vol. 1, pp. 41–4). He engaged in extensive correspondence throughout his career, with Ricardo and many others. More than 230 letters to and from over 50 correspondents are known to have survived.

Malthus's methodology: ‘the doctrine of proportions’

Before considering particular aspects of Malthus's political economy, it is important to understand some of the peculiar features of his methodology. Failure to do so has resulted in many misunderstandings and unnecessary disagreements among commentators.

One of the most important, but one of the most unrecognized, aspects of Malthus's methodology was the principle that he called the ‘doctrine of proportions’. This was the traditional ethical notion of the just mean or middle way. As Leslie Stephen (1893) said, in the first *Dictionary of National Biography*, Malthus was always ‘a lover of the golden mean’. The distinctive innovation of Malthus lay in applying the concept to political economy, and in giving it such a prominent and consistent role.

He stated that his aim was to show ‘how frequently the doctrine of proportions meets us at every turn, and how much the wealth of nations depends upon the relation of parts’. It was his view that ‘all the
great results in political economy, respecting wealth, depend upon *proportions*, and warned that the ‘tendency to extremes is one of the great sources of error in political economy, where so much depends upon proportions’. He added that ‘It is not, however, in political economy alone that so much depends upon proportions, but throughout the whole range of nature and art’ (1989b, vol. 1, pp. 352, 432; vol. 2, pp. 252, 269, 278).

Malthus's doctrine of proportions is thus essentially the same as the concept of the optimum. Although he did not use the term ‘optimum’, he must be recognized as having been one of the first to introduce the concept of the optimum into economics. In giving this central role to the doctrine of proportions, he has in effect said that the economic problem is the problem of balance, not the problem of choice. But, despite his widespread use of the doctrine of proportions, Malthus recognized that precise determination of optimum points would be difficult. In discussing the optimum level of saving, he acknowledged that ‘the resources of political economy may not be able to ascertain it’ (1989b, vol. 1, p. 9), and, in discussing the just means for saving and the division of landed property, he said ‘the extremes are obvious and striking, but the most advantageous mean cannot be marked’ (1989b, vol. 1, p. 10).

The moderation and balance implied by the doctrine of proportions was evident in Malthus's personal temperament. Bishop Otter, who knew Malthus for nearly 50 years, said that he ‘scarcely ever saw him ruffled, never angry, never above measure, elated or depressed’, and that Malthus possessed ‘a degree of temperance and prudence, very rare at that period, and carried by him even into his academical pursuits’ (in Otter, 1836, pp. xxxii, xlix); and William Empson said in reference to the doctrine of proportions: ‘The lesson which he sought to impress on others, he faithfully applied to himself; and so successfully, that few characters have ever existed of more perfect symmetry and order’ (Empson, 1837, pp. 476–7).

Malthus has been given credit for introducing or propagating, either alone or with others, a number of key ideas in the history of economics; notably, the principle of population, the law of diminishing returns, and the role of effective demand. The doctrine of proportions could be added to the list.

**Limitations and exceptions**

Another facet of Malthus's methodology was his insistence on limitations and exceptions to the general principles in political economy. This could be seen either as a corollary of his doctrine of proportions or as another way of expressing the same doctrine. He believed that there are some general principles in political economy to which exceptions are ‘most rare’, but added ‘yet there is no truth of which I feel a stronger conviction than that there are many important propositions in political economy which absolutely require limitations and exceptions’ (1989b, vol. 1, p. 8). In this respect, he departed from the absolutist and universalist aspirations of some of his contemporaries, who, anxious to promote the scientific credentials of political economy, pretentiously declared them to be ‘laws’. He was critical of the ‘precipitate attempt to simplify and generalize’, which he regarded as the ‘principal cause of error, and of the differences which prevail at present among the scientific writers on political economy’ (1989b, vol. 1, pp. 5–6).

Malthus has been accused, in his own day and now, of lacking in logic, especially by comparison with Ricardo. The accusation that his views did not constitute a logical and coherent system appears to have emanated from a failure to appreciate that his views were formulated in the context of his doctrine of
proportions, and that he believed exceptions and limitations frequently have to be admitted when principles are used to formulate policies for application to particular real-world circumstances.

**Laissez-faire and government intervention**

Malthus strongly supported the principle of laissez-faire or freedom of trade: ‘the wealth of nations is best secured by allowing every person, as long as he adheres to the rules of justice, to pursue his own interest in his own way’, and ‘governments should not interfere in the direction of capital and industry, but leave every person, so long as he obeys the laws of justice, to pursue his own interest in his own way’. He described this as a ‘great principle’ and as ‘one of the most general rules of political economy’ (1989b, vol. 1, pp. 3, 13, 518).

But he also argued that some exceptions to the principle of laissez-faire have to be recognized, and that the principle of non-interference is ‘necessarily limited in practice’ (1989b, vol. 1, 18–19, 525). He believed that there are certain duties that belong to the government – for example, in areas such as education; support of the poor; construction and maintenance of roads, canals, and public docks; colonization and emigration; and the support of forts and establishments in foreign countries – although he recognized that there may be differences of opinion about the extent to which government should share in such matters. In particular, the ‘necessity of taxation … impels the government to action, and puts an end to the possibility of letting things alone’ (1989b, vol. 1, pp. 18–19).

Thus, although Malthus strongly supported the principle of laissez-faire, his support, like that of Adam Smith, was pragmatic and conditional rather than dogmatic and absolute. There was, however, a major difference in their conception of the laissez-faire principle. In what Donald Winch has described as ‘an attack on a central feature of the *Wealth of Nations*’ and as ‘a major qualification to Smith's system of natural liberty’, Malthus doubted whether economic growth has always been, or will always be, advantageous to the mass of society. Malthus criticized Smith's view that the economic growth of Britain during the 18th century had improved the living standards of the labouring classes; he recognized that investments in trade and manufacturing had benefited individual capitalists, but argued that they were of less benefit to society as a whole. Thus Malthus raised the possibility of conflict between economic growth and human happiness, and implied that interventionist welfare policies by government might be justified. In this respect, as Winch has argued, ‘if general allegiance to the system of natural liberty, as interpreted by Smith and upheld under the different circumstances by some of his followers, is the hallmark of an orthodox political economist during the first half of the nineteenth century, Malthus occupies a decidedly ambivalent position’ (Winch, 1987, pp. 32, 59–61, 76–7).

**Population**

Malthus's first published work – *An Essay on the Principle of Population* (1798) – was written primarily to controvert the perfectibilist notions of Godwin and Condorcet. He believed that the growth of population presented a major obstacle to unlimited human progress. He argued that population will constantly tend to exceed the food supply, with the result that human progress will be neither rapid nor unlimited, and will be accompanied by sufferings and evils arising from the operation of unavoidable checks to population growth.
To support his views on the threat of overpopulation to human progress, Malthus introduced the notion of the two ratios. He argued that population will tend to increase in a geometrical ratio (1, 2, 4, 8 …) doubling every 25 years; but the food supply will increase only in an arithmetical ratio (1, 2, 3, 4 …). He believed that the population of ‘this Island’ was then about seven million, and that after the first 25 years it would reach 14 million, after 50 years 28 million, after 75 years 56 million, and so on. But the utmost that could be expected for the supply of food is that there would be sufficient to feed 14 million after 25 years, 21 million after 50 years, 28 million after 75 years, and so on. Thus, after the first 25 years, the food supply would become insufficient, and any further progress in the size of the population and the standard of living would be impossible. He concluded that this argument is conclusive against the perfectibility of the mass of mankind.

Opinions differ on whether Malthus's principle of population depends essentially on the empirical accuracy of these ratios or whether they were intended merely as approximate tendencies, or as a mathematical metaphor. Whatever his intention, there is no doubt that the ratios have exerted a powerful rhetorical influence in promoting his message and his fame.

Malthus was not the first writer to issue a warning about the dangers of overpopulation, as he himself acknowledged, but for a variety of reasons his arguments have become the best-known, and have exerted a great influence on human thought and human affairs. He alerted the world to the problem of overpopulation, and his views continue to affect the population policies of governments through the world today.

Having presented his basic arguments in the first two chapters of the *Essay*, Malthus then proceeded to discuss the ‘checks’ to population. As he said in his first postulate, people cannot live without food, and therefore it would be impossible to have a situation where 28 million people were in existence but the food supply was adequate for only 21 million. There must therefore be some mechanisms or checks whereby populations are prevented from exceeding the food supply. The bulk of the *Essay*, especially in the much enlarged later editions, was devoted to a detailed description of the checks that have operated in different countries and at different times.

He classified the checks as either positive checks that reduce normal life expectancy and increase the death rate, or preventive checks that reduce the birth rate. Among his list of positive checks he included common diseases, epidemics, wars, plagues, pestilence, famines, infanticide, unwholesome occupations and habitations, severe labour, exposure to the seasons, extreme poverty, bad nursing of children, great cities, and excesses of all kinds.

The preventive checks, described in circumspect language (‘vicious customs with respect to women’), included prostitution and birth control, but the only preventive check that he approved of and advocated was prudential restraint, by which he meant delaying marriage until sufficient resources of food, accommodation and other necessaries are available to provide the parents and the expected number of children with an acceptable standard of living. He noted that prudential restraint is practised, and should be practised, by those who want to maintain after marriage the social and economic status they enjoyed before marriage. The case for prudential restraint was even more vigorously argued in the later editions, where those who marry and raise children without ensuring that they have sufficient resources are accused of irresponsible and immoral behaviour.

He also classified the population checks as either vice or misery, but did not clearly show how the vice-and-misery classification is related to the positive-and-preventive. Presumably he meant that, among the positive checks, some, such as war and infanticide, are vices, and all lead to misery; and among the
preventive checks all except prudential restraint are vices, and all are likely to lead to misery; and although prudential restraint is a virtue, not a vice, it often leads to vice.

Restraints upon marriage are but too conspicuous in the consequent vices that are produced in almost every part of the world; vices, that are continually involving both sexes in ‘inextricable unhappiness’. (1986, vol. 1, p. 28)

In admitting that prudential restraint might also be a cause of misery, he might have been speaking from personal experience, being in 1798 a 32-year-old bachelor with an income as a curate insufficient to support a wife and family in a socially acceptable manner.

In the second and later editions, he introduced the expression ‘moral restraint’, by which he meant prudential restraint conducted in accordance with Christian moral precepts regarding premarital sex, but the concept of moral restraint is implicit in the first edition. It is unlikely that, in advocating prudential restraint, Malthus as a Protestant clergyman would have intended to condone prudential restraint that was accompanied by immoral sexual behaviour.

In the second (and later) editions of the Essay, he softened some of the harshest conclusions of the first by arguing that, if people could be made aware of the harm done by improvident procreation, then moral restraint, though still a difficult challenge, could be practised without causing misery and without leading to vicious practices. He objected to contraception on moral grounds and also because, by facilitating control of the birth rate and reducing the pressure of population, it would remove one of the incentives needed to overcome our natural indolence, to promote economic growth, and to encourage the ‘growth of mind’. It is ironical that the expression ‘Malthusian practices’ became synonymous with contraception, and that contraception has become the method most commonly adopted throughout the world to control population. The world has responded to Malthus’s warnings of the danger of overpopulation by adopting a remedy he strongly rejected.

**Arguments in favour of population growth**

The popular and superficial view of Malthus is that he was opposed to population growth. But there are numerous instances in his writings which show that he regarded an increase of population, under certain conditions, as desirable in itself, and as a necessary cause of economic growth. For example, he spoke of the ‘pursuit of the desirable object of population’ (1986, vol. 3, p. 455); and, referring to the possibility of a great increase of population in Ireland in the 19th century, he said ‘so great an increase of human beings, if they could be well supported, would be highly desirable’ (1986, vol. 4, p. 32). In a similar vein he said: ‘That an increase of population, when it follows in its natural order, is … a great positive good in itself, … I should be the last to deny’ (1989a, vol. 1, p. 439). And those who use Malthus to support a policy of population reduction forget that on one occasion he argued that a diminution of population would be harmful: ‘It is evidently therefore regulation and direction which are required with regard to the principle of population, not diminution or alteration’ (1989a, vol. 2, p. 94).

Some of his most forceful statements in favour of population growth occurred in the appendices added to the third (1806) and fifth (1817) editions of the Essay, in response to critics who had accused him of being anti-population. The fact that these appendices have been omitted from some modern reprints of the Essay might explain the limited awareness of his pro-population ideas.
Malthus's pro-population views can even be seen when he was advocating prudential restraint: ‘Prudential habits with regard to marriage carried to a considerable extent, among the labouring classes of a country mainly depending upon manufactures and commerce, might injure it’ (1989b, vol. 1, p. 236; vol. 2, p. 215). This is a surprising argument, given that he had said that the preventive check of prudential restraint should be a principal remedy for overpopulation. It shows that he wished the doctrine of proportions to be applied as a check to the preventive check! Malthus’s pro-population views can also be seen in his statements on population as a necessary cause of economic growth. He admitted that population growth alone will not promote economic growth; for example, he argued that ‘the increase of population alone … does not furnish an effective stimulus to the continued increase of wealth’ (1989b, vol. 1, pp. 347–8), ‘population alone cannot create an effective demand for wealth’ (1989b, vol. 1, p. 350) and ‘encouragements to population … will not alone furnish an adequate stimulus to the increase of wealth’ (1989b, vol. 1, p. 351). But he also stated:

That a permanent increase of population is a powerful and necessary element of increasing demand, will be most readily allowed. (1989b, vol. 1, p. 347; in the second edition, ‘permanent’ was changed to ‘continued’)

and

That an increase of population, when it follows in its natural order, is … absolutely necessary to a further increase in the annual produce of the land and labour of any country, I should be the last to deny. (1989a, vol. 1, p. 439)

In other words, although Malthus recognized that population growth is not a sufficient cause of economic growth, he nevertheless regarded it as a necessary cause.

In some circumstances, according to Malthus, an increase in population will bring about a decrease in living standards; but in other circumstances it will bring about an increase in living standards, and a decrease in population will bring about a decrease in living standards. Living standards can be both a direct and an inverse function of population. Some critics would regard this as self-contradictory, as proof of his lack of logic, and as a justification for William Cobbett's epithet ‘muddle-headed Malthus’. Others would see it as a reasonable, parabolic application of the doctrine of proportions.

Theological aspects of the principle of population

The early chapters of the first edition of the Essay have a rather pessimistic tone. They appear to be saying that the pressure of population against the food supply will keep the mass of the population at or near subsistence level, and that this struggle between food and population will be accompanied by miseries and vices. However, in the last two chapters of the first edition of the Essay Malthus explored the theological implications of his principle of population. His published contributions in theology are too limited for him to be considered as a theologian in a professional sense, but his theological views are interesting in their own right, because of their heterodox nature, and because they seem to have been presented, not as a mere afterthought or pious homily, but in an attempt to integrate his principle of
population into a comprehensive world view, in opposition to that of Godwin and Condorcet. As a Christian minister he would have been concerned to show that his view of population did not conflict with Christian ideas about the nature of God. He had due cause for concern. In saying that misery and vice can come from obeying the biblical injunction to go forth and multiply, he was accused by some critics of blasphemously denying the Creator's omnipotence, omniscience and benevolence. However, in the last two chapters of the first edition of the Essay he argued, on the contrary, that population pressure is providentially ordained by God as a means whereby human development (‘the growth of mind’) is stimulated. He argued that the constant pressure of population against food supply, although it might produce some moral and physical evils, would also produce an overbalance of good. The first edition of the Essay thus finished on a note of moral and theological optimism.

The last two chapters were omitted from subsequent editions of the Essay. Comments contained in his correspondence (1997, pp. 73–7) and remarks from other contemporaries indicate that the omission occurred at the instigation of friends. Some commentators interpret the omission as a recantation. Others find traces of his theology in the later editions, and argue that his growth-of-mind theology remained an essential, if only implicit, framework throughout all editions of the Essay. They argue that to ignore its theological aspect is to ignore an essential element of his total population theory and, contrary to his intentions, to reduce the Essay to a mere economic or political tract.

**Poor Laws**

Although Malthus believed that population pressure was a phenomenon common to most societies, he argued that the problem had been exacerbated in England by the Poor Laws. They were intended to alleviate poverty, but only succeeded in creating the poor they sought to maintain. They encouraged people to marry too early and have large families, in the expectation that food and accommodation would be provided for them; and they discouraged hard work and the development of productive skills. In his earlier writings Malthus had argued for abolition of the Poor Laws, both as a principle and as a practical policy; but in later writings and in correspondence (see James, 1979, p. 450; Winch, 1996, pp. 320–1) his position moved from complete abolition to gradual abolition, and then to administrative reform, arguing that a fundamental change involving complete abolition would present practical and political difficulties, and that the most that could be achieved in the current circumstances would be an amelioration of the present system through improved administration. This is an example of his insistence on the need for limitations and exceptions in the practical application of general principles. He did not see any contradiction in subscribing to the idea in principle while at the same time rejecting it as a practical policy for a particular place and time. Another example of this feature of his methodology occurred in his views on the Corn Laws.

**Corn Laws**

Although Malthus strongly supported the principle of laissez-faire, he published a pamphlet in 1815 supporting the retention of the Corn Laws which prohibited for example, the import of wheat when the home price fell below 80 shillings a quarter. This radical departure from laissez-faire caused dismay among other political economists and among his Whig friends who opposed the protectionist policy of...
the Tory government. In admitting this exception to the principle of laissez-faire, he was in effect reaffirming his view that, unlike the laws of mathematics, the principles of political economy should not be applied in an absolutist and universalist manner.

It has been argued that in his later years Malthus changed his mind and recanted his earlier support for the Corn Laws. The arguments for and against this change-of-mind hypothesis have been elaborated elsewhere (Hollander, 1992; 1995; Pullen, 1995), and are too detailed to be repeated here. It would probably be fair to say that, on the basis of the textual and contextual evidence so far presented, there is no clear, unambiguous statement of a recantation by Malthus. But it should also be said that Malthus was strongly in favour of the principle of free trade, and that he strongly regretted the need for an exception in the case of the Corn Laws. It is obvious from his writings and correspondence that, if the circumstances that necessitated the exception were removed, he would have gladly removed his support for agricultural protection.

Economic growth, effective demand and Say’s Law

Malthus’s views on economic growth are to be found scattered throughout his many publications, with his most systematic (but not comprehensive) treatment of this topic in the final chapter of the Principles, namely. chapter 7, ‘On the Immediate Causes of the Progress of Wealth’. He divided the immediate causes of progress into two categories: ‘the powers of production’ and ‘the means of distribution’. On the production side he discussed four causes: population, accumulation, soil fertility and inventions (which, by combining the second and the fourth, could be reclassified as labour, capital and land). On the distribution side he discussed three causes: the division of landed property, commerce (internal and external), and unproductive consumers. His views on the production side were unremarkable at the time, and would be quite acceptable in standard texts today, but his views on the distribution side have proved to be controversial because of their emphasis on the role of effective demand.

By effective or effectual demand Malthus meant the power to purchase at a price sufficient to cover the vendor’s costs and required profit, combined with the willingness to purchase. His distinction between power and will, or means and motives, was a recurring theme in his political economy. He stressed that production requires more than the power to produce; it requires also the motive to produce, which comes from effective demand.

... the powers of production, to whatever extent they may exist, are not alone sufficient to secure the creation of a proportionate degree of wealth. Something else seems to be necessary in order to call these powers fully into action. This is an effectual and unchecked demand for all that is produced. (1989b, vol. 1, p. 413; vol. 2, pp. 263, 447)

The powers of production will be ‘called into action, in proportion to the effective demand for them’ and ‘General wealth, like particular portions of it will always follow effective demand (1989b, vol. 1, pp. 414, 417). In effect he was saying that demand-side forces are as powerful and as necessary as the supply-side forces of natural resources, capital accumulation, division of labour, and so on. He believed that an important cause of an adequate level of effective demand was the existence of a body of ‘unproductive consumers’, who purchase material products but do not produce material
products. They would include menial servants, military personnel, actors, clergymen and other service providers. The concept was completely misunderstood by Ricardo who said that unproductive consumption is as useful as a fire in a warehouse or the destruction of war. Malthus later recognized that the term ‘unproductive’ had pejorative implications, and altered it to ‘the provision of services’. However, the concept could also include those who live on their investments in the national debt and those whose wealth enables them to consume without either producing material goods or providing services, thus inviting Marx's description of Malthus as a protector of the ruling classes and the idle rich.

Malthus's views on effective demand were largely rejected during his lifetime, and largely ignored for the next hundred years. It was generally believed with James Mill, Jean-Baptiste Say and others that the purchasing power generated during the production process would be sufficient for all the products to be sold, that aggregate demand deficiency would never be a cause of economic decline, and that a general glut of products would be impossible. This view, known as Say's Law or Mill's Principle, and popularly expressed as ‘supply creates its own demand’, became a standard theme of classical economics, and still finds its supporters, even though Malthus showed, and Say virtually admitted, that its validity relies on a tautological definition of ‘supply’ and ‘product’. The experience of the depression of the 1930s and the publication of J.M. Keynes's *General Theory* (1936) cast doubt on this conventional wisdom of Say's Law, and rescued Malthus's views on effective demand from oblivion.

**Effective demand and the division of landed property**

Malthus's views on effective demand as a stimulus to economic progress led him to advocate a wider distribution of wealth, because ‘Practically it has always been found that the excessive wealth of the few is in no respect equivalent, with regard to effective demand, to the mere moderate wealth of the many’ (1989b, vol. 1, p. 431). But this redistribution of property has often been neglected, and sometimes even denied, in the secondary literature. Karl Marx, in particular, misinterpreted Malthus in this regard, and some other commentators appear to have taken their views of Malthus from Marx; and, like Marx, have not bothered to test them against Malthus's text.

Admittedly, there are passages in some parts of Malthus's writings that support a pro-landlordism interpretation. But in other passages he was critical of the distribution of land and other property, and described the existing maldistribution as unjust and as an impediment to economic growth; for example

> A very large proprietor, surrounded by very poor peasants, presents a distribution of property most unfavourable to effective demand … Thirty or forty proprietors, with incomes answering to between one thousand and five thousand a year, would create a much more effective demand for wheaten bread, good meat, and manufactured products, than a single proprietor possessing a hundred thousand a year. (1989b, vol. 2, 373–4)

In his view, ‘the division of landed property is one of the great means of the distribution of wealth’, and without ‘an easy subdivision of landed property … a country with great natural resources might slumber for ages with an uncultivated soil, and a scanty yet starving population’ (1989b, vol. 1, pp. 439–40).

He did not propose that either private property in land or the class of landed proprietors should be abolished. He regarded both as necessary. But he did not regard ‘the present great inequality of property’
as ‘either necessary or useful to society’; and added that ‘On the contrary, it must certainly be considered as an evil, and every institution that promotes it is essentially bad and impolitic’ (Malthus, 1986, vol. 1, p. 102). Less inequality in land ownership would mean that rents would be enjoyed by a larger number of proprietors.
However, he did not wish the division of property to be pushed too far:

> The division and distribution of property, which is so beneficial when carried only to a certain extent, is fatal to production when pushed to extremity. (1989a, I, 372)

This argument is an excellent illustration of his characteristic middle-way methodology. He himself regarded the question of the division of property as the most important application of the doctrine of proportions.

> It will be found, I believe, true that all the great results in political economy, respecting wealth, depend upon proportions … But there is no part of the whole subject, where the efficacy of proportions in the production of wealth is so strikingly exemplified, as in the division of landed and other property; and where it is so very obvious that a division to a certain extent must be beneficial, and beyond a certain extent prejudicial to the increase of wealth. (1989b, vol. 1, pp. 432–3)

### Distribution as a factor of production

Other writers, before and after Malthus, have discussed production and distribution, but generally their approach has been to regard distribution as the process whereby the proceeds of production are shared out after they have been produced by the factors of production. Their theory of distribution is worked out independently of their theory of production.

Malthus also looked at the problem of distribution in this way, with separate chapters analysing the way in which wages, profits and rents are determined. But in addition he looked at distribution from another direction. For Malthus, distribution is not merely concerned with sharing out the spoils of production. It has a further function. It is an essential determinant of production, and an integral part of the production process considered in its totality. Without a proper distribution, there would be no production – except at a self-subsistence level. He saw distribution as a problem to be resolved before (as well as after) production takes place. Whereas others were concerned mainly with how the distribution of the product between wages, profits and rent is affected by economic development, Malthus made a major contribution by stressing that the distribution of the product in turn affects economic development. He was in effect saying, if not in these precise words, that distribution must be regarded as a factor of production, along with the conventional listing of the other factors of production – land, labour and capital. They represent only the supply side of the production process; but, if production is to occur, there must be a motive to produce as well as the means. In an exchange system, there will be no motive for producers to produce unless there are prospects of profits, and there will be no profit prospects unless there is an adequate effective demand for the products. This effective demand from potential consumers will not be forthcoming unless there has been a proper distribution of spending power. As Malthus said,
there is certainly no indirect cause of production as powerful as consumption’ (1989b, vol. 2, p. 34).

The effective demand generated by a proper distribution provides demanders with the power or means to
demand, and this provides suppliers with the will or motive to supply. It is obvious that, unless there has
been production, there can be no distribution. But Malthus insisted that maximum production will not be
achieved unless an optimum spread of distribution is established.

The separation and dichotomy between production and distribution that is presented in typical textbooks
would therefore have been unacceptable to Malthus, for whom any listing of the factors of production
would have to include distribution. It is this relationship of reciprocal causation between distribution and
production that makes Malthus's theory of distribution innovative and distinctive.

Saving, investment and hoarding

Some commentators have interpreted Malthus as holding that savings are always invested; and have
concluded that in Malthus's theory saving is not a leakage from the circular flow, does not constitute a
reduction in effective demand, is not an impediment to economic growth, and must always be beneficial.
In this respect, they see a major difference between Malthus and Keynes. They deny the claim that
Malthus was a precursor of Keynes, and argue that Keynes was mistaken in regarding Malthus as a
precursor. This interpretation appears to have been based in part on statements such as:

it is stated by Adam Smith, and it must be allowed to be stated justly, that the produce
which is annually saved is as regularly consumed as that which is annually spent, but that
it is consumed by a different set of people. (Malthus, 1989b, vol. 1, p. 31)

Malthus appears here to agree with Adam Smith that savings will always find an outlet in investment,
and that there will never be a surplus of savings over investment. However, that interpretation is
doubtful, given that ‘and it must be allowed to be stated justly’ was omitted from the second edition of
the Principles (see Malthus 1989b, vol. 2, pp. 28, 300–1). Ricardo in his Notes on Malthus had said that
a saving-equals-investment interpretation is inconsistent with the views expressed elsewhere by Malthus
on saving. It would be reasonable to conclude that the omission was made by Malthus in response to

Another possible source for attributing a saving-equals-investment view to Malthus might be Malthus's
statement ‘No political economist of the present day can by saving mean mere hoarding’ (1989b, vol. 1,
p. 32). Some commentators have interpreted this to mean that, in Malthus's view, savings are always
invested, never hoarded, and never intended to be hoarded. If correct, such an interpretation would also
constitute a major difference between Malthus and Keynes.

But there is another, more plausible, interpretation. Malthus here was not saying that savings are never
held as idle cash balances. He was not precluding the possibility that savings might remain uninvested
and idle, not on purpose but because a satisfactory investment outlet cannot be found. This alternative
interpretation negates a saving-equals-investment interpretation.

There are numerous instances in Malthus's writings that support this alternative interpretation. They
clearly show that, in his view, savings will not always be invested, and that excessive savings are
harmful. For example, Adam Smith had said that ‘every frugal man [appears to be] a publack benefactor’
and that the increase of wealth depends on a favourable balance of production over consumption (Smith, 1776, book II, ch. 3, para. 25; book IV, ch. 3, iii, para. c.15), but Malthus disagreed:

That these propositions are true to a great extent is perfectly unquestionable … but it is quite obvious that they are not true to an indefinite extent. (1989b, vol. 1, 8)

To say that Malthus identified or equated saving and investment is to ignore his frequent use of expressions such as redundant capital, excessive capital, idle capital, spare capital, premature supply of capital, unemployed capital, vacant capital, capitalists at a loss where they can safely employ their capitals, capitals at a loss for employment, and so on. These expressions refer to funds that arise through savings and are intended for investment but for which an actual investment, at an acceptable degree of profit and risk, cannot be found. Malthus was thus recognizing the possible existence of an inequality between \textit{ex ante} or intended investment and \textit{ex post} or actual investment, because of the exhaustion of profitable investment outlets. This gap between savings intended for investment and savings actually invested could be described as unintended or residual hoarding – although Malthus did not use those terms – as distinct from the intended hoarding of a miser, or ‘mere hoarding’.

**Malthus and Ricardo**

The correspondence between Malthus and Ricardo provides a revealing insight into the minds and characters of two of the most important contributors to the development of political economy in England during its formative years in the early 19th century (see Ricardo, 1951–73, vols 6–9). They expressed their arguments forcefully but politely, although at times hints of frustration and exasperation began to appear, as they struggled to comprehend and to counter the other's point of view, especially when in an era without carbon copies and photocopies they seemed to forget what they had previously written. And despite their doctrinal and methodological differences, they remained close friends, with frequent visits to one another's homes. Ricardo's last letter to Malthus concluded with the statement: 'I should not like you more than I do if you agreed in opinion with me' (Ricardo, 1951–73, vol. 9, p. 382); and Malthus, after the death of Ricardo, was reported to have said: 'I never loved any body out of my own family so much' (Empson, 1837, p. 489). Ricardo had offered to assist Malthus financially by investing money for him in a stockbroking venture; and at one stage Malthus might have been seriously considering a personal involvement in international trading in commodities and bullion, using statistics and advice provided by Ricardo (see Malthus, 2004, ch. 3). After Ricardo's death, Malthus defended him against critics who Malthus considered had gone too far in their criticisms; and, in lectures read to the Royal Society of Literature in 1825 and 1827, Malthus developed a theory of value which, while maintaining his previous emphasis on demand and supply as determinants of value, gave greater recognition to Ricardo's emphasis on the cost of production (Malthus, 1986, vol. 7, pp. 301–23).

Opinions differ on who was the greater economist – Malthus or Ricardo. Who made the more significant contributions to the development of economics? On the one hand there are those who see Malthus as muddle-headed, and Ricardo as the better logician. On the other hand, there are those who reject the claim that Ricardo was a better logician, and who argue that Malthus's understanding of the multi-causal complexity of the real world was of far greater value to the progress of economics than Ricardo's
abstract theorizing. The most famous member of the latter group, J.M. Keynes, said that the world would be ‘a much wiser and richer place’ if ‘Malthus, instead of Ricardo, had been the parent stem from which nineteenth-century economics proceeded’; and that ‘the almost total obliteration of Malthus’s line of approach and the complete domination of Ricardo's for a period of a hundred years has been a disaster to the progress of economics’ (Keynes, 1933, pp. 120, 117).

The Malthusian economy was the economic system that characterized almost all economies before the industrial revolution. In this regime fertility and mortality rates at different material income levels determined the average real income level and life expectancy at birth. Thus before 1800 the improvement of production technologies resulted only in population growth, and not in any gains in material living conditions beyond those that were found in the original hunter gatherer societies.

Article
The Malthusian economy is the economic system which prevails whenever a society's production technology advances so slowly that population growth forces incomes down to the subsistence level. In such an economy material welfare is independent of natural resources, technology and capital accumulation, but instead depends solely on the factors governing fertility and mortality. The resulting subsistence income can, however, vary widely across societies. Some Malthusian economies were rich by the standards of most countries in modern Africa, for example.

Almost all societies until 1800 were Malthusian, from the original foragers of the African savannah 50,000 years ago down through settled agrarian societies of considerable sophistication such as England, France, China and Japan in 1800. The operation of all human societies through history up until the Industrial Revolution can thus seemingly be described by this one simple economic system. An implication of this is that there was most likely no gain in material welfare between the evolution of anatomically modern humans and the onset of the Industrial Revolution.

Government actions, in so far as they change fertility or mortality, can influence material welfare in the Malthusian economy, but in a contradictory fashion. Good governments that reduced mortality through order and security made people poorer. Bad governments that increased mortality through warfare and banditry made them wealthier.

The economic logic of these societies was first, though only partially, appreciated by Thomas Malthus in his famous Essay on a Principle of Population of 1798. Malthus's insights were elaborated by writers such as David Ricardo and James Stuart Mill into the system called classical political economy in the early 19th century. Ironically, this intellectual development happened just as for the first time the rate of technological advance was becoming sufficiently rapid to bring the Malthusian era to a close.

Insight into the Malthusian economy starts from the insight that the biological capacity of women to produce offspring is much greater than the number of births required to reproduce the population. If fertility is unrestricted women can have 12 or more children. Social institutions regulating marriage and contraceptive practices will determine the actual numbers of births per women. In modern societies these institutions and practices vary greatly, so the number of births per women varies greatly. Completed fertility now ranges across the world from a low of 1.15 in Spain to a high of 8.0 in Niger. Only where women happen on average to have two children who survive to adulthood will population be stable. Even small deviations from this number will cause rapid increases or decreases in population. Thus modern populations are not stable.

Despite this potential for explosive population growth, pre-industrial populations were remarkably stable over the long run. The average annual growth rate of world population from 10,000 years bc to ad 1800 was 0.05 per cent. The typical woman before 1800 thus had 2.02 children who survived to reproductive age. As an extreme case the population of Egypt,
Malthusian economy: The New Palgrave Dictionary of Economics

for example, is estimated at between four million and five million at 1000 years bc. The population in Greek and Roman Egypt a millennium later is estimated at this same four million to five million. The first modern census in 1848 suggests a population of 4.5 million. Thus over nearly 3,000 years the Egyptian population growth rate was to a close approximation zero, and women on average had two surviving children. Yet it is estimated that in Roman Egypt the average woman gave birth to six children. Some mechanism kept fertility and mortality in balance in these pre-industrial economies.

The Malthusian equilibrium

The simple Malthusian model of how pre-industrial society functioned supplies an economic mechanism to explain its population stability. In its simplest version there are just three assumptions:

1. The birth rate, the number of births per year per thousand people, is a socially determined constant, independent of material living standards. Birth rates will vary across societies, but in this simplest model they are assumed to be independent in any given society of material living conditions.
2. The death rate, the number of deaths per year per thousand persons, declines as material living standards increase. Again, the death rate will differ across societies depending on climate and lifestyles, but it assumed that in all societies it will decline as material living conditions improve.
3. Material living standards decline as population increases.

Figure 1 shows the first two assumptions of the simple Malthusian model in graphical form in the upper panel. The birth and death rates are plotted on the vertical axis, material income per capita on the horizontal axis. The first two assumptions of the simple Malthusian model imply that there is only one level of real incomes at which the birth rate equals the death rate, denoted as $y^*$. And this constitutes a stable equilibrium. Thus $y^*$ is called the ‘subsistence income’ of the society: it is the income at which the population barely subsists, in the sense of just reproducing itself. This subsistence income is determined without any reference to the production technology. It depends only on the factors which determine birth and death rates. Once we know these factors we can determine the subsistence income.

Figure 1
Long-run equilibrium in the Malthusian economy
Another aspect of human welfare is life expectancy at birth, that is, the average number of years a person will live. In the Malthusian era life expectancy at birth also depended only on the factors determining birth and death rates. This is because with a *stable* population, where annual births have equalled deaths for a long time, life expectancy at birth is the inverse of the crude birth rate. With fertility not restricted in any way crude birth rates would be 50–60 per thousand in pre-industrial populations (based on modern experience). This would imply a life expectancy at birth of 20 years or less.

The term ‘subsistence income’ can lead to the confused notion that in the Malthusian economy people were always living on the edge of starvation. In fact, in almost all Malthusian economies the subsistence income was considerably above the income required for the physiological minimum daily diet. All pre-industrial societies for which we have good demographic records limited fertility below the biological maximum. Differences in the location of the mortality and fertility schedules generated subsistence incomes at very different levels. Thus, both 1450 and 1650 were periods of population stability in England, and hence periods where by definition income was at subsistence. But the wage of unskilled agricultural labourers was equivalent to about 6 lb of wheat flour per day in 1650, compared with 18 lb in 1450. Even the 1650 unskilled wage was well above the physiological minimum. A diet of about 1.33 lb of wheat flour per day would keep a labourer alive and fit for work (it would supply about 2,400 calories per day). Thus, pre-industrial societies, while they were subsistence societies, were not starvation regimes. England in 1450, indeed, was wealthy even by the standards of many modern societies such as those in sub-Saharan Africa.

The bottom panel of Figure 1 illustrates the third assumption. The panel has on the vertical axis the population, \( N \), and on the horizontal axis the material income. As population increased material income per person by assumption declined. The justification for this assumption is the law of diminishing returns. Since one important factor of production, land, is always in fixed supply in pre-industrial economies, the law of diminishing returns implies that average output per worker fell as the labour supply increased as long as the technology remained static. Thus the average amount of material consumption available per person fell with population.

Figure 1 also shows how an equilibrium birth rate, death rate, population level and real income were arrived at in the long run in a pre-industrial economy. Suppose we start at an arbitrary initial population \( N_0 \) in the diagram, greater than \( N^* \). This generates an income \( y_0 \), above the subsistence income. At this income the birth rate exceeds the death rate, so population grows until income falls to \( y^* \) and population equals \( N^* \).

### Changes in the birth rate, death rate and ‘technology’ schedules

Suppose that the birth rate schedule in Figure 1 was higher. Then at the equilibrium, real income would be lower, and the population greater. Thus any increase in birth rates in the Malthusian world drove down real incomes and reduced life expectancy. Conversely, anything which limited birth rates drove up real incomes and increased life expectancy. Thus in the pre-industrial era birth rates were a crucial determinant of material living conditions.

If the death rate schedule was higher, so that at each income there was a higher death rate, then the equilibrium real income would be higher. But if the birth rate was not responsive to income then a greater death rate increased real incomes but in the long run had no effect on the annual death rate or on life expectancy at birth. Thus in this simplest Malthusian model higher mortality risks at a given income were unambiguously a good thing, at least in the long run.

The simple Malthusian world thus exhibits an almost counter-intuitive logic. Anything that raised the death rate schedule, the death rate at a given income, such as war, disorder, disease or poor sanitary practices, increased material living standards without changing life expectancy at birth. Anything that reduced the death rate schedule, such as advances in medical technology, or better public sanitation, or public provision for harvest failures, or peace, reduced material living standards without any gain in life expectancy at birth.

While the real income was determined from the birth and death schedules, the population size depended on the schedule linking population and real incomes. Above I labelled this the ‘technology’ schedule, because in general the major cause of changes in this schedule has been technological advances. But other things could shift this schedule – a larger capital stock, improvements in the terms of trade, climate improvements, and a more productive organization of the economy. A shift upwards in this schedule, in the short run, since population can change only slowly, would have increased real incomes. But the increased real incomes reduced the death rate, so that births exceeded deaths and population began...
The growth of population ended only when the income returned to the subsistence level, \( y^* \). At this new equilibrium the only effect of the technological change was to increase the population supported. There was no lasting change in the living standards of the average person.

**More complicated Malthusian models**

An issue that has exercised historical demographers is whether the birth rate in pre-industrial societies was ‘self-regulating’. What they mean by this is shown in Figure 2, which shows the birth and death schedules of a simplified Malthusian model, as well as a modified birth schedule, which slopes upwards with material incomes. In the modified Malthusian model it is assumed that in good times people married earlier and more people married, so that fertility increased, whereas in bad times fewer married, and they married later, so that fertility declined.

**Figure 2**

A Malthusian model where births increase with income
It should be clear that a positive association of fertility and income does not change the basic equilibrium of the model. The only difference is that increases in the death rate at any given material income are now not so unambiguously good, since they will be associated with higher fertility and mortality rates and hence lower incomes. The evidence for societies such as pre-industrial England, however, shows no response of fertility to income (Wrigley et al., 1997). Thus the simple model may well describe pre-industrial societies well.

What causes many more potential complications is a birth schedule that declines with material incomes. Suppose that as real incomes go up one of the responses of people is to desire fewer children. With a birth rate that declines with real incomes the model could have multiple crossings between the birth rate and death rate schedules. At those places where the birth rate schedule was declining more steeply than the death rate schedule the equilibrium would be unstable. Figure 3 gives a declining birth rate schedule that twice intersects the death rate schedule. The intersection at the lower real income, $y_0$, is a stable equilibrium. But the second higher income equilibrium at $y_1$ is unstable. If real incomes drop below this level by any amount then population starts to grow, leading real incomes all the way down to the stable equilibrium at $y_0$. Conversely if they increase at all above $y_1$ then deaths will exceed births and real incomes continue to grow indefinitely. The population will fall eventually to zero.

Figure 3
A Malthusian model where births decline with income
In this case there is a ‘Malthusian trap’ in the pre-industrial economy. A society can be stuck in the subsistence income equilibrium unless some jolt such as acquiring extra land, experiencing a much higher death rate, or experiencing faster technological progress pushes up wages enough so that fertility falls permanently. The shock of the Black Death, however, which tripled real incomes for the poorest workers in England by 1450, did not lead to any permanent movement towards lower fertility and the escape from the Malthusian trap. Again, the evidence for pre-industrial demography suggests no declines in fertility with higher incomes.

The empirical implications of the Malthusian model

The most interesting empirical implication of the Malthusian model is that material living conditions for people, including life expectancy at birth, may well have been unchanged between the dawn of humanity and ad 1800. Were the people in sophisticated societies such as England, France, the Netherlands, Japan and China in 1800 really no better off than the original hunter-gatherers? This seems particularly counter-intuitive for England, reckoned to be the richest country the world by 1800.

By then England was a society that would not seem that different from our own. The middle and upper classes in London breakfasted at coffee shops as they read the daily newspapers. They dwelled in homes of brick and glass with water supplied by lead pipes, lighted at night by oil harvested from sperm whales taken thousands of miles away in the oceans. There was extensive trade for luxury products from the tropics – cottons, silks, spices. How could the material condition of humanity not be better then than in the savage past when our ancestors faced the elements naked, and sought shelter at night in depressions in the ground or in crude lean-tos?

But even in England in 1800 the living conditions of the mass of the population were still primitive. The largest employment was still agriculture, where the average day wage in 1800–9 was the equivalent of 5.7 lb of wheat flour. This was enough to keep a family fed only if most of the income was spent on the cheapest forms of food such as bread. Farm labourers lived in simple structures little better than those of the medieval period. They slept when it was dark because they could not afford lighting. They could afford one new set of clothing per year. English farm labourers six hundred years before, in 1200–9, received a wage which was the equivalent of 12 lb of flour, significantly more than in 1800. And at the best time for pre-industrial workers in England, circa 1450, when the population losses of the plagues which ravaged Europe from 1348 on were their greatest, the real wage was much higher, equivalent to 18 lb of flour. In the years 1200–1800 in England there is no sign of long-run gains in real wages for the mass of workers. We know also the real day wage of farm workers in Roman Egypt circa ad 250 was the equivalent of 5 lb of flour, not much less than England in 1800.

How did English material living conditions around 1800 compare with hunter-gatherer societies such as those that constituted society through the great bulk of human history? We can obtain insight on this in two ways. The first is by comparing living conditions in England in 1800 with those of the few surviving hunter-gatherer groups. Since the diets were very different here we have to use measures such as the number of calories consumed per person per day. In 1787–96 for the families of English farm workers this was a meagre 1,508 calories. For a group of eight hunter-gatherer societies studied in the 1960s to 1980s the average consumption was 2,272 calories, much better than for England. On this measure the English on the eve of the Industrial Revolution seem to have lived less well than the average hunter-gatherer. Another aspect of the quality of life is life expectancy at birth. One measure of this is the fraction of infants that survived the first year of life. In England as a whole this is estimated at 83 per cent in the second half of the 18th century. For modern hunter-gatherer societies survival rates were a little lower at 79 per cent. But this is still not that much lower than for the richest society in the world in 1800. And survival rates for infants in London, the richest part of England, were only 70 per cent because of the health hazards of city life.

A second measure is the average stature of people. Height is a good index of material living conditions, since it depends on both food consumption and the amount of sickness people experience as they grow. Average heights for adult males in England circa 1800 were 67 inches or less. This was very good by the standards of societies just before industrialization. Average male heights in Japan in the late 19th century were 61 inches and in India in the early 19th century 64 inches. Yet these heights in England are little if any better than those recorded from skeletons of hunter-gatherers in the Mesolithic (10,000–5000 bc) and Neolithic (5000–1000 bc) in Europe. Average male height from these skeletons is estimated at 66 inches. So overall, if we look at agrarian societies across the world in 1800 ad, the stature evidence suggests a decline in living conditions from hunter-gatherer society.
Thus, the evidence is that for the mass of humanity on the eve of the Industrial Revolution living conditions were no better and probably worse than in the hunter-gatherer past.

Article

A merchant of English parentage, born in Antwerp at an unknown date, Malynes was a commissioner of trade in the Low Countries about 1586. He came to London and was frequently consulted on commercial questions by the Privy Council in the reigns of Elizabeth I and James I. He became an assay master at the mint and obtained a patent to supply farthings; he was imprisoned for a time, complaining later that he had been ruined by being paid in his own coins. He also served as a spy for England. Called on by the standing commission on trade for evidence on the state of the coinage, he published a series of pamphlets on money and prices. A mercantilist and a bullionist, he was heavily influenced by Scholastic literature. Malynes viewed individual commodity prices as determined by demand and supply. However, he was more interested in the price level, governed by the quantity of money (Malynes, 1601b; 1603). An expanding money supply, associated with a rising price level, decreased interest rates and stimulated the economy (1601b; 1622a). Therefore Malynes viewed usury as at best a necessary evil (see Muchmore, 1969, p. 346) and, above all, opposed any export of specie whatsoever.

Rejecting the balance of trade theory, Malynes charged that 'bankers' (exchange dealers) controlled the exchange rate (1601b; 1622a; 1622b; 1623). By their incorporation of usury in the price of a bill of exchange and through speculation, they conspired to undervalue sterling, leading to a deterioration in England's terms of trade (‘overbalancing’) and a specie outflow (1601b; 1622a; 1623). But overvalued sterling would not lead to a specie inflow, because the export proceeds would be spent on luxury imports (1601b). Yet Malynes (1601b) has a theory of price level changes in response to exchange rates differing from mint parity and money flowing between countries – a price specie-flow mechanism, marred only by the assumption of inelastic demand. His solution to the twin problems of specie outflow and terms of trade deterioration is comprehensive exchange control with enforced exchange dealings at rates fixed at
mint parities (Malynes, 1601b; 1622a; 1622b; Muchmore, 1969, pp. 347–8).

The Manchester School was the name given by Disraeli after the event to the leaders of the successful agitation conducted between 1838 and 1846 to abolish the Corn Laws. It is wrongly associated with the arch-advocacy of laissez-faire. The people of the School were not in fact united by any single idea, other than believing in the complete and immediate repeal of the tariff on grain. Within the School there were five discernible groups in the sense of there being five different reasons why people wanted repeal or purposes that directed them. Some were compatible with others, and one group could agree with another over what was important but differ over how important it was. The arguments that each group made do not, when taken together, constitute a cogent or even coherent whole but taken separately could be both, and are always interesting. Moreover, the campaign for repeal is itself an instructive event in the history of economic policy.

(1) One group was the mill-owners of Lancashire who provided most of the money for the campaign and formed the National Anti-Corn Law League to conduct it. Some believed that repeal, by reducing the price of bread, would reduce money wages, hence the cost of production in their mills. The belief comes from the Ricardian principle that real wages are constant in the long run. It could have made the businessmen believe the export of grain should be protected, since that too could reduce its price, hence have placed them in the interesting but not unusual position of half-believing in the free market. They in fact did not support protection because a greater reason for their wanting repeal was to increase the export of manufactured goods. The economic argument most often made was that importing more grain would provide foreigners with more income to spend on British exports, with the result that income and employment would increase at home. The mill-owners were repeatedly accused of simply wanting to cut wages. Cobden privately warned them to stay out of the repeal campaign if they could not come in with clean hands. Publicly he offered to support a Factory Bill of Lord Ashley – the ‘universal
Another economic argument for repeal was that it would retard the growth of manufacturing abroad and so keep Britain in its leading industrial position. Why the owner of a small mill would profit by his country's having more mills than any other was not made clear (although he might by way of an externality of some sort). The argument is nevertheless noteworthy. It was revived after 1945, when the undeveloped countries hastened to industrialize in the belief that doing so was a necessary condition of their progress. The argument is also part of the curious notion, entertained by historians, that Britain's free trade was an instrument of its imperialism. They reason that Britain, by keeping others in a non-industrial condition, could dominate them, exploit them, and/or make them dependent on it. Why one country would choose to be mistreated by another when it could choose a trading partner that did not mistreat it, as in a system of free trade it could do, is not explained. Or is there an explanation of why a dollar's worth of manufactured goods adds more to total welfare than a dollar's worth of goods that are not manufactured?

(2) Among the businessmen working for repeal were those who believed it would make life better for the lower classes. They have been called the humanitarian employers. They did more for their workers than the market or the law required, providing schools for the children, reading rooms and meeting places for the men and women, helping them to form friendly societies, cooperatives and cultural groups. Some employed a ‘salaried visitor’ (social worker) to call at the homes. These business people also undertook to improve the communities where they were established. One such effort was the Manchester Statistical Society which collected information on living conditions and used it to improve them. The Greg family stood out in this group.

(3) The radical businessmen, working on a larger scale than the humanitarians, aspired to improve the nation and the world. In economic affairs their great end was free trade and after the repeal of the Corn Laws they had a part in the abolition of the Navigation Laws. In politics they looked toward democratic government and worked to extend the franchise until all adult males had the right to vote. The radicals believed free trade would first increase the influence of the business classes, increase their members in Parliament, then (in a way not fully explained) increase the power of the working classes. John Bright was the leader of this group, which itself was the Manchester version of the middle-class radicalism of the time. It had a finger or a hand or more in most reform movements, great and small, from the abolition of slavery and removal of religious disabilities to the penny post and repeal of the taxes on knowledge. The radicals were disrespectful of authority, indifferent to custom, unmindful of the ridiculous figure they often cut, and they were meddlesome, tiresome, persistent and effective. Like Pancks, what they did, they did, they did indeed, and when they finished there were noble institutions in ruins.

(4) The Philosophic or London Radicals had a different place from that of the radical businessmen, grounding their reform on a considered application of Bentham's utilitarianism and conducting themselves in the mannerly, measured way that made them heard and respected but unheeded and ineffectual. They did not care for the rough and ready way of Manchester and had to be reminded of where they were before it took on the repeal of the Corn Laws. Before them, Charles Villiers, a leading Benthamite, had each year moved in the House that it constitute itself a committee of the whole to consider the repeal of the Corn Laws, and each year the motion was defeated. The leadership of the free trade bloc passed to Cobden when he became a Member of Parliament, an instance, his friends said, of
talent giving way to genius. Francis Place, who was on the edge of the London Radicals, put things plainly and said that when the Manchester people wanted something done they did it.

(5) Cobden represented the pacifists of the School. They believed that trading nations had a material interest in peace, an idea Ricardo had stated in his *Essay on Profits* in 1815, and that they were natural friends by virtue of meeting on the market, an idea Ricardo was too realistic to entertain. Oddly, the pacifists seem not to have noticed they could have drawn an argument from the *Wealth of Nations*. No pacifist himself, Smith said Britain should not engage in trade that would diminish its military power. The implication is that free trade makes nations unable to go to war as well as unwilling.

The pacifists, although not the largest group within the School, were even more influential than the radicals. Cobden wanted to graft the peace movement onto the repeal campaign although he would not permit the franchise to be so joined, as Bright wanted to do. After repeal, the franchise had more public support than the peace movement and grew until all adults had the vote. Nevertheless those who believe free trade is conducive to peace can and do point out that the 19th century was a time when trade was freer than ever and was the only century in recent history when there has not been a world war.

Cobden wanted free trade because it would bring peace, Bright because it would bring the franchise. Others in the School had each of them his own purpose. They made common cause for seven years until the Corn Laws were brought down, then returned to their separate ways.

The Manchester School was a coalition around a single issue. It was not a group of ideologues committed to laissez-faire, as historians have carelessly said, nor did it express the pure spirit of the middle class, as some contemporaries believed. It was not a rent-seeking force, as Public Choice economists are tempted to say, nor did it preach the principles of huckstering (Disraeli), nor were its leaders 'bartering Jews' (Engels), nor were they 'the official representatives of the bourgeoisie' (Marx). If the Manchester School is to be described simply, it was a remarkably successful effort to remove a major obstacle in the way of the market.

mandated employer provision of employee benefits

Jonathan Gruber
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Mandated employer provision of social benefits is of rising importance in the United States. As highlighted by Summers (1989), the efficiency losses from such mandates may be much lower than those of taxation due to tax–benefit linkages. I review the theory underlying this observation and the empirical evidence which documents full shifting to wages (and therefore little efficiency cost) of mandated benefits. A host of important questions about mechanisms remains unanswered, however.

Keywords

adverse selection; anti-discrimination law; cost shifting; health insurance; labour supply; mandating employer provision of employee benefits; minimum wages; payroll taxation; unemployment insurance; workers’ compensation insurance

Article

The provision of social benefits can be financed in a number of different ways: through broad income taxation, through taxation of payroll only, or through mandates on employers to provide those benefits for their employees. The last channel is one of sizable and growing importance in the United States, although less so in other nations that tend to rely more on tax-financed government provision. Yet, until the late 1980s, the impacts of mandates were not much studied. The implicit assumption in economic analysis was that such mandates could be analysed using the standard tools of tax incidence and efficiency.

A very influential article by Summers (1989) changed all that. Summers pointed out that mandating employer provision of benefits to their employees had two effects on labour market equilibrium. On the one hand, a reduction in labour demand naturally accompanies the imposition of extra costs on employers. On the other hand, however, mandates should also cause an outward shift in labour supply, since individuals are now being effectively compensated more highly for their labour; they are receiving
mandated employer provision of employee benefits: The New Palgrave Dictionary of Economics

their previous compensation plus the mandated benefit. This shifts more of the costs of benefits to workers and reduces the deadweight loss from their provision. Indeed, as Summers pointed out, if employees valued the mandated benefit at its cost to the employer, then these supply and demand shifts would be equal. The end result would be ‘full shifting to wages’: a decline in wages by exactly the cost of the benefit with no impact on total labour supplied to the market and no efficiency consequences. Employees would simply be buying a benefit they value with their wages.

This article inspired a large follow-up literature, mostly empirical, investigating the equity and efficiency properties of mandates. I review that literature here, in three steps. First, I comment on the theoretical points made by Summers. Second, I discuss the empirical evidence available on the impacts of mandates. Finally, I discuss the key unanswered questions that must be addressed by future research.

**Theoretical background**

Summers’ analysis was as straightforward as it was insightful, highlighting the impacts of mandates in a simple demand and supply framework. The mathematics behind this analysis is explored in Gruber (1992), Gruber and Krueger (1991) and Anderson and Meyer (1997). These analyses show that the incidence of mandated benefits depends on the elasticities of supply and demand, as with any tax, along with a new parameter: the valuation of the benefit by employees. If valuation is equal to the cost paid by the employer for the benefit, then there is full shifting to wages.

But this analysis misses an important point: Summers’ analysis is in no way restricted to mandates. Indeed, the analysis is exactly the same for Unemployment Insurance, a US programme which provides tax-financed benefit to unemployed workers. The key to Summers’ analysis is not the form of provision (mandate or tax); rather, the key is that the benefits are restricted to workers, generating the labour supply increase that offsets some of the efficiency consequences of the intervention. For example, a payroll tax-financed expansion of health insurance to workers fits into this framework, but a payroll tax-financed expansion of health insurance to all individuals in society does not. In the latter case, there would not be the corresponding increase in labour supply, since individuals would not have to work to receive the benefit.

Another question raised by Summers’ analysis is this: if there were full incidence on wages, why wouldn't employers simply provide the benefit voluntarily? Why is government coercion necessary to promote employer provision of a benefit fully valued by employees? The best answer here, as pointed out by Summers, is that there may be market failures that lead employers to not reflect workers’ valuation of this programme without a government mandate. Most obviously, adverse selection in the market for benefits could cause employer reluctance to be, for example, the one employer in town that offered health insurance or paid maternity leave. This standard adverse selection problem may keep employers from offering benefits that are fully valued by employees. (Indeed, if there is such a market failure, it is feasible that a programme such as workers’ compensation could raise the quantity of labour in the market. If workers value workers’ compensation at more than its cost to employers – as might be the case if workers are risk averse – the labour supply curve would shift out by more than the demand curve shifted in; workers would be willing to accept a wage cut of more than the cost of workers’ compensation in order to have this benefit. This would actually raise employment.)
Empirical evidence

During the 1990s a large number of articles explored the empirical impact of mandates, in particular the extent to which mandated costs were shifted to wages. This literature is reviewed in detail in Gruber (2001); I provide an overview here. The consensus of this literature is that, over the medium to long term, the cost of mandates is fully reflected in wages.

Gruber and Krueger (1991) provide the first such analysis, dealing with increases in the employer costs of Workers’ Compensation (WC) insurance across US industries and states over time. WC provides cash benefits and health coverage to workers injured on the job, and much of the variation in costs in the authors’ data comes from increases in the health care component of this programme. They focus on workers in five industries for which WC costs are high and rapidly growing; in some industries and states, these costs amounted to over 25 per cent of payroll by 1987, the end of their sample period. They use both micro-data on wages and aggregate data on employment and wages by state/industry. They include state and industry fixed effects in their models, so that they are controlling for general differences in pay across industries and places, and estimating only how that pay changed when the costs of WC rose. In both data-sets, they find that for these sets of industries 85 per cent of increases in workers compensation costs were shifted to wages.

Anderson and Meyer (1997) undertake a similar analysis for Unemployment Insurance (UI), which provides cash benefits to unemployed workers. This programme is not a mandate, but it should operate in the same fashion as it levies payroll taxes on firms to provide benefits to their workers. Anderson and Meyer’s conclusion is similar to Gruber and Krueger: general differences in UI payroll taxes appear to be fully reflected in wages with little effect on labour supply.

There is also a long literature on the impact of payroll taxation on wages that is reviewed by Hamermesh (1987). This literature is much more mixed in its conclusions, although the variation in payroll taxes mostly comes over time, and it is difficult to estimate its incidence separately from other time series factors in the United States where there is little variation across workers in payroll tax rates. More recent evidence is consistent, however, with the notion of full shifting to wages in other countries (for example, Gruber, 1997).

Labour supply is not simply a discrete choice, however, but rather a combination of participation and hours of work decisions. Increases in costs will effect both the supply of and the demand for work hours conditional on participation. From the employer perspective, increases in health insurance costs are an increase in the fixed cost of employment and are as a result more costly (as a fraction of labour payments) for low-hours employees. Employers will therefore desire increased hours by fewer workers, lowering the cost per hour of the health insurance for a given total labour supply. Of course, if the wage offset is lower for low-hours workers, workers will demand the opposite outcome: there will be increasing demand for part-time work, with hours falling and employment increasing. Moreover, since part-time workers may be more readily excluded from health insurance coverage, there may also be a countervailing effect on the employer side, as full-time employees are replaced with their (uninsured) part-time counterparts. In this case as well, hours would fall and employment would rise. Thus, the effect on hours of work is uncertain. Several studies have addressed this issue, and the general consensus is that mandating fixed costs of employment leads to rises in hours and falls in employment (Gruber, 1994; Cutler and Madrian, 1998).
Remaining questions

While there have been significant gains in our understanding of the impacts of mandates, important questions remain unanswered. The most important is the question of heterogeneity across workers: how do mandates affect workers differentially within the workplace? Consider the example of mandated health insurance. The cost of health insurance will not be uniform throughout the workplace; costs are higher for family insurance than for individual coverage, or for older workers than for younger workers. In the limit, with extensive experience rating, costs vary worker by worker, depending on their underlying health status. Gruber (1992) extends the model of Gruber and Krueger (1991) to the case of two groups of workers, where costs increase for one but not the other. If there is group-specific shifting, then the solution collapses to the one group model. If not, however, the substitutability of these groups will also determine the resulting labour market equilibrium; in general, there will be effects on both the group for which costs increase and the group for which they do not.

In practice, there may be a number of barriers to group-specific, and in particular individual-specific, shifting. Most obviously, there are anti-discrimination regulations which prohibit differential pay for the same job across particular demographic groups, or which prevent differential promotion decisions by demographic characteristic. Workplace norms which prohibit different pay across groups or union rules about equality of pay may have similar effects. Thus, a central question for incidence analysis is how finely firms can shift increased costs to workers’ wages. If there is imperfect group- or worker-specific shifting, there may be pressure on employers to discriminate against costly workers in their hiring decisions.

Two studies suggest that there is within-workplace shifting to wages. Gruber (1994) studied the effect of state laws (and a follow-up federal law) that mandated in the mid-1970s that the costs of pregnancy and childbirth be covered comprehensively. Before this time, health insurance plans provided very little coverage for the costs associated with normal pregnancy and childbirth, while providing generous coverage for other medical conditions. This distinction was viewed as discriminatory by some state governments, leading to the state laws mandating that pregnancy costs be covered as completely as other medical costs. These laws significantly increased the insurance costs for women of childbearing age in those states, thereby raising the costs of employing a specific group of workers (or their husbands, who may provide them with insurance). I estimated full shifting to wages for these groups. Further corroborating evidence on this point is provided by Sheiner (1999), who found that, when health-care costs rise in a city, the wages of workers who have the highest costs (older and married workers) fall the most.

This research suggests that within-workplace shifting to wages is possible. The news here is good for efficiency: mandates which have differential effects across broad groups of workers will not necessarily lead to displacement of the high-cost group. The news is potentially bad for equity, however: other groups will not cross-subsidize the high costs imposed on one group in the workplace. In any case, neither of these studies addresses the extent to which within-firm shifting is possible; in the limit, it is hard to conceive that employers could shift costs to wages on a worker-by-worker basis.

Other questions have not been addressed at all by the literature. First, how rapidly does shifting to wages occur? Despite the evidence that mandates are fully reflected in wages, employers vociferously oppose mandated benefits as costing jobs. The reason for their opposition could be that wages cannot adjust
quickly enough in the short run to offset displacement effects; the studies cited earlier show full shifting only over several-year periods.

Second, what are the effects of existing constraints on compensation design in the labour market? For example, for workers already at the minimum wage, firms will be unable to shift to wages increases in the cost of health insurance. Similarly, union contract or other workplace pay norms may interfere with the adjustment of wages to reflect higher costs. These institutional features could increase the disemployment effects of rising health costs.

Third, what is the underlying structural mechanism behind a finding of full shifting to wages? In the simple labour market framework above, there are two reasons why increased costs might be shifted to wages: because individuals value the benefits that they are getting fully; or because labour supply is perfectly inelastic. Disentangling these alternatives is very important for future policy analysis. Consider the example of national health insurance, which is financed by a mandate, with an additional payroll tax to cover non-workers. If the full shifting documented earlier is due to full employee valuation with somewhat elastic labour supply, then national health insurance will have important disemployment effects, since labour supply will not increase in response to a benefit that is not restricted to workers. If full shifting is due to inelastic supply, however, then the population which is receiving benefits is irrelevant; in any case the costs will be passed on to workers’ wages, so national health insurance will not cause disemployment. Existing evidence, as reviewed in Gruber (2001), is mixed on which of these channels is at work.

Conclusion

Since the early 1990s there has been a substantial growth in research on mandated benefits. The conclusions from the work to date are clear: the costs of mandated benefits are fully shifted onto wages, with little impact on total labour supply. But important questions about the mechanisms behind such shifting remain unanswered.

Mandel, Ernest (1923–1995)

Geoffrey M. Hodgson
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

capitalism; central planning; Kondratieff cycles; labour theory of value; long waves; Mandel, E.; Marx, K.; neo-liberalism; socialism; Soviet Union; Trotsky, L.; unemployment

Article

Ernest Mandel was born of Jewish parents in Frankfurt-am-Main on 5 April 1923. The family emigrated to Antwerp. By 1939 he was actively involved in socialist and trade union politics. When the Nazis invaded Belgium in 1940, he became a member of the resistance. On three occasions he was arrested and imprisoned, but each time he escaped. He was arrested for a final time in October 1944 and liberated by the Allies in March 1945. He obtained a higher education in Brussels and Paris. His name was prominent in academia in the 1960s and 1970s when Marxism and Trotskyism enjoyed significant popularity, particularly among university students. He died on 20 July 1995.

His Marxist Economic Theory was first published in French in 1962 and in English in 1968. When student revolts and labour unrest broke out in the late 1960s, Mandel's text and the much shorter Introduction to Marxist Economic Theory (1967) were available for the growing numbers interested in Marxist economics. His Marxist Economic Theory was widely praised and his Introduction sold over half a million copies and was translated into 30 languages.

His Formation of the Economic Thought of Karl Marx was published in French in 1967 and in English in 1971. It was one of the first works in English to analyse Marx's Grundrisse, which did not appear in complete form in English until 1973.

In his Europe vs. America – published in German in 1968 and in English in 1970 – he predicted relative economic decline and increasing 'public squalor' in the United States, sustained rapid economic growth in Japan, and the achievement of productivity levels in the western European 'core' regions to rival those in America.

In his Late Capitalism – published in German in 1972 and in English in 1975 – he revisited the idea that capitalism was subject to repeated waves of boom and stagnation in 45–60 year cycles. Not only did Mandel predict the downturn of the 1970s on the basis of this analysis, but also this work help to revive
academic interest in the study of long waves, which has continued to the present day. However, his analysis has been criticized for misunderstanding Trotsky's criticisms of Kondratiev (Day, 1976) and lacking a plausible mechanism to explain the complete long-wave cycle (Tylecote, 1992).

Mandel wrote introductions to the new English translations of the three volumes of Marx's *Capital*, published by Penguin (Marx, 1976; 1978; 1981). He was obliged to consider the stormy technical debates in the 1970s over the labour theory of value and Marx's theory of the tendency of the rate of profit to fall (Steedman, 1977). However, instead of addressing the detailed critical arguments, he simply brushed them aside.

In 1978 Mandel was invited by the University of Cambridge to give the prestigious Alfred Marshall Memorial lectures. These were published as *Long Waves of Capitalist Development* (1980): a restatement and development of ideas in *Late Capitalism*. Further weaknesses in his position emerged when it became clear that mass unemployment in the West was not leading to political advances for socialism. Instead the period saw a resurgent political individualism and neoliberalism.

Like Trotsky, Mandel opposed the view that the Soviet-type economies were another type of ‘capitalism’, envisaged a collapse of the Soviet regimes, and expected that the working class would rise up in defence of state planning and nationalized property. Even after their collapse in 1989–91, in his *Power and Money* (1992) he hoped for a new workers’ movement in eastern Europe and predicted that capitalism would not be easily re-established. Overall, the theoretical weakness of his outlook became increasingly clear in the last 15 years of his life.

Mandeville, Bernard (1670–1733)

N. Rosenberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
division of labour; laissez-faire; Mandeville, B.; self-interest; Smith, A.

Article

Mandeville was born in or near Rotterdam in 1670 and died in Hackney, London, in 1733. He was awarded the degree of Doctor of Medicine from the University of Leyden in 1691. He took up the practice of medicine, specializing in the ‘Hypochondriack and Hysterick Diseases’, a subject on which he later published a treatise. Mandeville travelled to England, married there in 1699, and lived in England for the rest of his life. He was very widely read in the 18th century. His writings have often led to his being referred to as a satirist, but that is an inadequate and misleading classification.

Although Mandeville was not an economist, his writings were influential in shaping the direction of economic thinking in the 18th century. In 1705 he published a pamphlet, in doggerel verse, under the title *The Grumbling Hive: Or Knaves turn’d Honest*. In 1714 it was republished under its better-known title, *The Fable of the Bees: or, Private Vices, Publick Benefits*. This and subsequent editions included extensive expansions, clarifications and ‘vindications’ of his earlier themes. The grumbling hive was originally a thriving and powerful community. When, however, its inhabitants were suddenly and miraculously converted from a vicious to a virtuous moral condition, the community was swiftly reduced to an impoverished and depopulated state.

Mandeville's central theme is that public benefits are the product of private vices and not of private virtues. His paradox, which was widely regarded as scandalous, was achieved by employing a highly ascetic and self-denying definition of virtue. Since behaviour that could be shown to be actuated by even the slightest degree of self-regarding motive – pride, vanity, avarice or lust – was classified as vice, Mandeville had little difficulty in concluding that a successful social order must inevitably be one where public benefits are built upon a foundation of private vices.

… I flatter myself to have demonstrated that, neither the Friendly Qualities and kind Affections that are natural to Man, nor the real Virtues he is capable of acquiring by
Reason and Self-Denial, are the Foundation of Society; but that what we call Evil in this World, Moral as well as Natural, is the grand Principle that makes us sociable Creatures, the solid Basis, the Life and Support of all Trades and Employments without Exception: That there we must look for the true Origin of all Arts and Sciences, and that the Moment Evil ceases, the Society must be spoiled, if not totally dissolved. (Mandeville, 1732, vol. 1, p. 369)

What was of more enduring significance in Mandeville's views was his forceful and unapologetic popularization of the belief that socially desirable consequences would flow from the individual pursuit of self-interest. It is an essential part of Mandeville's argument that a viable social order can emerge out of the spontaneous actions of purely egoistic impulses, requiring neither the regulation of government officials, on the one hand, nor altruistic individual behaviour, on the other.

As it is Folly to set up Trades that are not wanted, so what is next to it is to increase in any one Trade the Numbers beyond what are required. As things are managed with us, it would be preposterous to have as many Brewers as there are Bakers, or as many Woolen-drapers as there are Shoe-makers. This Proportion as to Numbers in every Trade finds it self, and is never better kept than when nobody meddles or interferes with it. (Mandeville, 1732, vol. 1, pp. 299–300)

Thus, Mandeville enunciates a vision of an economy that organizes itself and that allocates resources through the market place. Although there is no serious analysis of the workings of the market mechanism, there is the clear assertion that the unregulated market provides a system of signals and inducements such that the interactions of purely egoistic motives will somehow produce results that will advance the public good.

In developing his views, Mandeville offered many acute observations on the causes as well as the consequences of the division of labour in society. He regarded the division of labour as the great engine of economic improvement over the ages. It is the most reliable way for ‘savage People’ to go about ‘meliorating their Condition’. For

… if one will wholly apply himself to the making of Bows and Arrows, whilst another provides Food, a third builds Huts, a fourth makes Garments, and a fifth Utensils, they not only become useful to one another, but the Callings and Employments themselves will in the same Number of Years receive much greater Improvements, than if all had been promiscuously follow'd by every one of the Five. (Mandeville, 1729, vol. 2, p. 284)

Although one can identify a number of possible precursors to Adam Smith's celebrated views on the division of labour, it is well established that Smith had in fact read and digested Mandeville carefully. Smith's marvellous description of the extensive division of labour involved in the production of a day-labourer's coat, with which he closes the first chapter of the Wealth of Nations, may be traced to Mandeville's earlier treatment of the same subject – a treatment which, indeed, Smith extensively paraphrases. Moreover, the passage in the Wealth of Nations containing the often quoted statement that
‘It is not from the benevolence of the butcher, the brewer, or the baker, that we expect our dinner, but from their regard to their own interest’ (Smith, 1776, p. 14) is in a direct lineage from Mandeville's earlier observation:

… The whole Superstructure [of Civil Society] is made up of the reciprocal Services, which Men do to each other. How to get these Services perform'd by others, when we have Occasion for them, is the grand and almost constant Sollicitude in Life of every individual Person. To expect, that others should serve us for nothing, is unreasonable; therefore all Commerce, that Men can have together, must be a continual bartering of one thing for another. (Mandeville, 1729, vol. 2, p. 349)

Thus Mandeville was, in some important respects, an early advocate of laissez-faire (although this advocacy did not extend to foreign trade, where Mandeville's views were still distinctly Mercantilist). He articulated a vision of the role of the division of labour in society, and of the forces making for social change and evolution, as well as for social cohesion, that were in many respects distinctly precocious, and that exercised a powerful influence in shaping the intellectual agenda of economists and other social scientists later in the 18th century.

Mangoldt, Hans Karl Emil von (1824-1868)

H.C. Recktenwald
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
entrepreneurship; equilibrium; Historical School, German; joint supply and demand; Mangoldt, H. K. E. von; multiple equilibria; price theory; product life cycle; profit and profit theory; rents of differential ability

Article
Mangoldt was born in Dresden in 1824 and died in 1868 of a heart attack after a short life. He was an eminent theorist in economics, yet greatly underrated by his German contemporaries. He received his doctorate in Tübingen (1847) and was afterwards a civil servant in the Ministry of Foreign Affairs – a post he resigned for political reasons – and became editor of the official Weimarer Zeitung (1852). His academic career began in 1855 as Privatdozent in Göttingen and ended as Professor of Political Science and Political Economic after only six years (1862–8) at the University of Freiburg (Breisgau). Mangoldt ranks among those pioneers in Germany, like von Thünen, von Buquoy, von Hermann, Gossen and Launhardt, who applied formal analysis to explain economic phenomena. Yet the predominant influence of the Historical School diminished the impact of his methods and ideas on German university economists. He shared this fate with Cournot and Walras. A second reason for this underrating of his pioneering achievements at home was his strong interest in classical economics. Thus it is not surprising that his reputation was much higher in England (via Edgeworth and Marshall) than in 19th-century Germany.

In his most important books, Unternehmergewinn (1855) and Grundriss (1863), he argues in the classic tradition, examines its hypotheses in the light of economic and political reality and modifies them considerably. Like Cournot (earlier) and Marshall (later) Mangoldt uses a novel apparatus of partial analysis – Frisch's microanalysis – to expound originally a mathematical theory of prices that goes far beyond Cournot. He describes in a very modern way the process from one equilibrium to another, analyses multiple equilibria and explains joint supplies and demands, a concept which Marshall would take up later on. Further, he has deeply influenced our theories of profit and rent by interpreting the entrepreneurial gain as rents of differential ability. Indeed, Mangoldt definitely anticipates Schumpeter’s
theory of the entrepreneur. He clearly distinguishes profit as an independent category of income from interest (of the capitalist), by stressing different elements of gain such as the compensation for risk-bearing or for new goods or techniques of production and sale. The pioneer function of the entrepreneur, motivated also by intangibles, as in Smith's concept, is clearly expressed in the statement

… die Auffindung und Verwirklichung der besten Produktionsmethoden … die Ausbeutung der von der Natur gegebenen Hilfsmittel, die Herstellung der Güter in der für das Bedürfnis dienlichsten Weise [the discovery and realization of the best methods of production, … the exploitation of natural resources, the manufacturing of goods in a way that is most appropriate for the need]. (1855, p. 68)

This means, of course, novel improvements as well. Unfortunately, Mangoldt did not attempt to make these realistic and dynamic elements an essential part of his price theory via a notion of evolutionary competition as did Smith and Schumpeter. Thus he neglected the different properties and intensities of competition in different stages in the life cycle of a product. Furthermore, his contribution to allocation theory was as pioneering as his analysis of coalitions on the labour market. Here he objected to profit participation by workers without risk-sharing. Finally, it is notable that Mangoldt originally extended Ricardo's theory of comparative costs by applying, although in rather vague terms, the notion of elasticity of demand and supply in the theory of international trade. Mangoldt was, no doubt, one of the eminent theorists and rare pioneers in the 19th century whose achievements are still underrated and whose use of mathematics seems to be rather overrated. Though an abstract thinker, he seldom lost the binding ties to reality.

Maoist economics

Wei Li

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

During the Maoist era (1949–76), China attempted to adopt Soviet-style central planning in her first Five-Year Plan, but soon changed course. Under the heavy hand of Chairman Mao Zedong, China created a unique style of central planning where the centre enunciated broad policy directives in the form of slogans that could be easily passed down to local cadres, who were given strong incentives to find ways to implement them. This article outlines a consistent framework for analysing the policy changes during the Maoist era and their dramatic impact on the Chinese economy.

Article

Ten thousand years is too long; seize the day, seize the hour.
(Mao Zedong, Mengjianghong – A Reply to Comrade Guo Moruo, 1963)

Had Mao died in 1956, there would be no doubt that he was a great leader of the Chinese people, a respected, loved and outstanding great man in the proletarian revolutionary movement of the world. Had he died in 1966, his meritorious achievements would have been somewhat tarnished but still very good. Since he actually died in 1976, there is nothing we can do about it.

(Chen Yun at the Central Party Work Conference, November–December 1978. Quoted...
‘Maoist economics’ refers to the collection of economic policies implemented by the Communist Party of China (CPC) during the Maoist era, which began with the founding of the People's Republic in 1949 and ended shortly after the demise of Chairman Mao Zedong in 1976. Thanks to the CPC's meticulous cultivation of Mao's personality cult, Mao was able to exploit his ‘mass line’ political strategy by exhorting the masses to follow his vision when the CPC hierarchy was unwilling. As a result, Mao could set major policy initiatives with few checks and balances. But to attribute all major decisions to Mao would be an oversimplification, especially before 1958. The leadership of the CPC in Beijing and local cadres, often split into factions with different policy agendas and preferences (for a detailed historical account of the policy debates within the leadership circle in China in the 1950s and 1960s, see for example, Lardy and Lieberthal, 1983; Riskin, 1987; and Bachman, 1997), contributed not only to policy implementation but also to policy formulation. Maoist economics is therefore not synonymous with ‘Mao Zedong Thought’ on economic matters. (‘Mao Zedong Thought’ is considered an extension of Marxism–Leninism derived from the teachings of Mao Zedong and the distillation of the experience of the Communist revolution in China. It has been enshrined in the Constitution of the CPC as part of the party's official ideology since 1945. As China has embarked on market-oriented reforms since 1978, ‘Deng Xiaoping Theory’, which advocated the pragmatic concept of ‘socialism with Chinese characteristics’, has served as the party's working doctrine.)

The aim of this article is to outline a consistent framework for organizing and understanding the economic policies that were formulated and implemented during the Maoist era.

**Agricultural taxation and the Chinese-style central planning**

When on 1 October 1949 Chairman Mao proclaimed that the Chinese people had finally stood up at the ceremony for the founding of the People's Republic, China was a desperately poor agrarian economy ravaged by more than a century of internal turmoil, foreign invasions and civil wars. With most of her industrial assets either destroyed or looted by the Soviet forces that occupied Manchuria at the end of the Second World War, or removed to Taiwan and Hong Kong ahead of advancing Communist troops, China was ‘poor and blank’, as Mao (1958) put it. With 90 per cent of her population of 550 million living in abject poverty in the countryside and toiling on small plots of land using traditional labour-intensive farming technology, China was barely able to feed and clothe her population.

Since poor peasants made up the vast majority of the population, the CPC under Mao had focused on building its support base among peasants by, among other things, promising to deliver what every peasant wanted: a private plot of land. Between 1946 and 1953, the CPC launched land reform, first in the territories under its control and then in all ethnically Chinese areas on the mainland after 1949. The process generally involved assigning each rural family a class status; motivating the poor, lower-middle, middle and initially the ‘rich’ peasants to engage in ‘class struggle’ against landlords; and expropriating land, draft animals, farm implements and property from landlords and redistributing them to landless peasants (Fairbank, 1992). The ‘class struggle’, which included public trials, denunciations and mass executions of landlords and counter-revolutionaries, created an atmosphere of terror. But the land reform solidified support for the CPC among the poor and middle peasantry. (For an on-the-ground observation...
As the CPC secured military and political control of the mainland, its priority shifted to managing and rebuilding the war-torn economy. With the economy rebounding quickly, Chinese leaders turned their attention to long-run economic development, aimed at building a socialist, industrial nation. Having secured material and technical support from the Soviet Union, they adopted a Soviet-style, heavy-industry-oriented development strategy in the first Five Year Plan (FYP 1953–7). The plan called for massive industrial investment, including the construction of 156 industrial plants outfitted with imported Soviet equipment. The Soviet contributions to this big push included loans amounting to about four per cent of the total investment, technology transfers and 10,000 Soviet specialists (Fairbank, 1992). The success of this ambitious plan therefore hinged on the ability of the government to mobilize investable surplus internally. Without a significant industrial and commercial sector, the government had to extract the needed surplus from the vast agricultural sector.

Throughout Chinese history, agricultural taxes, collected in kind, have been the primary source of government revenue. (Indeed the Chinese character for tax, shui, as a portmanteau of grain and convert, refers to a levy on the use of land payable in grain.) In the 1950s, China had a three-tiered agricultural tax structure. At the first tier was an in-kind levy on grain production, known as the ‘government grain’. Peasants received no compensation for turning over the government grain to the State Grain Bureau. At a statutory rate of 15 per cent in 1950, this tax accounted for 39 per cent of government revenue. (This figure is calculated using data posted on the official website of China's Ministry of Finance.) In later years, as the price scissors – the differences between the prices on industrial and agricultural goods – widened, and as the industrial sector grew rapidly because of the massive capital expenditure funded largely by agricultural taxes, the share of explicit agricultural taxes dropped to six per cent by 1976.) At the second tier was an implicit tax, a grain procurement quota, which dictated how much each peasant household had to sell to the State Grain Bureau out of their after-tax grain at below-market procurement prices. After meeting these two obligations, peasants would usually be left with just enough grain to sustain a subsistent living. Markets still existed in the early 1950s, where peasants could exchange some of their surplus produce for other goods. At the third tier was an in-kind levy on rural labour. Under the traditional subsistence farming practice in China, peasants would take a break or work less intensively during agricultural off-seasons in order to conserve food energy. To the government, this idling was unacceptable. Dams, irrigation systems, roads and other large-scale infrastructure projects could be worked on more intensively during off-seasons by drafting peasants to carry out backbreaking manual labour. Utilizing a mixture of exhortation and coercion, the government mobilized tens of millions of peasants for large construction projects in the 1950s.

Collecting the three-tiered taxes from hundreds of millions of independent peasant households was a daunting task. Tax enforcement became even harder when market prices of grain rose substantially in 1952 as a result of increased demand caused by rapid industrialization and urbanization and by the need to export agricultural products in exchange for Soviet equipment. In response, the government in 1953 closed the grain market and monopolized grain trade by fiat, making it illegal for anyone other than the government to engage in large-scale grain trade. In 1954, it expanded the control to include oil seeds, cotton, pork, and other key agricultural commodities.

Extracting agricultural surplus was further hampered by the lower level of agricultural productivity in China than in more developed countries. With nearly 90 per cent of the population living in the countryside, China was producing barely enough food and wearable fibres to meet basic domestic needs.
Estimates by Ashton et al. (1984) suggest that the daily average food energy intake in China in the 1950s was around 2,000 calories per capita, below the 2,350 calories recommended by the United Nations. To further improve its extractive capability and to raise agricultural productivity, the government turned to collectivization. By organizing peasant households into collectives, the CPC could extend its political control down to the village level. The grass-roots party organizations could effectively monitor production to further improve tax compliance. Rooted in the prevailing ideology, Chinese leaders also believed that collectivization would enable peasants to take advantage of economies of scale, to learn best practices in scientific farming, to accelerate the adoption of high-yield seeds and modern inputs, and therefore to realize a great leap in agricultural productivity. (Apparently influenced by Soviet propaganda, Chinese leaders were taken in by the miraculous claims of productivity-boosting farming techniques made by a group of pseudo-scientists who dominated the Soviet agricultural science establishment. Because these pseudoscientific techniques contradicted the farming experience of Chinese peasants, the only way to propagate them was to make it a political task for rural collectives and grass-roots party organizations. For an account of Lysenkoism in the Soviet Union and its influence in China during the Maoist era, see Becker, 1996.)

Collectivization, however, represented a radical reorganization of rural life in China. Given the importance of agriculture in the Chinese economy and the traumatic experience of forced collectivization in the Soviet Union (Becker, 1996), China's first FYP emphasized voluntary participation and set out a relatively conservative and flexible timetable, calling for socialist transformation in agriculture to be accomplished in 10–15 years. Between 1952 and 1954, collectivization proceeded gradually. By 1954, only 11 per cent of peasant households were enrolled in elementary Agricultural Producers’ Cooperatives (APCs), where members pooled their privately owned land, draft animals and large tools and used them jointly. APC members were paid wages for their labour as well as rents for their contributions in land and capital. While wage rates and rents were supposedly set at market levels, actual practice left many richer peasants complaining that the rents were insufficient. Reports of richer peasants exiting the cooperatives, selling and killing their draft animals, and downing trees on their plots in 1954 started to alarm leaders in Beijing. In January 1955, the CPC issued an urgent order for the protection of draft animals. The combination of state monopolization of grain trade and collectivization had, by the authorities’ own admission, dampened the ‘enthusiasm’ of the peasants for production. Emergency measures that the government implemented included fixing procurement quotas and putting on hold any further push for collectivization in the spring of 1955. But any reprieve that peasants got was short-lived.

By the summer of 1955, imbalances in the economy from implementing the aggressive first FYP had reached record levels. The supply of agricultural products, raw materials and consumer goods could not keep up with the growing demand. With tax revenues insufficient to meet the funding needs in the first FYP, the government was running a large fiscal deficit. (In 1955, debt issuance by the government reached a record high of 2.5 per cent of GDP.) Factors that contributed to the imbalances included the agricultural bottleneck exacerbated by the collectivization movement, the ambitious first FYP that allocated massive investment to heavy industry, and the inherent difficulties of managing a centrally planned economy.

Mao’s own analysis, however, identified over-centralization as a serious problem of the Soviet-style central planning whereby the planners tried to do what could be done better by local cadres. The solution that Mao put forth was not to stop the expansion of the role of the state in the economy, but to limit the
Maoist economics: The New Palgrave Dictionary of Economics

role of the nascent central planning bureaucracy and expand the role of local governments. He faulted the planners in Beijing for not doing enough to harness the enthusiasm of local cadres, workers and peasants for socialist transformation both in industry and in agriculture. In a policy speech delivered on 31 July 1955, Mao made the argument for accelerating socialist transformation in general and collectivization in particular.

[Some] comrades fail to understand that socialist industrialization cannot be carried out in isolation from the cooperative transformation of agriculture. In the first place, as everyone knows, China's current level of production of commodity grain and raw materials for industry is low, whereas the state's need for them is growing year by year, and this presents a sharp contradiction. If we cannot basically solve the problem of agricultural cooperation within roughly three five-year plans, that is to say, if our agriculture cannot make a leap from small-scale farming with animal-drawn implements to large-scale mechanized farming, ... then we shall fail to resolve the contradiction between the ever-increasing need for commodity grain and industrial raw materials and the present generally low output of staple crops, and we shall run into formidable difficulties in our socialist industrialization and be unable to complete it. (Mao, 1977, pp. 196–7)

To ensure that Mao's vision was turned quickly into action, the CPC passed in October 1955 a resolution that reiterated the policy directive for accelerating collectivization and authorized the party hierarchy to criticize any party member who disagreed with the policy as a 'right-leaning opportunist'. ('The Resolution Regarding Agricultural Collectivization' was passed in the 6th Plenary Meeting of the 7th CPC Congress held in Beijing from 4–11 October 1955.)

As local cadres who moved decisively and quickly to implement this policy directive were publicly praised, and laggards were publicly criticized, local cadres found themselves locked into a rat race on who could coerce peasants to form bigger collectives at a faster pace. By the end of 1956, 96.3 per cent of all peasant households had joined collectives, more than ten years ahead of the schedule set in the first FYP.

Mao's administrative decentralization was not a repudiation of the concept of central planning. It was an attempt to redefine central planning in the Chinese context with perhaps an implicit intent to enlarge the sphere of Mao's influence. By weakening the nascent central planning bureaucracy, Mao effectively strengthened his own influence in enunciating broad policy directives in the form of slogans that could be easily passed down to local cadres. To align the interests of local cadres with the centre, Mao offered high-powered incentives: those who found innovative ways to implement the centre's directives irrespective of economic consequences were rewarded with public praise and promotion, while those who ignored the centre's policy directives were punished with the humiliation of public criticism and denunciation. In more serious cases, those who resisted the centre's policy directives could be purged as 'rightists' or 'counter-revolutionaries'. Mao also made frequent use of brutal political campaigns against nonconformists and instilled an atmosphere of terror. (One of the most notorious political campaigns was the 1957 'anti-rightist' campaign; Fairbank, 1992.) The resulting political system was one in which Mao could exploit his personality cult in enunciating broad policy directives without the inconveniences of checks and balances. Mao's administrative decentralization thus marked the beginning of the politicization of economic policy formulation and implementation in China. When Mao launched the
Great Leap Forward (GLF) movement in 1958, the inaugural year of the second FYP, there was hardly any dissenting voice.

The Great Leap Forward

By setting production targets even more aggressively in the second FYP, the CPC hoped that China would grow out of the imbalances created during the first FYP by exhorting local cadres and the masses to make selfless sacrifices in order to transform China into an industrial, socialist nation. In March 1958, the CPC issued a new directive, calling local cadres to amalgamate smaller cooperatives into larger ones. Zealous local cadres in Henan province created township-sized collectives, dubbed ‘People’s Communes’. Each of the communes was an all-encompassing institution that functioned as a local government, an agricultural collective, local government-owned industrial and commercial enterprises (one of the enduring legacies of Mao’s administrative decentralization was the policy directive that encouraged the creation of local government-owned enterprises), local schools, and a militia integrated into the national defence system. In these collectives, communalization went beyond all means of production and invaded the private lives of peasants. For example, family kitchens were banned and were replaced by communal kitchens that offered members free meals (Li and Yang, 2005). ‘People's Communes are good because they are big and communal’, declared Mao. By early autumn, communes had spread across China.

Believing that collectivization significantly boosted agricultural productivity, the CPC created a new rat race for local cadres by exhorting them to ‘overcome reactionary conservatism’ (People’s Daily, 10 September 1958). Unable to deliver the expected increase in grain output, local cadres started to outdo each other in statistical gamesmanship by making wild claims about grain output. An initial tally of the 1958 grain output after the autumn harvest pegged it at 525 million metric tons (MMTs), up by nearly 170 per cent from 1957. The figure was subsequently revised down to a more modest 375 MMTs. (The downward revisions did not stop here. Two more were made: first to 250 on 22 August 1959 and then to 200 in 1979; Li and Yang, 2005.)

With the numbers indicating that collectivization had permanently resolved China’s agricultural bottleneck, the government raised agricultural taxes: grain procurement (including government grain) was increased from 46 million metric tons in 1957 to 64 in 1959; 16.4 million peasants, about twice the size of the industrial labour force in 1957, were relocated to cities in 1958 to support the expansion of industry and construction; and more than 100 million peasants were mobilized in the winter of 1957–8 to undertake large irrigation and land reclamation projects, and to operate millions of small ‘backyard iron furnaces’. (Built using mud and bricks, these furnaces melted scrap metal – for example, iron woks made obsolete by communal kitchens – to produce iron, which even the government admitted was of useless quality; Becker, 1996.) The increase in agricultural taxes allowed the government to raise national savings from 24.9 per cent of national income (measured by net material product) in 1957 to 43.8 per cent in 1959. These savings were almost exclusively invested in heavy industries (Riskin, 1987, p. 142). Grain export was raised from an average of 2.11 million tons between 1953 and 1957 to 3.95 million tons in 1959 to meet payment obligations for importing capital goods.

The collectivization miracle was, however, a mirage. Lin (1990) finds that incentive problems within large collectives had deleterious effects on agricultural productivity. With actual grain output
Maoist economics: The New Palgrave Dictionary of Economics

significantly lower than the falsified statistics, the agricultural taxes were excessive. Grain retained in rural areas fell sharply from 273 kg per capita in 1957 to 193 kg in 1959, and further down to 182 kg in 1960. Since grain was the primary source of food energy in China at the time, the drop in per capita food availability coincided with the onset of worst famine in human history. (Demographers who extrapolated mortality trends in China estimated the total number of premature deaths during the GLF famine at between 16.5 and 30 million; see Li and Yang, 2005.)

As the disastrous consequences of the GLF policies became known in 1959, Mao temporarily stepped aside to let his pragmatic colleagues, Liu Shaoqi and Deng Xiaoping, take responsibility in managing both government and party affairs. The pragmatic leaders started to reverse course: they reduced grain procurement by ten million tons, increased agricultural labour force by more than 50 million between 1958 and 1962 by sending back new industrial recruits back to the countryside, dismantled communal kitchens, downsized the collectives and started to import grain. More importantly, they allowed spontaneous, bottom-up experimentation with market-oriented reforms in 1961. Grain output began to recover in 1961, but did not surpass its pre-GLF level of 195 million metric tons (recorded in 1957) until 1966, the first year of yet another political upheaval – the Cultural Revolution.

Themodel

To better understand the trade-offs faced by Chinese policymakers and the key factors that contributed to the GLF disaster, I turn next to Mao's policy directive for accelerating collectivization with the aid of a simple two-sector dynamic model developed in Li and Yang (2005).

A key feature of the Li–Yang model is the explicit dependence of agricultural labour productivity on nutrition. For simplicity, assume that in the agricultural sector labour is the only factor and the technology exhibits constant returns to scale. If $L_t$ is labour allocated to agriculture, the aggregate grain output in year $t$ can be written as

$$Q_t = af(c_t)L_t$$

(1)

where $af(c_t)$ measures the contribution of nutrition to the labour productivity of an average worker who consumes $c_t$ amount of grain in year $t$, and $a$ is a productivity parameter. Experimental and empirical studies have found that $f(\cdot)$ tends to be an increasing, S-shaped function with $f''(c) \geq 0$ at a very low level of food intake, and $f''(c) < 0$ as food intake reaches a sufficiently high level. (For a survey on health, nutrition and economic development, see Strauss and Thomas, 1998.) If the government taxes away $p_t$ amount of grain output from each agricultural worker after the harvest in year $t$, the amount of grain saved for consumption in year $t+1$ is then
The industrial sector uses a Leontief technology that produces one unit of industrial output by employing one unit of labour, \(d\) units of capital service and \(m\) units of grain as an intermediate input in fixed proportions. Assume that all capital goods must be imported and paid for by exporting grain, and the exchange rate is one unit of grain to one unit of capital service. With abundant grain supply and the economy's labour supply normalized to 1, the industrial output is simply \(1 - L_t\). The government is assumed to maximize a discounted flow of industrial output, \(\sum_{t=0}^{\infty} \beta^t (1 - L_t)\), subject to the following budget constraint:

\[
p_t L_t \geq (d + m + n) (1 - L_t),
\]

where \(\beta < 1\) is the government's discount factor and \(n\) is the food entitlement of each industrial worker. (For more discussion on food entitlement, see Li and Yang, 2005. In 1956, the national average of monthly ration of grain for labourers assigned to the most physically demanding jobs was 25•kg. Retail prices of food items in stores were set by the government and played little role in resource allocation.) This constraint, which captures China's key bottleneck during the Maoist era, states that the amount of grain procured must be sufficient to meet export demand for the importation of capital goods, industrial demand for intermediate inputs, and food demand from industrial workers.

Given the government objective, the optimal solution calls for allocating just enough labour to grain production, so the constraint (3) is binding in each year. This implies that the optimal allocation of labour to grain production should be \(L_t = (d + m + n) / (\rho_t + d + m + n)\). Substituting this binding constraint into eq. (2), one can show that the government's optimal policy is a solution to the following Euler equation for a given initial level of food consumption \(c_0\):

\[
a \beta f' (c_{t+1}) = \left( \frac{af (c_{t+1}) - c_{t+2} + d + m + n}{af (c_t) - c_{t+1} + d + m + n} \right)^2.
\]

The optimal steady state policy is to set the food consumption per agricultural work \(\bar{c}\) such that \(f' (\bar{c}) = (a \beta)^{-1}\). The steady state is asymptotically stable if \(f'' (\bar{c}) < 0\). This stability condition is
satisfied if the productivity effect of nutrition exhibits diminishing returns around the steady state per capita food consumption, which is consistent with previous experimental findings. Under the stability condition, the steady state grain procurement $\bar{p}$ and industrial output $1 - \bar{L}$ are both increasing functions of agricultural productivity $a$ and the discount factor $\beta$. The model therefore validates Mao's claim in his quoted policy speech that raising agricultural productivity would contribute to the relaxation of the agricultural bottleneck and hence permit a faster pace of industrialization. It also proves that patience is a virtue: a more patient government, one that uses a larger discount factor $\beta$ (or a lower discount rate) in setting intertemporal policies, can sustain a higher level of steady state agricultural and industrial production. The intuition is as follows. A more patient government, one that discounts future industrial production at a lower rate and is content with a lower growth rate, would set a lower tax rate on peasants, allowing them to improve nutrition and labour productivity. The improved productivity would in turn increase the tax base sufficiently high to more than compensate for any revenue loss from lowering the tax rate. As a result, both the grain procurement and industrial production are higher in the steady state for a more patient government.

Like Stalin, Mao was impatient. (In a speech delivered in 1931, Stalin, 1952, used nationalistic rhetoric to demonstrate the imperative to press on with rapid industrialization regardless of the obstacles during the first Five Year Plan of 1928–32 in the USSR.) And, like Stalin, Mao saw collectivization as a means to achieve rapid industrialization. Expecting collectivization to raise $a$, the increasingly impatient planners exhorted local cadres to increase grain procurement and to divert more agricultural labour to industrial production and large infrastructure projects. Since collectivization actually caused $a$ to fall, the GLF policies left many peasants with insufficient amount of grain for consumption. Malnutrition (and famine in several grain-producing provinces) significantly reduced labour productivity, leading to a collapse in grain production. The further reduction in grain output caused malnutrition, and famine to spread from the countryside into cities. The linkage between nutrition and productivity thus offers a dynamic explanation of why the negative incentive effect of collectivization could cascade into a major catastrophe. Empirical investigation by Li and Yang (2005) finds that the GLF policies were principally responsible for this disaster. As the GLF policies were reversed by Liu Shaoqi and Deng Xiaoping, the Chinese economy began to stabilize in 1962. In 1966, when the economy appeared to have fully recovered by 1966, Mao launched another political campaign – the Great Proletarian Cultural Revolution.

The Cultural Revolution

The post-GLF policies had some noteworthy features. First, the centre–province distribution of power was rebalanced in favour of the centre. The task of collecting reliable information on the prevalence and severity of famine was simply too important to be delegated to local cadres. Second, collectives were downsized by making village-level ‘production brigades’ responsible for their own finances, and communal kitchens were closed. More important, the policies permitted spontaneous experimentation with household responsibility schemes within collectives, allowed peasant families to keep small private plots, and reopened markets in which peasants could sell their surplus produce. These policies arrested the downward momentum and brought about a gradual recovery. But they represented a humiliating retreat in the campaign towards socialism. As long as the retreat was
tactical, Mao was content standing on the sideline. However, Khrushchev's denunciation of Stalin's rule in 1956 and the subsequent de-Stalinization in the Soviet Union gave Mao reasons to be concerned about his own legacy. As soon as the economy recovered, Mao moved to reclaim power so that he could purge those who had the potential to become China's Khrushchev. In 1966, Mao turned against Liu and Deng. Exploiting his personality cult, Mao kicked off the ‘Great Proletarian Cultural Revolution’ in 1966 by exhorting the Red Guards, made up primarily of students and other urban youths, to rebel against the power base of Liu and Deng – the government and party hierarchy. Liu and Deng, along with many of their colleagues, were labelled ‘capitalist roaders’ and were purged in 1968.

Mindful of the fragile conditions in the Chinese countryside, moderate leaders did their best to keep the revolution from spreading into the countryside, preventing a rerun of the famine during the GLF. But the market-oriented reforms permitted under Liu and Deng were nullified. Agricultural productivity continued to stagnate until market-oriented reforms were restarted in 1978. The demand for food, however, continued to grow as a result of the post-war baby boom. Unable to raise grain procurement quotas to meet the growing demand for food rations in the cities, the government resorted to sending millions of urban youths to the countryside to grow their own food and to receive ‘re-education’.

The Cultural Revolution brought politicization to every facet of life in China. It was better to be revolutionary (that is, loyal to Mao) than productive. Intellectuals and experts, considered less loyal to Mao, were sent to re-education camps in the countryside. Colleges were closed at first and were reopened later to admit only students from ‘revolutionary families’ – families of workers, peasants and soldiers – based on recommendations from grass-roots party organizations. Seasoned bureaucrats and factory managers were purged by the Red Guards, and ‘Revolutionary Committees’, comprised of workers, peasants and students, took over government offices and state-owned enterprises.

The revolution paralysed the government and the nascent economic planning apparatus. With neither the plan nor the market to guide the allocation of resources, the economy fell into a state of anarchy. As coordination across regions fell by the wayside, regional self-sufficiency, a policy stance endorsed by Mao, became a necessity. Specialization based on regional comparative advantage gave way to the duplication of industrial structure across provinces. The economy stagnated until 1978, when a rehabilitated Deng Xiaoping restarted market-oriented reforms.

Discussion

One of the classic tenets of Marxian economics is that, with planning eliminating the ‘anarchy of production’, a planned economy can avoid or at least better manage large aggregate economic fluctuations (Ellman, 1989). The experience of the Chinese-style central planning offers little support for this claim. The analysis of the GLF disaster by Li and Yang (2005) suggests that, on the contrary, central planning as practised in China exposed the economy to a new systemic risk. Because policy directives formulated at the centre had to be carried out in all localities, policy failures had generated large economic imbalances, severe economic and political crises, and prolonged stagnation. The source of the risk is the concentration of economic and political power in the hands of the planners. In the case of China, Chairman Mao, a charismatic leader, maintained a near monopoly on economic and political policies. With no effective checks and balances during the Maoist era, the economic and political system in China was incapable of arresting the momentum of apparently deleterious policy directives. The Maoist era was tumultuous. It saw spectacular post-war reconstruction, the build-up of a
rudimentary industrial economy aided by Soviet assistance, and the formation of a decentralized
government administration that emphasized regional self-sufficiency on the one hand and economic
collapse, stagnation, a personality cult and brutal ‘class struggle’ on the other. It conditioned a
generation of pragmatic leaders who, after the demise of Mao, would restart market-oriented reforms
through decentralized regional experimentation, disown the personality cult, ban mass movements and
depoliticize economic policymaking, while resolutely maintaining the CPC's hold on power. The
historical significance of Maoist economics may lie not in what it is but in what it is not.

Marcet, Jane Haldimand (1769-1858)

Robert W. Dimand and Evelyn L. Forget

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

British classical economics; Malthus, T. R.; Marcet, J. H.; Martineau, H.; Say, J.-B.; utility

Article

The classical political economist Jane Haldimand Marcet was born in London, the eldest of ten children of Anthony (Antoine) Haldimand, a Swiss citizen who was a successful London banker and property developer, and his English wife, Jane Pickersgill. She was tutored at home, studying the same subjects as her brothers, and took charge of the household at the age of 15, when her mother died. In December 1799 she married Alexander Marcet, a London physician from Geneva. Since her father bequeathed all his children an equal share of the family fortune, regardless of gender, she was independently wealthy, with no need to write for money. Nonetheless, she wrote 30 educational books on chemistry, political economy, botany, mineralogy, grammar and history, many written in the form of conversations. Her first book, an introduction to experimental chemistry, was published in 1806 after attending Humphrey Davy's lectures at the Royal Institution and after repeating Davy's experiments at home in Alexander Marcet's laboratory. The book was adapted in the United States as a college text, and its tremendous commercial success is shown by the many plagiarized editions that emerged in a period with no effective international copyright law. It introduced the young Michael Faraday to science.

Jane Marcet encountered the ideas of Adam Smith through Sydney Smith's lectures on moral philosophy at the Royal Institution in 1804 and 1806. Alexander Marcet and David Ricardo were both elected to the Geological Society in 1808. Jane Marcet's younger brother, William Haldimand (who lived with the Marcets), was elected a director of the Bank of England in 1809 at the age of 25, and, like his sister, shared Ricardo's attribution of the rising price of bullion to the excessive issue of bank notes, which was very much a minority view among the directors of the Bank of England. James Mill and Thomas Robert Malthus were also friends of the Marcets. Jane Marcet's Conversations on Political Economy, published anonymously in 1816, attempted to make the economic ideas of Smith, Malthus, Ricardo and Jean-Baptiste Say accessible to a wider public. Robert Torrens declared her 'one female, at least, fully competent to instruct the members of the present cabinet in Political Economy', while J.R. McCulloch
considered her book ‘on the whole, the best introduction to the science that has yet appeared’. Ricardo’s daughter read the book at her father’s recommendation, and Say wrote for permission to ‘translate sizeable passages from her excellent book’ for his political economy class (Polkinghorn, 1993, p. 55).

Jane Marcet (1816; 1833; 1851) was a successful popularizer of classical political economy, but she was also fully capable of independent judgement, sharing Ricardo’s opposition to the Corn Laws rather than Malthus’s support for them, and supporting the proposed Factory Act in 1833, contrary to the beliefs of her younger friend, Harriet Martineau. Marcet was more optimistic than Ricardo or Malthus about the prospects for economic growth, being less concerned that the working class would erode gains in the standard of living by heedlessly multiplying. Like Say, she placed more emphasis on utility than labour cost as a source of value: when Malthus, after high praise of her discussion of rent, protested that ‘I think you have given too much sanction to Mr. Say’s opinion reflecting utility’, she cut out and discarded the rest of his letter (Polkinghorn, 1986). A talented educational writer and the first woman to expound the principles of economics, Jane Marcet succeeded in bringing classical political economy (and other disciplines such as chemistry, botany and mineralogy) to a wider public.

Marget, Arthur William (1899–1962)

Donald A. Walker

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
cash-balance approach; Keynesian Revolution; Marget, A. W.; quantity theory of money; velocity of circulation

Article

A leading monetary theorist during the first half of his career, Marget went on to make an even greater contribution by formulating and implementing government policies regarding international banking and finance. Born in Chelsea, Massachusetts, on 17 October 1899, he graduated from Harvard with AB (1920) and MA (1921) degrees in Semitics, and a Ph.D. in economics (1927). He taught economics at Harvard (1920–7) and the University of Minnesota (1927–43; resigned 1948). He died in Guatemala City on 5 September 1962.

As an academian, Marget's principal concern was with the central problems of monetary theory, and since these had been so strikingly shaped by John Maynard Keynes, much of Marget's work became a critique of his views. Marget regarded himself as building upon an enduring neoclassical tradition, and saw the Keynesian Revolution as a largely misdirected episode that had the merit, however, of making some genuine contributions, and especially of stimulating the sort of re-examinations and refinements of doctrine exemplified by his own writings. His most significant critical contributions were his evaluations of Keynes's *Treatise on Money*, of liquidity preference, of Keynes's treatment of expectations, and of the implications of Keynes's *General Theory of Employment, Interest and Money* for the theory of prices (Marget, 1938; 1942). Marget's principal positive contributions were an extension and refinement of the concepts of the velocity of circulation of money and of goods; his reformulation of the quantity equation relating prices, output and money; his argument that the cash-balance approach is useful only in connection with the analysis of changes in the velocity of the circulation of money; and his analysis of the relevance of particular demand curves and their elasticity to the structure of money prices (Marget, 1938; 1942). The valuable elements of his critique of 20th-century theory and of his constructive writings have been assimilated into the discipline and are no longer a focus of discussion. Marget also undertook some studies in the history of thought which are among the best work on the subjects with
which he dealt. Particularly worthy of note are his examinations of the monetary theory of 19th-century neoclassical economists (Marget, 1931; 1935; 1938; 1942).

As an applied economist, Marget was concerned with international financial policies. While a major (1943–5) and a lieutenant colonel (1945) in the US Army, he devoted himself to preparations to bring about the economic and financial rehabilitation of Austria. He then became chief of the finance division of the US Allied Command for Austria (1946–9); a member of the US delegation in London that prepared for the treaty with Austria (1947); and a member of the US delegation to the Council of Foreign Ministers, which was charged with negotiating that treaty in London and Moscow (1947). His subsequent career included the positions of Chief of the Finance Division at the headquarters of the Marshall Plan in Paris (July 1948–December 1949), consultant to the US Treasury (1948), and Director of the Division of International Finance of the Federal Reserve Board of Governors (January 1950–April 1961). Among other activities, he represented the Board at meetings of the central banks of the western hemisphere in Bogotá (1956) and Guatemala City (1958). He then became the US representative to the Central American Common Market in Guatemala City and an adviser to the Common Market Bank in Honduras (April 1961–September 1962). In the latter roles he was instrumental in promoting the effectiveness of the Common Market policies.

Marget's scholarly work was distinguished by an insistence on logical clarity and an amassing of scholarly detail in the presentation of his expositions. His bureaucratic work was distinguished by an outstanding ability to suggest workable new financial institutions and procedures.

marginal and average cost pricing

William Vickrey
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Under perfect competition, marginal cost and average cost of a product are equal to each other and to its price, an arrangement that is Pareto-optimal in the absence of neighbourhood effects. Technical progress is making it possible to vary the prices of some products (such as telephony and electricity) from moment to moment in accordance with marginal cost. Such responsive pricing would help guarantee essential services and reduce the cost of providing reserve capacity. Where there are economies of scale, prices set at marginal cost will fail to cover total costs, thus requiring a subsidy.

Article

In a pure and simple static world of perfect competition, where production units purchase or rent all their inputs in competitive markets and each sells a single homogeneous product competitively, production takes place at a point of constant returns to scale where the marginal cost and average cost of the product are equal to each other and to its price. If in addition there are no neighbourhood effects or externalities operating outside the market, the result will be Pareto efficient, meaning that there is no feasible alternative arrangement that would be better for someone and no worse for anyone.

Difficulties with the concept of average cost

As soon as production takes place with durable capital facilities that must be adapted to the needs of an individual firm there may no longer be an effective market for these facilities and a cost of their use during any particular period must be determined by other means. In the rather extreme case of the ‘one-horse-shay’ asset that in a static environment yields a stream of identical services over a known lifetime, a constant periodic rental cost can be derived by the use of a ‘sinking fund’ method of depreciation in which the rent is the sum of an increasing depreciation charge and a decreasing interest charge on the net value. But where the value of the service varies over time, whether because of physical deterioration, an increasing cost of maintenance needed to keep the item in ‘as new’ condition, or shifts in demand, this would in principle cause depreciation charges to vary; in practice this is done in one of a number of arbitrary ways by using ‘straight-line’ or various forms of ‘accelerated’ depreciation. If these charges are used as a basis for pricing, where competition is imperfect enough to give some leeway, the results can be correspondingly arbitrary.

More serious problems arise in the increasingly widespread cases of joint production of several distinguishable products or services. Where competitive markets exist, the market conditions dictate the allocation of joint costs among the various products, as when a meat-packing establishment produces steaks, hides, glue and offals. There is no way in which one can determine a meaningful average cost of hides by considering only the production process. Where the products, though economically widely different, are physically similar, it is tempting to cut the Gordian knot and average over the entire output, often at the cost of serious impairment of economic efficiency. Even when elaborate rationales are concocted by cost accountants, unless demand conditions as well as production conditions are taken into account the results are essentially arbitrary.

One can do a little better with marginal cost, at least if one is seeking a short-run marginal social cost (hereafter SRMSC), which is the concept that would be relevant for efficiency-promoting pricing decisions. Unless a consumer is presented with a price that correctly represents the marginal social cost associated with the various alternatives open to him, he is likely to make inefficient decisions.

The importance of emphasizing the short run

One often finds in the literature proposals to use a ‘long-run marginal cost’ as a basis for setting rates. The trouble is that in an operation producing a multitude of products with interrelated costs it is not possible even to define in any precise way what could be meant by a ‘long-run marginal cost’, any more than one could define a relevant long-run marginal cost for the hides and steak that are derived from the same carcass in the face of fluctuations over time in relative demand. The attempt to use a long-run concept seems to be motivated in part by the notion that in some sense the long-run concept is more inclusive in that it allows for variation in capital investment and would include a return on such investment, whereas short-run marginal costs would fail to cover the costs of capital investment. In the single-product steady-state case, however, which is the only case for which the long-run marginal cost can be clearly defined, if the investment in plant is at the optimal level, i.e. the level which will result in the given output being produced at the lowest total cost, short- and long-run average cost curves will be tangent to each other at the given output, and short- and long-term marginal costs will be equal. Short run marginal-cost prices will therefore cover just as much of the total cost as will prices based on ‘long-run marginal cost’. If short-run marginal cost is below the long-run marginal cost, this would indicate that the installed plant is larger than optimum, and conversely if plant is below
Flexible versus stable prices

A long-run approach is sometimes advocated on the ground that it results in more stable prices. Price rigidity, however, exacts a high toll in terms of reduced efficiency. It is sometimes argued that stable prices are required for intelligent planning for installations that commit the investor to the use of a given volume of service. There is nothing in a SRMSC pricing policy, however, that precludes providing the consumer with estimates of the probable course of prices in the longer term, or even entering into long-term contracts to purchase specified quantities of service. If they are not to interfere with efficiency, however, such contracts should allow for the possibility of purchasing additional amounts at the eventual going rates, or of selling back some of the contracted-for output if this should prove profitable for the consumer.

Lack of flexibility in pricing has, indeed, been a major source of inefficiency in the use of utility services, whether arising as a result of the cumbersomeness of the regulatory procedures in privately owned utilities, or of bureaucratic inertia in publicly owned ones. At times it has even appeared that it takes longer to carry out the bureaucratic procedures involved in altering a price than to install additional capacity, whereas in terms of the underlying capabilities prices can and should be altered on shorter notice than the time taken to adjust fixed capital installations.

Optimal decision-making sequence

The efficient pattern of decision-making consists of first establishing a pricing policy to be followed in the future (as distinct from the application of that policy to produce a specific set of prices), then planning adjustments to fixed capital installations according to a cost-benefit analysis based on predicted demand patterns and predicted application of the pricing policy, subject to whatever financial constraints may be applicable, and then eventually determining prices on a day-to-day or month-to-month basis in terms of conditions as they actually develop.

Too often a rigid adherence to inappropriate financial constraints results in a pattern of pricing over time that leads to gross inefficiency in the utilization of facilities that are added in large increments. In the setting of tolls on bridges, for example, a high fixed toll is often imposed from the start in an attempt to minimize early shortfalls of revenues below interest and amortization charges. When the indebtedness incurred to finance the facility is finally paid off, tolls are often eliminated, sometimes just at the time that they should be increased in order to check the growth of traffic and congestion and defer the necessity for the construction of additional facilities.

The forward-looking character of marginal cost

Since changes in present usage cannot affect costs incurred or irrevocably committed to in the past, it is only present and future costs that are of concern in the determination of marginal cost. Past recorded costs are relevant only as predictors of what current and future costs will turn out to be. The marginal cost of ten gallons of gasoline pumped into a car is not determined by what the service station paid for
that gasoline, but by the cost expected to be incurred to replace that gasoline at the next delivery. The substantial time-lag that often exists between a change in price at the raw material level and its reflection at the retail level is one of the pervasive failings that contributes to the inefficiency of the economic system.

Another more important case in which future impacts are of vital importance in the calculation of marginal cost is where congestion accumulates a backlog of demand that has to be worked off over a period of time. A particularly striking case of this occurs when traffic regularly accumulates in a queue during rush hours at a bottleneck such as a toll bridge. The consequence of adding a car to the traffic stream is that there will be one more car waiting in the queue from the time the car joins the queue until the queue is eventually worked off, assuming that the flow through the bottleneck will be unaffected by the lengthening of the queue.

The marginal cost of a vehicle trip will be measured in terms of a number of vehicle hours of delay equal to the interval from the time the car would have arrived at the choke point if there had been no delay, to the time the queue is finally worked off. This is not measured by the length of the queue at the moment, but will be determined by the subsequent arrival of traffic over an extended period. A car arriving at the queue after it began to accumulate at 7:30 may get through the bottleneck at 8:00, after being delayed by only 15 minutes, but if the bottleneck will not be worked off until 10:00 the marginal cost will be 2 1/4 vehicle hours of which only 1/4 hour is borne by the added car itself. The remaining two hours, if evaluated at $5 per vehicle hour, would indicate that under these conditions the toll that would represent this externality would be $10. Marginal cost cannot be determined exclusively from conditions at the moment, but may well depend, often to an important extent, on predictions as to what the impact of current consumption will be on conditions some distance into the future.

Marginal cost of heterogeneous sets of uses

It will often happen, for various reasons, that the same price will have to be applied to a non-homogeneous set of uses. To set such a price properly, the marginal costs of the various uses within the set covered must be combined in some way to get a marginal cost relevant to this decision. It would be wrong, however, merely to average the marginal costs of all the uses for which this price is to be charged. Rather, the decision as to whether a decrease in a given price is desirable must consider the cost of the increments or decrements in the various outputs that will be bought as a result of the price change. In averaging the marginal costs of the various usage categories, the weighting will have to be in proportion to the responsiveness of each usage category to the change in price.

For example, if a price is to be set for electricity consumption on summer weekday afternoons, in a system where air-conditioning is an important load, consumption and marginal cost may be higher on hot days than on warm days, but it may be considered too difficult to differentiate in price between the two categories of days. An increase in the price for this entire set of periods may induce some customers to adjust the thermostat setting. But during hot days the equipment may work full tilt without reducing the temperature to the thermostat setting, whereas on warm days there will be a reduction in power consumption. The marginal cost relevant to the setting of the common price would then be determined predominantly by the lower marginal cost of the warm-day consumption, and relatively little, if at all, by the higher marginal cost hot-day consumption.
**Marginal and Average Cost Pricing:** The New Palgrave Dictionary of Economics

**Anticipatory Marginal Cost**

In many cases a customer will make his effective decision to consume an item some time in advance, and it will be the expected price as perceived by him at that time that determines his decision. If, as in services subject to reservation, a firm price must be quoted the time the reservation is made, it is the expected marginal cost as of that moment that should govern the price charged. In the case of a service where the demand is highly variable and to a considerable extent unpredictable, such an expected marginal cost would be an average of marginal costs that might arise under alternative possible developments, possibly ranging from a very low value, if there turns out to be unused capacity, to the possibly quite high value if another latecomer must be turned away. The respective probabilities of these outcomes, as estimated at a given time, will vary with the proportion of the total supply already sold, the time remaining to the delivery of the service, and the pricing policy to be followed in the interim.

At one extreme, for long-haul airline reservations where the unit of sale is large, one might find it worth while to have a fairly elaborate pricing scheme in which the price quoted would vary according to the proportion of seats on a given flight already sold and the time remaining to departure, in simulation of what an ideal speculators’ market might produce, the price at any time being an estimate of the price which, if maintained thereafter, would result in all the remaining seats being just sold out at departure time. This would correspond to marginal cost in that the sale of a seat at any given time would slightly raise the price during the remaining period to decrease demand by one unit, at a price that would be expected to be on the average equal to the price at which the seat was sold, indicating that the price was equal to the value of the seat to the alternative passenger.

**Quality-Volume Interrelationships**

In principle, in the absence of barriers to entry, competition would induce the supply of just sufficient seats on the various routes to cause revenues produced by such pricing to just cover costs. Even this, however, would be optimal only on those routes where traffic is so heavy that even with planes of a size producing the lowest cost per seat, further increases in service frequency would be of negligible value. On most routes there will remain economies of scale in that either providing more seats at the same frequency of service with larger planes would reduce costs per seat, or providing more seats with the same size of planes would provide an increased frequency of service that would be of value to others than the additional riders. In the latter case the marginal cost of providing for the additional passengers would be calculated by deducting the increase in the value of the service by reason of increased frequency from the cost of providing the added seats.

If it were possible to adjust plane size and frequency in a continuous fashion, then if the situation is optimal the two marginal costs would be equal. In practice both plane size and service frequency can be varied only in discrete jumps, so that this relation would be only approximate. Optimal price would be above a downward marginal cost calculated on the basis of a reduction in service, and below an upward marginal cost calculated on the basis of an increase in service. The decreases and increases might involve a combination of frequency and plane size changes. To preserve the formulation that price should equal marginal cost it may be useful to define marginal cost in such cases as consisting of the range between these upward and downward values rather than as a single point.
In practice, between the existence of economies of scale and the imperfect cross-elasticity of demand between flights at various times and with different amenities, removal of regulation tends to result in an emphasis on non-price competition, attempts to subdivide the market by various devices and restrictions to permit discriminatory pricing, and a bunching of service schedules at salient times and places that provides a lower overall level of convenience than would be possible were the given number of seat miles distributed more efficiently.

Where the unit of sale is small it may not be worth while to incur the transaction costs of varying price in strict conformity with SRMSC. One could, in theory, apply the same principle to the sale of newspapers at a given outlet. The price of a newspaper would vary according to the number of unsold papers remaining and the time of day. This would result in less disappointment of customers having an urgent desire for a paper late in the day and encountering a sold-out condition, and fewer unsold papers returned. But unless some ingenious device can be found for executing such a programme at low transaction costs, it probably would not be considered worth while, even by the most sanguine advocate of marginal cost pricing.

**Wear and tear, depreciation and marginal cost**

Even in the absence of lumpiness or technological change, existing methods of charging for capital use often fail to give a proper evaluation of marginal cost. This is especially true where the useful life of a unit of equipment is determined more by amount of use than by lapse of time. In the extreme case of equipment that must be retired at the end of a given number of miles or hours of active service, or after the production of so many kwh of energy, and which, in one-horse-shay fashion, gives a uniform quality of service over its lifetime without requiring increasing levels of maintenance, the marginal cost of use at a given time will be the consequent advancing of the time of retirement of the equipment. The marginal cost of using the newest units will be the lowest, and will advance over time at a rate equal to the rate of interest as the equipment ages and the advancement of replacement consequent upon use becomes less and less remote.

In a service subject to daily and weekly peaks, the newest equipment will be allocated to the heaviest service, operating during both peak and off-peak hours. Equipment will be relegated to less and less intense service as it ages. The marginal cost of service at a particular moment will be that for the oldest unit that has to be pressed into service at that instant. The rental charge for the use of the unit will vary gradually over the entire range of demands, rather than dropping off to zero whenever the full complement of equipment is not required. At the other end, in this extreme case, the service provided would not necessarily be held constant by price variation over an extended peak period: under the conditions postulated it would be possible to provide for needle peaks by planning for the stretching out over time of the final service units of the oldest equipment. In this way the required peak capacity can be provided at a cost much lower than that which would be calculated by loading all the capital charges for the added equipment on this brief period of use.

Another way of looking at the matter is to appeal to the proposition that perfect competition under conditions of perfect foresight will produce optimal results. To this end one can suppose a situation in which vehicles are rented by the hour from a large number of lessors operating in a competitive market. For simplicity, initially, one can assume all vehicles to be of the one-horse-shay variety, being equivalent to bundles of hours of active service, with the quality of service being independent of age up
to a final 'bubble-burst' collapse. Also, for simplicity, assume a steady state in which vehicles are scrapped and replaced at a constant rate over time, so that at any given moment vehicles are evenly distributed by age.

A common market rental price for all vehicles at any given time of the week will emerge, being higher as the number of vehicles in service at the time is greater. During any given week, each renter will have a reservation price for his vehicle, such that he will rent his vehicle during those hours for which the market rental is above this reservation price and never when the market rate is lower. This reservation price will increase over time for any given vehicle at the market rate of interest, since a renter will rent his vehicle if and only if the net present value of the rental discounted back to the time of purchase exceeds some fixed amount. The owner would not want to rent his vehicle for a net present value less than he could have got by selling one of this stock of service units at some other time at or just below his reservation price. New buses will have the lowest reservation price and will be assigned to the schedules calling for the most hours of service per week, while old buses will be held idle during slack hours and used only for peak service. As each bus ages it will be assigned to less and less heavy service along the load-duration curve.

This pattern of usage can be regarded as resulting from a desire to recover the capital tied up in the usage units of each bus as rapidly as possible. It is related to the practice in electric utilities of using the newest units for peak service, in that case motivated in part by the tendency for the newer units to be more efficient in thermal terms. To be sure, occasionally new units are designed specifically for peaking service, with a correspondingly low capital cost, though this is a relatively recent phenomenon related to a slowing-down of secular increases in potential thermal efficiency.

In any case, where wear-and-tear is a factor, one cannot properly allocate depreciation charges primarily to peak service, however defined, nor should they be spread evenly over all service, much less spread evenly over hours of the week so that vehicle hours in off-peak periods would get higher charges than during the peak. Rather the depreciation charge per vehicle hour will vary gradually and in a positive direction with the intensity of use of the equipment at any given hour.

The analysis becomes a little complicated when equipment life is dependent on mileage or loading or intensity of use as well as hours of active service, so that different rentals would properly be chargeable according to the nature of the service for which the unit is being rented. Also further analysis is required if equipment is laid up between runs at isolated terminals rather than at a central depot where a market could be postulated, or if the fleet contains vehicles varying in size or other characteristics. It would even be theoretically appropriate to charge different fares for the same trip at the same time if made on vehicles with different origins or destinations. (In Hong Kong, indeed, the practice is to charge a flat fare on each route, but to differentiate the fare fairly elaborately as among routes. On segments where routes converge, this has the unfortunate result of unduly concentrating riding on buses with the lower fares, even where the higher fare buses have empty seats and are making stops in any case for other passengers.)

Costs of major overhauls that are performed at relatively long intervals would also complicate the picture. There are also problems associated with gradual or sudden changes in overall demand levels, or special events that can be anticipated sufficiently to present an opportunity for reacting in terms of a change in price. The picture can be further complicated if, as was discussed above, there are changes in available technologies or other changes in quality or cost. But the same method of analysis in terms of a hypothetical competitive market can be used to obtain appropriate results.
For the sake of simplicity the above analysis has been couched mainly in terms of a bus service, but the analysis is applicable wherever the useful life of equipment is in part a function of the intensity with which it is used.

**Responsive pricing**

In some cases, notably in telephone and electric power services, the technical possibility exists for conveying information as to the current price to customers at the instant of consumption, and for customers to respond to such information in a worthwhile manner at modest cost. In the case of telephone service the information as to the level of charges for local calls can be substituted for the dial tone, with information on rates for long distance calls provided to users who wait for it before dialling the final digits. If the charge exceeds what the customer is willing to pay the call can be aborted with little occupancy of equipment or inconvenience to the user. Prices can be varied from moment to moment in accordance with marginal cost, as estimated from the degree of busyness of the relevant sets of equipment.

In the case of electric power, the costs of providing for a variation of the price according to the conditions of the moment would be somewhat greater. But if the facilities take the form of remote meter reading, either by carrier current over the power lines or by a separate communications channel, much of the cost would be covered by the avoidance of costs involved in manual meter reading. A signal of rate changes can then be provided to the customer as a by-product of the signal required to initiate a new rate period. The customer can then respond either manually or by installing automatic equipment which will adjust the operation of such items as air-conditioning and refrigeration compressors, water heaters and the like, according to the level of rates in a manner determined by the customer himself. Retrofitting of existing meters by attaching a pulse-generating device such as a mirror and photo-electric cell to the rotor shaft of the existing meter and feeding the pulses to electronic counters and registers should be possible at relatively low cost.

Such responsive pricing would be especially valuable in dealing with emergencies, providing greater assurance of the maintenance of essential services than is possible with existing techniques, and making it possible to reduce substantially the cost of providing reserve capacity. In the case of floods, conflagrations, breakdowns in transit, or other emergencies that under present conditions tend to result in the overloading of telephone facilities and difficulties in completing calls of a vital nature, rates can be charged that are high enough to inhibit a sufficient number of less important calls so that the ability of the system to handle vital calls promptly is preserved. This is difficult to do with present techniques, for while it is relatively easy to give priority to calls originating at such points as police stations, hospitals, and the like, most emergency calls are calls to rather than from these points and it is much more difficult to distinguish such calls close to the point of origin. And there are always a certain number of vital calls not distinguishable in terms of either origin or destination.

Again, in the case of unscheduled power cuts, it would be possible to cause an almost instantaneous shedding of substantial water-heating and refrigeration loads, followed, in the case of an extended cut, by partial shedding of elevator, transit and batch process loads for which it is more inconvenient to respond quite so promptly, after which a sufficient refrigeration load can be picked up as needed to avoid food spoilage. Many of the serious consequences of major power blackouts could have been avoided had such a system been in place at the time. Reserve capacity might well be cut back to
provision for scheduled maintenance, leaving the load-shedding capability of responsive pricing to function as a reserve. In many cases the speed of response possible with responsive pricing would be faster than the reaction time within which reserve capacity can pick up load, leading to better voltage regulation and a higher quality of service to customers remaining on the line. And if, in spite of everything, areas must be cut off completely, responsive pricing would also be of considerable help in facilitating a smooth recovery from an outage: instead of having a whole army of motors trying to start up at once upon the restoration of power, with consequent load surges, voltage fluctuations, and malfunction of equipment, load could be picked up smoothly and gradually as the price is lowered from the inhibiting level.

Preserving incentives with escrow funds

With privately owned utilities the regulatory process is too slow to permit prices established directly by regulation to be constantly adjusted to changing current conditions, unless indeed the regulators were to assume a large part of what are normally the responsibilities of management. The problem thus arises of how to allow the prices to be paid by customers to be varied by the utility management without giving rise to incentives for behaviour contrary to the public interest. Even if a formula could be devised that would require the utility to adjust prices to track short-run marginal cost, if the utility were allowed to keep the revenues thus generated without restriction, this would set up undesirable incentives for the utility to skimp on the provision of capacity in order to drive up the marginal cost, price, revenues, and profits.

A resolution of this dilemma can be achieved by separating the revenue to be retained by the utility from the amounts to be paid by customers. We can have the ‘responsive’ prices paid by customers vary according to short-run marginal social cost, while the revenues to be retained by the utility are determined by a ‘standard’ price schedule fixed by regulation in the normal manner, the difference being paid into or out of an escrow fund. Failure of the utility to expand capacity adequately would drive marginal cost up, and with it the responsive price, causing revenues to flow into the escrow fund, but the only way the utility could draw on these funds would be to expand capacity sufficiently to drive marginal cost down, causing the responsive rate to fall below the standard rate on the average, entitling the utility to make up the difference from the escrow fund as long as it lasts. Excessive expansion would result in the escrow fund being exhausted, with a corresponding constraint on the revenues obtainable by the utility from the unaugmented low responsive rates.

The setting of the responsive rates would have to be to a large extent at the discretion of the operating utility, though the regulatory commission could monitor the process and even attempt to establish guidelines according to which the responsive price should be set. The utility would normally have no incentive to set the responsive rate below marginal cost, since this would merely increase sales and hence costs by more than any possible long-run increase in revenues to the utility. To be sure, in the short run it might be able to draw on the escrow fund to the extent of the excess, if any, of the standard rate over the responsive rate, but since from a long-run perspective there will normally be other more advantageous ways of drawing on this fund this will not be attractive.

When marginal cost is below the standard price, which would tend to be the usual situation, the utility would in general have an incentive to set the price between the marginal cost and the standard price, since each additional sale produced by the lower price will yield an immediate net revenue equal to the...
marginal and average cost pricing: The New Palgrave Dictionary of Economics

difference between marginal cost and the standard price, offset only by the drawing down of the escrow fund by the difference between the responsive and the standard price. When marginal cost is above the standard price, which with a properly designed standard rate schedule with time-of-day variation should happen relatively rarely, the utility would have an incentive to set the price at least at the marginal cost level, since to set it lower would tend to increase output at a cost in excess of anything the utility could ever recover. How much higher than marginal cost the price might be set would in theory be limited by the condition that the price could not be high enough to curtail demand sufficiently to drive marginal cost below the standard price. If the standard price has an adequate time-of-day variation, this constraint, loose as it may seem, may be sufficient. Additional guidelines could of course be imposed by the regulatory commission for those rare occasions where this constraint might seem insufficient to keep prices within bounds.

Actual steps towards responsive pricing

Some actual practices of utility companies are steps in the direction of responsive pricing. Contracts for ‘interruptible’ power provide for load shedding at the discretion of the utility subject to some overall limits. As these are fairly long-term contracts that usually require ad hoc communication between the utility and the customer, their applicability is limited and there is no assurance that the necessary shedding will be done in the most economical manner. Many customers are reluctant to submit to load shedding that is not under their control at least to some extent, and that might be imposed under awkward circumstances. Where reserves are ample and interruption is highly unlikely, such contracts have been challenged as being a form of concealed discriminatory concession. On the other hand customers entering into such contracts in the expectation of not being interrupted may feel aggrieved if interruption actually takes place.

Another experimental provision applied by a company with a heavy summer air-conditioning load is for a special surcharge to be applied to the usage of larger customers on days when the temperature at some standard location exceeds a critical level. And another company bases its demand charge on the individual customer's demand recorded at the time that turns out to have been the monthly system peak load, supplying the customers with information as to moment-to-moment variations in the system load. This leads to interesting game-playing on the part of customers as they attempt to keep their own consumption down at times that look as though they might become the monthly peak, with the result that this action may itself shift the peak to another time.

Economies of scale, subsidy and second best pricing

Where there are economies of scale, prices set at marginal cost will fail to cover total costs, thus requiring a subsidy. One reason for wanting to avoid such a subsidy is that if an agency is considered eligible for a subsidy much of the pressure on management to operate efficiently will be lost and management effort will be diverted from controlling costs to pleading for an enhancement of the subsidy. This effect can be minimized by establishing the base for the subsidy in a manner as little susceptible as possible to untoward pressure from management. But it is unlikely that this can be as effective in preserving incentives for cost containment as a requirement that the operation be financially self-sustaining. To achieve this, prices must be raised above marginal cost, and in a multi-product
operation the question arises as to how these margins should vary from one price to another within the agency.

Another objection to subsidy is that it raises hard questions of who should bear the burden of the subsidy. More fundamentally the taxes imposed to provide the subsidy will often have distorting effects of their own, and minimizing the overall distortion would again require prices to be raised above marginal cost. One can, indeed, regard these excesses of price over marginal cost as excise taxes comparable to other excise taxes that might be levied to raise a specified amount of revenue.

The answer given to the problem of how to allocate excise taxes and other margins of price above marginal cost so as to minimize the overall loss of economic efficiency given by Frank Ramsey in 1927 can be expressed for the case of independent demands as the inverse elasticity rule, which says that the margin of price over marginal cost as a percentage of the price shall be inversely proportional to the elasticity of demand. A more general formulation is one that states that prices shall be such that consumption of the various services would be decreased by a uniform percentage from that which would have been consumed if price had been set at marginal cost and demand had been a linear extrapolation from the neighbourhood of the ‘second-best’ point.

A more transparent formulation, devised by Bernard Sobin in work for the US Postal Service, is the requirement of a uniform ‘leakage ratio’, leakage being the difference between the net revenue actually derivable from a small increment in a particular price and the hypothetical revenue that would have been obtained had there been no change in consumption as a result of this increment. Leakage is the algebraic sum of the products of the changes in consumption of the various related products induced by the small change in a given price, and the respective margins between their prices and marginal costs. Leakage is a measure of the loss of efficiency resulting from the change in the particular price, and the leakage ratio is the ratio of this loss of efficiency to the hypothetical gain in gross revenue if there had been no change in consumption. If one leakage ratio should be greater than another, the same net revenue could be obtained at greater economic efficiency by getting more revenue from the price with the smaller leakage ratio and less from the other. The second-best solution accordingly requires that all leakage ratios be equal.

This analysis can be extended to the case where the agency is being subsidized by taxes which involve an adverse impact on the economy, in terms of marginal distorting effects, compliance costs, and collection costs, which can be expressed as the ‘marginal cost of public funds’ (MCPF). For a net decrease in the subsidy derived by increasing a price, which can be considered to be equivalent to imposing a tax equal to the difference between the marginal cost and the price, $MCPF = LR / (1 - LR)$, where LR is the leakage ratio. A second-best optimum is then one where the MCPF’s are equalized over both external and internal taxes.

**Special sources of subsidy: land rents and congestion charges**

In the case of goods and services with economies of scale that are provided primarily to consumers within a particular urbanized area, methods of financing may be available that involve no marginal cost of public funds or even result in an enhancement of efficiency. The existence of large cities, indeed, is to a predominant extent due to the availability in the city of goods and services produced under conditions of economies of scale: if there were no economies of scale, activity could be scattered about the landscape in hamlets, with great reduction in the high transportation costs involved in movement about a
large city. If prices of these services are reduced to marginal cost, the increased attractiveness of the city as a consequence would tend to drive up land rents within the city, and it appears quite appropriate that a levy on such rents should be used to finance the required subsidies. And while there are practical and conceptual difficulties in defining exactly how land rents or land values should be specified for purposes of levying a tax, it is generally considered that a tax on land values, properly defined, has negligible adverse impacts on the efficient allocation of resources.

Indeed, there is a theorem of spatial economics which states that in a system of perfect competition among cities, the availability in the city of services and products subject to economies of scale, priced at their respective marginal social costs, will generate land rents just sufficient to supply the subsidies required to permit prices to be lowered to marginal cost. Among the more important of these services are utility services such as electric power, telephone, cable communications, water supply, mail collection and delivery, sewers and waste disposal, and local transit. It is not clear just how broad the conditions are under which this theorem would hold, and there are difficulties in capturing all land rents for subsidy purposes, but steps in this direction are clearly desirable.

On a more intuitive level, one can note that a person who occupies or uses land that is provided with services such as the availability of transit, electricity, telephone, mail delivery and the like will be requiring that these services be carried past his property to serve others whether or not he himself uses them. The user of tennis courts located conveniently in a built-up area should no more be excused from contributing to the costs of carrying these services past the courts, even though no direct use is made of electric power, telephone, mail, or other services, than he should expect his auto dealer to cut the price of an automobile by the cost of the headlights and windshield wipers merely because he asserts that he will never drive at night or in bad weather. Tennis players will indeed pay a rent enhanced by the presence of these services and the consequent greater demand for the land for other purposes, but the rent will go to the landlord, not to the purveyor of the services, and the price of the services to those who do use them will be too high for efficiency, unless indeed they are subsidized by other taxes that have their own distorting effects.

It is a corollary of this theorem that it would be to the advantage of the landlords in the area, faute de mieux, to agree collectively to pay a tax based on their land values, in order to subsidize the various utility services to enable the prices to be set closer to marginal social cost. They could expect in the long run that this action would increase their rents by as much or more than the taxes. To be sure, they might do better by getting someone else to pull their chestnuts out of the fire, but they can do this only at considerable damage to the overall efficiency of the economy of the city, to say nothing of the inequity of such a parasitic relationship.

In addition to land rents in the conventional sense, there is the land used for city streets for the use of which no adequate rental is generally charged. Charging on the basis of SRMSC for the use of congested city streets would in most cases yield a revenue far in excess of the cost of maintaining such facilities, which could appropriately be used for the subsidy of other urban facilities. Properly adjusted, such charges would increase efficiency by bringing home to the users the costs that their use directly imposes on others.

Formerly it would have been considered impractical to attempt to charge for the use of city streets according to the amount of congestion caused: the collection of tolls by manual methods at a multitude of points within the city might well create more congestion than it averted. Advances in technology have, however, made it possible to do this at minimal interference with traffic flow and at modest cost.
One method, proposed as long ago as 1959 and recently carried to the point, is to require all vehicles using the congested facilities to be equipped with electronic response units which will permit individual vehicles to be identified as they pass scanning stations suitably distributed within and around the congested area so that the records thus generated can be processed by computer and appropriate bills sent to the registered owners at convenient intervals. If properly done, this would greatly improve traffic conditions so that the net cost of the revenue to the road users would be far less than the amount collected as revenue. A pilot installation has recently been tested in Hong Kong with satisfactory results, but full implementation appears to have been deferred, because of the political situation associated with the impending transfer of sovereignty.

Indeed, one can define ‘hypercongestion’ as a condition where so many cars are attempting to move in a given area that fewer vehicle miles of travel are being accomplished than could be if fewer vehicles were in the area but could move more rapidly; for example if 1000 vehicles in an area move at 8 mph and produce 8000 vehicle miles of travel per hour, reducing the number of cars in the area at a given time to 800 might raise speed to 11 mph producing 8800 vehicle miles of travel per hour. By restricting the flow of traffic in the period leading up to the hypercongestion period, road pricing could prevent hypercongestion from occurring, except possibly sporadically, and in any case so improve conditions that more movement would be accomplished during the peak period at faster speeds. The improvement during peak periods might even be such that total movement throughout the day would be increased, and where conditions are now severe users could find that they are better off than before, even inclusive of the payment of the congestion charge.

If there are bridges, tunnels, or other special facilities for which a toll is already being charged, and which regularly back up a queue during the morning rush-hour, substantial revenues can be obtained at no overall net cost to the users by adding a surcharge to the toll during the period where queueing regularly threatens, rising gradually from zero to a maximum and down again in such a way that by gradual adjustment regular queueing is substantially eliminated. The toll surcharge will then be taking the place of the queue in influencing decisions as to when to travel, and in general those who plan their trips in terms of time of arrival at their destination will be able to leave as many minutes later as they formerly wasted in the queue, pass the bottleneck at the same time as before, and arrive at their destinations at the same time as before. The extra toll will be roughly the equivalent of the value of the extra time enjoyed at the origin point, and the revenue will in effect be obtained at no net burden on the users. In practice the results may be even better than this as a result of the added encouragement to car-pooling, the reduction of obstruction to cross-traffic, and the expediting of emergency or other trips where the delay had been a particularly serious matter.

Gains in the evening may be not quite so dramatic. The situation is not symmetrical, as typically the timing of the trip will be determined in terms of time of departure, which is separated by the queue from the time at the bottleneck. On the other hand the risk of conditions approaching gridlock is greater, since the accumulation of queues inside circumferential bottlenecks is more likely to create congestion, and there is less of a physical barrier to the simultaneous emergence of large quantities of traffic from parking lots into the downtown streets than there is in the morning to the convergence on the congested area of traffic arriving from the outside.

Congestion charges should be imposed, at least notionally, without exception on all forms of traffic. Such charges would be a necessary element in the cost-benefit analysis by which decisions are made as to the level and pattern of bus service to be provided, even though they would not be directly relevant to
the determination of the price structure to be applied to that service.

**Paradoxes in the behaviour of marginal social cost**

A strict calculation of marginal social cost in particular circumstances may produce what may appear to be quite paradoxical results. For example, in many circumstances it will be optimal, and even essential, to maintain at least a minimum frequency of service in off-peak hours with buses of a standard size, resulting in there being practically always a large number of empty seats in each bus. Under these circumstances the cost of carrying additional passengers is predominantly the cost of boarding and alighting, including the time of the driver and the other passengers on the bus who are delayed in the process. This cost will be relatively higher if the bus is half full than if it is nearly empty. The result is likely to be that the cost of a trip from a point near one end of the run to a point near the other end, at both of which points the bus is likely to be lightly loaded, may be smaller than for a shorter trip between points near the middle of the run where the bus is likely to be more heavily loaded. This is not a trivial matter: if it were there would be no sense to the refusal of express buses with empty seats to pick up local passengers. It is highly unlikely, however, that fares based on such a seemingly perverse behaviour of cost would meet with popular approval. Indeed, the original US interstate commerce legislation contained prohibitions against higher rates being charged shorter hauls than for any longer hauls within which they might be included.

Another paradoxical example can occur in mixed hydrothermal electric power systems: an increase in fuel prices could result in the marginal cost of power at particular times being reduced rather than increased. If hydro dams are spilling water at certain seasons of the year, increased fuel costs may make it economical to increase the installed generating capacity to make use of the spilling water, even for a briefer period of time over the year than was previously worth while. If during the wet season installed hydro generating capacity is more than sufficient to meet trough demand, marginal cost during such periods will be substantially zero, or at most limited to a small element of wear and tear on equipment pressed into service. Installing more turbo-generators would expand the period during which this low marginal cost is effective, so that while increased fuel costs cause marginal cost to rise during the peak, the result could also be to lower marginal cost in these intervals into which the period of exclusive hydro supply expands.

In the case of long distance telephone service, the drastic reductions in the cost of bulk line-haul transmission have created a situation where distance, especially beyond the range where separate wire transmission is economical, is relatively unimportant as a cost factor, and where satellite transmission is involved, ground distance is indeed irrelevant. What remains important is the number of successive circuits, with their associated termination and switching equipment, involved in the making of a call. Thus a call between two small communities over a moderate distance, for which the volume of calling is insufficient to warrant the provision of a separate circuit, will generally cost substantially more than a call between important centres over a much longer distance, since the latter will involve only a single long-haul circuit, while the former will require patching through two or more long-haul circuits. Another anomaly occurs when an innovation promising substantial reductions in costs appears on the horizon, such as has happened repeatedly in telecommunications. Any further installation of the old technology in the interim before the new technology is actually available will involve an investment which will have its capital value diminished over a brief period to that determined by its competition
with the new technology. High depreciation or obsolescence charges are in order, and the prospect of the new lower costs results in higher current prices which would serve to hold back current demand and lessen the amount of old technology required to be installed. Marginal cost pricing is thus not a matter of merely lowering the general level of prices with the aid of a subsidy; with or without subsidy it calls for drastic restructuring of pricing practices, with opportunities for very substantial improvements in efficiency at critical points.

Marginal productivity theory is an approach to explaining the rewards received by the various factors or resources that cooperate in production. Broadly stated, it holds that the wage or other payment for the services of a unit of a factor is equal to the decrease in the value of commodities produced that would result if any unit of that factor were withdrawn from the productive process, the amounts of all other factors remaining the same.

The basic justification of this assertion is highly intuitive. It rests on three assumptions: that the product is sold and the factor services are purchased in competitive markets; that the firms in those markets operate so as to maximize their profits; and that the products sold are produced by technologies that satisfy the ‘law of variable proportions’, which holds that successive equal increments of one factor of production, the amounts of all other factors remaining unchanged, will yield successively smaller increments of physical output. It follows immediately from these assumptions that if the wage of any factor exceeds the value of the output that would be lost if a unit less of that factor were employed, then a unit less of that factor will be employed, and successive units will be released until the inequality is annihilated. Similarly, if the wage of any factor is less than the value of the output that an additional unit could produce, successive units of that factor will be employed until the inequality vanishes.

The motivating concept in the foregoing argument was the effect on the value of output of small changes in the quantities used of different factors of production. This idea is so important that a special vocabulary has developed in order to discuss it with precision. The marginal product of a factor of production is the ratio of the greatest change in the output of some product that can be obtained by a small change in the use of the factor to the change in the use of the factor. The marginal product multiplied by the price of the product is the value of the marginal product. Marginal productivity theory holds that the payment for any factor of production tends to be about equal to the value of its marginal product, where, in a multiproduct firm, the product used in the calculation is the one for which the value of marginal product is greatest.

Clearly, the marginal product and its value may depend on the size of the ‘small’ change in the amount of the factor that is used in the calculation. To avoid being ambiguous when the amount of the factor is a continuous variable, the concept of marginal productivity is used: the marginal productivity of a factor is the limit that its marginal product approaches as the change in the quantity of the factor approaches zero.
The result of multiplying the marginal productivity by the price of the product is called, somewhat inaccurately, the value of the marginal product; confusion rarely results.

Two of the assumptions made above to justify the marginal productivity doctrine can be relaxed. First, if the assumption that the firm produces for a competitive market is dropped, the conclusions of the theorem has to be weakened slightly. If a firm produces for a market that is not perfectly competitive, it will recognize that it cannot change the quantity of any of the commodities it sells without simultaneously changing the price. Consequently, it will take account of the fact that if it changes the amount used of any factor, the resulting change in sales revenue will not equal the value of the factor's marginal product, but that value adjusted for the induced change in price. The ratio of the change in sales revenue to the change in the employment of a factor, for 'small' changes, is called the factor's marginal revenue product. Then the reasoning used to deduce the marginal productivity doctrine leads to the conclusion that the firm will employ each factor at the level where its marginal revenue product equals its rate of pay, whether or not the firm sells in a competitive market. In competitive markets, the marginal revenue product of a factor equals the value of its marginal product, but not necessarily in other market types.

The assumption that firms operate so as to maximize their profits can also be weakened for some purposes. If the firm operates only so as to produce its outputs at the lowest possible total cost, the same line of argument shows that the rates of pay for any two factors used by the firm will be proportional to the marginal revenue products of the factors. This is a weaker conclusion than was found for profit-maximizing firms, and does not imply any particular relationship between a factor's rate of pay and its marginal revenue product or the value of its marginal product.

**Development of the concept**

Simple as it may appear, the marginal productivity principle was seen clearly only after a long, slow evolution. It was first presented in essentially its modern form around 1890, by J.B. Clark and Alfred Marshall, who apparently arrived at it independently. Their formulation built on the work of numerous predecessors, each of whom saw an important aspect of the principle but did not perceive its full generality.

The problem that gave rise to the marginal productivity principle – to explain the distribution of the national income among the great social classes and, especially to explain the shares claimed by the owners of capital and land – was at the top of the agenda of 19th-century economics. Thus, originally, only three very broad factors of production were considered: land, labour and capital, corresponding to the three social classes.

The first application of the principle occurred in the Malthus–Ricardo theory of rent, in particular in the concept of the intensive margin, which held that doses of labour and capital (in unspecified proportions) would be applied to each parcel of land until the value of the increase in product equalled the cost of the dose. The separate rewards to labour and capital were explained on other grounds.

In 1833, Longfield argued that the rate of interest was governed by the earnings of the least productive unit of capital, using a marginal argument. But he did not extend the reasoning to wages. At around the same time, von Thünen applied the principle to both wages and interest but did not publish his findings until much later, and then so obscurely that they had no influence. Jevons, in 1871, accounted for the rate of interest by a marginal argument, but explained wages as a residual after rent and interest were
paid. Indeed, Jevons's theory is remarkably similar to Longfield's. The ingredient that all these applications of the marginal principle missed was that the equality of marginal product and factor reward applied to all factors. Walras in 1874 (and, indeed, J.-B. Say three-quarters of a century before) insisted on treating the various factors of production symmetrically, but he did not derive any of the factor shares by a marginal argument until the later editions of the Elements, and then only awkwardly. Thus the marginal insight was not applied symmetrically to all factors until Clark published the papers that led to his The Distribution of Wealth (1899), and Marshall published his Principles of Economics (1890), thereby introducing a unified theory of income distribution. The achievement of the unified theory raised a puzzling question: if each unit of every factor was paid the value of that factor's marginal product, would the total value produced be neither more nor less than just sufficient to make all the factor payments? In 1894 Philip Wicksteed showed that the answer is affirmative for production processes with constant returns to scale, thus establishing the internal consistency of the marginal productivity principle. (Clark had believed it all along, but on inadequate grounds.) Wicksteed's proof amounted to an independent rediscovery of part of Euler's Theorem for Homogeneous Functions.

Beginning with the late 1880s, when the various partial glimpses of the doctrine congealed, marginal productivity theory became an essential part of the accepted explanation of the general level of wages and of the rate of interest, with important implications for practical economic issues. For example, it is often held that unions are powerless to raise the average level of wages because wages are governed by the marginal productivity of the labour force, which union activity cannot affect. Although the marginal productivity concept was originally applied to explain the rewards of the broad social classes – the workers, landowners and entrepreneur–capitalists – beginning with Walras it became absorbed into the general theory of production and value. In that context it is used to explain the payments for the services of all the classes of factors that enter into production, and the definitions of these classes can be chosen freely to fit the problem under study. The tripartite classification continues to be used frequently, however.

Qualifications

The marginal productivity doctrine does not purport to be a complete explanation, even in principle, of the payments received by factors of production. As the simple, basic argument indicated, it explains only the amount of each factor that an enterprise will employ at different rates of payment for its services and in the presence of given quantities of the other factors used; that is, the demand curves for the factors. Supply curves also are needed to complete the explanation of the equilibrium level of use and rate of payment for the factors. Furthermore, especially in the version that deals with numerous factors, rather than just two, a high degree of simultaneity arises. The demand curve for each factor depends on the amounts used of the other factors, but those amounts, depend on the amount used of the first factor, so, in the end, the rates of payment and the quantities used of all the factors are determined simultaneously. Consequently, the rates of payment for the various factors cannot be explained except in the context of a full-fledged general equilibrium model. Still, in such a model it often turns out that the payment received by each factor corresponds to its marginal productivity in each productive process in which it is used and in which marginal productivity is a well-defined concept. These complications will be clarified by considering a
Formal derivation of the marginal productivity thesis

The theory is based on the behaviour of a profit-maximizing firm in a competitive industry. To describe that behaviour, imagine a firm that produces $m$ products by the use of $n$ factors or inputs. Suppose that the price of the $i$th product is $p_i$ and that the quantity produced (per year) is $y_i$. Then the gross revenues per year will be $R = \sum p_i y_i$. Similarly, let $w_j$ be the price per unit of the $j$th factor used. If the $j$th factor is a kind of labour or a purchased input $w_j$ is simply its price or wage, but if it is a kind of fixed capital, then $w_j$ should be regarded as its rental cost, normally interest on its purchase or construction cost plus a depreciation allowance. The amount of the $j$th factor used will be denoted by $x_j$. Then the total cost incurred per year will be $C = \sum w_j x_j$. The profit that the firm seeks to maximize is $R - C$.

The quantities (per year) of output, $y_i$ and input $x_j$, cannot be chosen freely. This basic presentation will be limited to the simplest situation, in which the choices are constrained only by an explicit, differentiable production function, which will be written $g(y_1, \ldots, y_m, x_1, \ldots, x_n) = c$. The implicit constraint that none of the arguments of $g(\ldots, \ldots)$ can be negative has important consequences that will be noted below.

In this set-up, invoking the assumptions mentioned in the second paragraph of this entry, the necessary conditions for a choice of $y$ and $x$ to maximize the firm's profits are the familiar marginal equalities. Specifically:

1. (1) Marginal rates of substitution. The marginal rate of substitution between two factors, say the $j$th and the $k$th, is the rate at which small amounts of the $j$th factor can be substituted for the $k$th with no effect on the rates of output in accordance with the production function constraint. Denote it by $\delta x_j / \delta x_k$. Mathematically, it is the ratio of the partial derivatives of the production function, or $\delta x_j / \delta x_k = - (\partial g / \partial x_k) / (\partial g / \partial x_k)$. Economically, when the firm's profits are being maximized, $\delta x_j / \delta x_k = w_k / w_j$. The intuitive content is clearest when the maximizing condition is written as $w_j \delta x_j = w_k \delta x_k$ which requires that when profits are being maximized the amounts of factors that can be substituted for each other in accordance with the production function must have equal monetary value.

2. (2) Marginal rates of transformation. There is a similar relationship among the rates at which the outputs can be 'transformed' into one another in accordance with the production function constraint. Let $\delta y_i / \delta y_k$ denote the ratio at which production of the $i$th output can replace production of the $k$th. Mathematically, $\delta y_i / \delta y_k = - (\partial g / \partial y_k) / (\partial g / \partial y_i)$. Economically, when profits are being maximized $\delta y_i / \delta y_k = p_k / p_i$. Again, this result asserts that when profits are being maximized a small quantity of one of the outputs can be replaced by a quantity of equal value of any of the other outputs.

3. (3) Marginal productivity of a factor. The final necessary marginal equality relates small changes in the quantity of an input, say $x_j$, to the resulting changes in the quantity of any of the outputs, say $y_i$, in accordance with the production function. Mathematically,
Marginal productivity theory: The New Palgrave Dictionary of Economics

When profits are being maximized
\[ \frac{\delta y_i}{\delta x_j} = -\frac{(\partial g / \partial x_j)}{(\partial g / \partial y_i)}. \]

Economically, this is seen to require that if any output is increased by a small amount, the use of some factor must be increased by an amount of equal value.

This third differential equality, of course, is the marginal productivity doctrine, which is seen to be one of the consequences of the theory of profit maximization under competitive conditions. It is often written in the form \( \text{VMP}_j = p_j(\delta y_i / \delta x_j) = w_j \), for all values of \( i \). This formula defines the value of the marginal product of the \( j \)th factor to be the increase in the value produced of any product for which that factor is used, per unit increase in the use of the factor, and holds that the price per unit of that factor’s services will be equal to the VMP when profits are being maximized.

Evaluation

At present the marginal productivity principle is used to explain the demand for factors of production in both a two-factor version using aggregate capital and aggregate labour as the factors, and an \( n \)-factor version, where \( n \) is the number of distinguishable factors used in the production process.

To use the two-factor version it is necessary to establish quantitative measures of the aggregates of dissimilar objects that are given the names ‘capital’ and ‘labour’, a task that has never been performed to anyone’s satisfaction. For a long time, until the publication of J. Robinson’s disturbing paper, ‘The production function and the theory of capital’ (1953), the lack of satisfactory measures of the aggregates was regarded as a technicality that did not affect the essential insight. But that paper drove home the realization that in the absence of those measures the marginal productivities, i.e. \( \partial g / \partial K \) and \( \partial g / \partial L \), were essentially undefined. From that time forth, analyses that use the two-factor version have been regarded as simplified ‘parables’, useful for making an intuitive point, but not to be taken literally. Clarifying the meaning of ‘capital’ and ‘labour’ regarded as homogeneous factors of production continues to be one of the main problems of capital theory.

The \( n \)-factor version avoids the impossible task of aggregating apples and bulldozers, but has problems of its own. The formulation considered in this article is too simple to fit most industrial or commercial situations. It presumes that the constraints on choices can be described reasonably well by a single well-behaved, differentiable production function. This is generally not the case. Extreme examples are production functions in which factors are used or outputs are produced in fixed proportions. Any cooking recipe provides an example. More usual are cases in which the choices of input and output quantities are constrained by several functional relationships. The typical example is a firm or industry in which several different machines are each used in the production of several different products. Then there will be a functional relationship for each type of machine, to express the capacity of that type required for each combination of quantities of the different products. This is the sort of problem that has given rise to the use of linear programming in production planning and economic planning generally.

Where there are several constraints, the formulation used above does not apply because, essentially, the amounts of the inputs and outputs cannot be varied two at a time if they are connected by more than a single constraint. Marginal productivity is still a well-defined concept, but it no longer satisfies simple formulas like \( \text{MP}_j = p_j(\delta y_i / \delta x_j) \) for any value of \( i \). Instead, the marginal productivities, as defined above, are identified with the shadow prices in the solution to a mathematical programming problem.
which is a considerably less intuitive concept. Very frequently, if the problem of finding the combination of factor inputs that maximizes profits is solved straightforwardly, some of the input levels in the solution turn out to be negative – which is nonsense. Then, again, resort must be had to mathematical programming types of formulation and interpretation. The essential perceptions of marginal productivity theory still apply, but they can no longer be expressed by equalities between price ratios and ratios of marginal changes.

marginal revolution

Roger E. Backhouse
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The marginal revolution saw the introduction of the idea of marginal utility into economics in the early 1870s by Jevons, Walras and Menger. This change in economic theory was a slower process than the word ‘revolution’ suggests, and, to understand the changes associated with it, it is necessary to explore the scientific, social and political context in which they occurred.

Article

The marginal revolution (sometimes called the marginal utility revolution) refers to the introduction into economics, in 1870–1, of the concept of marginal utility by William Stanley Jevons, Léon Walras and Carl Menger and which has widely been seen as involving a revolutionary break with the ‘classical’ economics of David Ricardo, John Stuart Mill and many of their contemporaries (see Blaug, 1996, ch. 8). The value of a commodity was no longer explained in terms of its cost of production (possibly reducible to the labour required to produce it) but in terms of its value to the consumer. The concept of utility was used to explain consumer choices, marginal utility being seen by some (though not all) authors as replacing cost of production as the foundation on which the theory of value rested. In the 1890s marginal techniques were then applied systematically to the problem of income distribution. This
change, it is argued, revolutionized economics, laying the foundations on which modern economic theory is built. Its many dimensions – viewing behaviour as optimization, using utility to describe individual behaviour, focusing on individual agents, the use of mathematics – attest to its importance (Hutchison, 1978, provides a longer list; Maas, 2005, ch. 1, sketches more recent attempts to choose between them). There is disagreement over the extent to which the change should be described as a revolutionary or as an evolutionary change going back many decades, and over its exact significance; but the marginal revolution is firmly established in histories of economic thought. However, while it describes certain developments in economic theory, to understand the changes that took place in economics around this time one should place it in a broader historical context.

Varieties of marginalism

The most important qualification to the idea of a marginal revolution is the heterogeneity of economics during this period. Classical ideas were dominant in Britain, but even within classical economics there was great variety, and it has even been argued that marginalist ideas can be traced back as far as Steuart (see English School of political economy). At some time, virtually every element in the classical system outlined above had been challenged, many of these challenges leaving their mark. Much of this variety was captured within Mill's Principles of Political Economy, which went through seven editions between 1848 and 1873, and was undoubtedly the leading treatment of the subject: he worked with a very broad supply and demand theory of value and had accommodated many modifications to the Ricardian theory of income distribution. From Mill, the jump to marginalist theories was much easier than from Ricardo. Indeed, Alfred Marshall, though unfairly praising Ricardo at the expense of Mill (see O'Brien, 1990), derived his theory of value by translating Mill into mathematics during the 1860s; when he encountered Jevons's work, it was a simple matter to graft marginal utility on to a mathematical treatment of supply and demand (Whitaker, 1975).

There was also great variety across countries. In Ireland, it has been argued that an independent tradition of subjective value theory had been established at Trinity College Dublin, by successive holders of the Whately Chair (Black, 1945). Ireland also produced two leading exponents of a historical approach to economics, T.E. Cliffe Leslie and John Kells Ingram. Leslie's assault on deductive theorizing was a significant factor in the shaking of confidence in classical economics in Britain in the 1870s (see Hutchison, 1953). In Germany, supply and demand theories had a long history, a supply and demand diagram having been used in a textbook as early as 1843 by Heinrich Rau (see Streissler, 1990). In France, Smithian political economy had been mediated not through Ricardo but through Jean-Baptiste Say. The work of Augustin Cournot and the engineers of the École des ponts et chaussées, whose analysis rested on the concept of a demand curve, created an intellectual background very different from that prevailing in Britain.

These differences, together with profound differences in their personal backgrounds, meant that the work of Jevons, Walras and Menger, though often bracketed together, was far from homogeneous (see Jaffe, 1975). Though Jevons and Walras both advocated the importance of mathematical argument, their emphases differed. Walras, closer to French rationalism, saw his general equilibrium equations as an abstract system that could solve the same problem that was solved in the real world by other means. Jevons focused on mechanical analogies and the notion that the same methods could be applied to
physical and social sciences (Maas, 2005). The contrast was even more marked in their applied work, where Jevons was a pioneer in the use of statistics but Walras was not. Menger, in contrast with both of them, rejected the use of mathematics, seeing the use of simultaneous equations as incompatible with identifying the causal relations between human needs and the value of commodities.

The varieties of marginalism increase further when later marginalists are brought into the account. Jevons, Walras and Menger did have disciples, most of them took their analysis in new directions and many are in many ways originals, the best examples being Marshall, Joseph Alois Schumpeter (Austrian, geographically and intellectually, yet an admirer of Walras), Knut Wicksell (whose Swedish synthesis of Austrian and Walrasian ideas bore little resemblance to Schumpeter's) and John Bates Clark (who constructed a non-mathematical American version of marginalism). Given this variety, it is not surprising that the marginal revolution can also be portrayed as a very slow process. Even in the 1880s and 1890s, some economists were still writing textbooks organized on classical lines, marginalist ways of thinking co-existing with other lines of enquiry.

The wider context

While scholars might, at one time, have been content to explain the advent of marginalist ideas in terms of economists coming to see the truth about consumers and value, historians are no longer satisfied with such explanations, arguing that economic ideas have to be explained in terms of the context out of which they arose. One context is that of 19th-century science. The most widely discussed explanation has been Mirowski’s (1984; 1989) argument that marginalist economics reflects developments in physics (see De Marchi, 1993). The 1860s saw the rise of energetics – the attempt to reduce all physical phenomena to energy. If physical phenomena could be reduced to energy, then so should social phenomena. More than that, adopting the methods of physical scientists and the mathematics of maximization and energy conservation offered economists the possibility of acquiring the status of physicists, adopting similar standards of rigour. Mirowski directed historians’ attention to the many passages where Jevons, Walras and others stated explicitly that this was what they were doing. Though Mirowski drew normative conclusions about which many historians have been sceptical, and though his interpretation clearly does not fit some of the most important marginalists (notably Menger and Marshall), historians have taken up the idea that a major dimension to the marginal revolution was seeing economics as amenable to the methods of the physical sciences rather than as something radically different (see Maas, 2005; Schabas, 2005).

Moreover, at this period, physics was not the only prestigious natural science: controversies over evolution were at their height, following the publication of Charles Darwin’s *Origin of Species* and the application of evolutionary arguments to human society by Herbert Spencer. This cannot explain the advent of marginalism, but it represents an important additional connection between economics and contemporary science and helps explain why economics looked very different at the end of the 19th century from the way it looked in the 1860s. Raffaelli (2003) has pointed out that Marshall, perhaps the most significant figure in late-19th century marginalist economics, based his economics, not on the Benthamite utilitarianism used by Jevons, but on evolutionary psychology. Human nature was moulded by experience. Evolutionary ideas thus reinforced the notion that human beings had to be seen as different from one another and that they could be changed. This way of thinking could lead into
eugenics, a widely entertained body of ideas that developed towards the end of the century (see Peart and Levy, 2005). But such ideas also served to undermine the Malthusian bogey that had provided an argument against much social reform throughout the century (Stedman Jones, 1984). Marshall, for example, though he used the static, mechanical apparatus of supply and demand, used it to discuss dynamic processes. He saw industries evolving as biological species, and human character changing in response to human activities, a process that was too complicated to be represented mathematically, and as a result never worked with formal dynamic models: they would have been too mechanical. Against such arguments that evolution became influential at that time, Schabas (2005), though stressing that neoclassical economists were very interested in psychology, has recently questioned whether Darwin has as much influence as has been claimed.

The significance of evolutionary ideas points to another aspect of the context against which the advent of marginalist ideas needs to be set: the political climate. The late 19th century has been called the liberal age, when Europe moved towards freer trade and the franchise became more democratic. The progress of liberal ideas and policies varied greatly from country to country, but everywhere there was debate over the merits of liberalism and collectivism, with the latter taking many forms, ranging from Fabian ‘municipal socialism’ to Marxian socialism. In Britain, the mid-century radicals, amongst whom Mill was pre-eminent, were liberals who wanted to reform the institutions of society in ways consistent with their liberalism. But, by the end of the century, following the extension of the franchise to much of the working class in 1867 and 1884, radicalism became increasingly collectivist. Against Social Darwinist arguments for individualism were ranged ethical arguments for reform, from the American Social Gospel movement to the variety of movements for social reform inspired in Britain by the Oxford philosopher T.H. Green (see Richter, 1964). In the same way that the Great Depression motivated many who came into economics in the 1930s and 1940s, the problem of poverty affected this earlier generation. Economists’ attitudes towards policy changed (see Hutchison, 1978), as did the way they developed their theories, the most noticeable example being the development of welfare economics by the Cambridge School, J.A. Hobson, and others.

Though it was again a process the speed of which varied greatly from country to country, a further element of the context in which the marginal revolution took place was the professionalization of economics. By the middle of the 19th century, economics was being developed by a mixture of academics and members of a broader educated elite; those recognized as economists might be politicians or businessmen. Specialist journals existed in some countries, but original work in the subject was also published in journals read by non-specialists. By the end of the century economics, like many other disciplines, had changed, becoming an academic discipline in which the main communication was between specialists. This made possible a different type of discourse, more technical and addressing issues that might seem more tenuously related to issues of concern to lay people.

Conclusions

The marginal revolution, like other revolutions in economics, is associated with changes in economic theory that undoubtedly altered the way economics was conceived. However, picking out a single theoretical or methodological innovation that explains why the marginal revolution was apparently so important has proved difficult. The reason may be that, in the case of the Keynesian Revolution,
though economics changed profoundly in the closing decades of the 19th century, these changes owed as much, if not more, to deeper changes in the social, political and intellectual context in which economists were working as to any specific innovation in economic theory.

Abstract

Alfred Marshall identified the area to the left of a demand curve as consumer surplus, but he added that his discussion was valid only under the assumption of ‘constant marginal utility of money’. For much of the 20th century economists debated the meaning of that phrase and its relevance to consumer surplus. The analysis became clear only after the development of duality theory, particularly the properties of the expenditure function. Marshall's caution becomes unnecessary with a proper definition of consumer surplus.

Article

Interest in the marginal utility of money probably dates from Alfred Marshall's identification of consumer surplus as the area under the demand curve. Marshall went on to add a qualification to his analysis:

In the same way if we were to neglect for the moment the fact that the same sum of money represents a different amount of pleasure to different people, we might measure the surplus satisfaction which the sale of tea affords, say, in the London market, by the aggregate of the sums by which the prices shown in a complete list of demand prices of tea exceeds its selling price. (Marshall, 1920, p. 106)

In the mathematical appendix (Note VI), Marshall identifies the ‘total utility of the commodity’ with the area under the demand curve, defined by an integral, but then qualifies that analysis by saying ‘we
assume that the marginal utility of money to the individual purchaser is the same throughout'. The meaning of these phrases is anything but clear. The text phrase seems to indicate that interpersonal comparisons of utility are a necessary prerequisite for the use of consumer’s surplus; in the appendix, Marshall’s concern is that, as more of a commodity is purchased, money will yield less satisfaction to the consumer, destroying any linear relationship between money and utility.

Later interpretation of ‘constant marginal utility of money’ was further complicated by the use of the word ‘money’ in two different contexts. To Marshall, money provided no direct utility to the consumer; it was a device solely for lowering the transactions cost of exchange. The concurrently developed general equilibrium theory of Walras, however, treated money as that one good which happened to have the additional property of serving as the medium of exchange, a numéraire commodity whose price was unity.

We now analyse the connection between the marginal utility of money and consumer’s surplus. The consumer is assumed to maximize $U = U(x_1, \ldots, x_n)$ subject to $\sum p_i x_i = M$. We derive the Marshallian (money income held constant) demand functions $x_i = x_i^M (p_1, \ldots, p_n, M)$ along with $\lambda^M (p_1, \ldots, p_n, M)$ using the Lagrangian $L = U + \lambda(M - \sum p_i x_i)$.

The indirect utility function $U^* (p_1, \ldots, p_n, M) = U(x_1^M, \ldots, x_n^M)$ indicates the maximum utility for given prices and money income. Using the envelope theorem, $\partial U^* \partial M = \lambda^M$, the marginal utility of money income. Also, $\partial U^* \partial p_i = - \lambda^M x_i^M$ (Roy’s identity). The Hicksian (utility held constant) or ‘compensated’ demand functions $x_i^U (p_1, \ldots, p_n, U)$ are derived from minimizing $M = \sum p_i x_i$ subject to $U(x_1, \ldots, x_n) = U_0$. The expenditure function $M^* (p_1, \ldots, p_n, U_0) = \sum p_i x_i^U$ indicates the minimum cost of maintaining utility level $U_0$ for arbitrary prices $p_1, \ldots, p_n$. By the envelope theorem, the Hicksian demands are the first partials of the expenditure function: $x_i^U = \partial M^*/\partial p_i$. (See Hicksian and Marshallian demands.)

The area to the left of a consumer’s demand curve between two prices (where the initial price is higher than the final price), is $- \int x_i \partial p_i$. The units of this integral are that of money income, being price times quantity. Suppose this area equals some value $A$. The issue is: what question does $A$ answer, and what is the relation between that answer and the marginal utility of money? Since a Hicksian demand function is the first partial of the expenditure function, the area to the left of this demand curve is simply a change in the expenditure function:

$$-\int x_i^U \partial p_i = -\int (\partial M^*/\partial p_i) \partial p_i = M^*(p, U_0) - M^*(p^0, U_0)$$

where $p^0$ and $p^1$ are the initial and final price vectors over which the integral is taken. The area to the left of Hicksian demand function therefore represents a change in expenditure with utility held constant; this area indicates the amount a consumer would be willing to pay (or have to be paid) to willingly
accept some change in the purchase price of some good. Moreover, there is no need to invoke any assumption at all about the marginal utility of money.

The area to the left of the Marshallian demand function, however, has no such easy interpretation, because unlike the Hicksian demands, the Marshallian demand functions are not in general the partial derivatives of some integral function; therefore the integrals of the Marshallian demands are not expressible in terms of changes in some well-defined function of the initial and final prices and income levels. From Roy's equality, the Marshallian demands are the first partials of the indirect utility function divided by the marginal utility of income. Thus

\[-\int x_i^M \, dp_i = -\int \left(\frac{1}{\lambda_i^M}\right) \left(\lambda_i^M x_i^M \right) \, dp_i = \int \left(\frac{1}{\lambda_i^M}\right) \left(\frac{\partial U^*}{\partial p_i} \right) \, dp_i\]

However, if the marginal utility of money term is ‘constant’, that is, independent of prices, it can be moved in front of the integral sign; only then can this expression be integrated to yield a function of the endpoint prices (and money income):

\[-\int x_i^M \, dp_i = \left(\frac{1}{\lambda_i^M}\right) \int \left(\frac{\partial U^*}{\partial p_i}\right) \, dp_i = \left(\frac{1}{\lambda_i^M}\right) \left[U(p^1) - U(p^0)\right].\]

Thus, in this case, the area to the left of the Marshallian demand function would equal a change in utility divided by the marginal utility of money, thus converting that change in utility into units of money. Marshall’s claim that the area to the left of a demand curve may be interpreted as a change in utility under the assumption of constant marginal utility of money would thus be technically correct for the demand functions derived from utility maximization, though how much of the above discussion he had in mind can easily be debated.

The problem with this analysis is that \(\lambda_i^M\) cannot literally be a ‘constant,’ as shown by Samuelson (1942). Since \(\lambda_i^M = \frac{U_i}{p_i}\), a proportionate change (for example, doubling) of prices and income leaves the amount of the goods consumed unchanged (since the Marshallian demand functions are homogeneous of degree zero in prices and income), and thus the numerator of this expression unchanged. However, the denominator has doubled, meaning \(\lambda_i^M\) has halved. Thus \(\lambda_i^M = (p_1, \ldots, p_n, M)\) must be homogeneous of degree \(-1\); it can be independent of at most \(n\) of its arguments. It can, for example, be independent of all prices, but not income also, or it can be independent of \(n - 1\) prices and income.

Since \(\frac{\partial U^*}{\partial p_i} = -\lambda_i^M x_i^M\) and \(\frac{\partial U^*}{\partial M} = \lambda_i^M\), Young’s theorem on invariance of partial derivatives to the order of differentiation yields (omitting superscripts)
Suppose

\[ \frac{\partial \lambda^M}{\partial p_i} = 0, \ i = 1, \ldots, n. \]

Then

\[ (M / x_j)(\partial x_j / \partial M) = - (M / \lambda)(\partial \lambda / \partial M) \text{ for } i = 1, \ldots, n. \]

That is, the income elasticities are all equal (necessarily to unity, from the budget constraint); thus the utility function must be homothetic. Denoting the Marshallian area \( CS \), we have

\[ CS = \left( \frac{1}{\lambda^M} \right) \left[ u^*(p^1, M) - u^*(p^0, M) \right]. \]

Thus for homothetic utility functions, where the indifference curves are all radial blow-ups of each other, the Marshallian area represents the unique monetary equivalent of a change in utility; the coefficient which converts ‘utiles’ to money income is invariant over the price change.

Suppose now that \( \lambda^M \) is a function of one price only, say \( p_n \). Then from the above equation,

\[ \frac{\partial x_j^M}{\partial M} = 0, \ i = 1, \ldots, n - 1. \]

Since there is no income effect for goods 1 to \( n - 1 \), the Marshallian demand functions for those goods coincide with the Hicksian demands. This is the famous case of ‘vertically parallel’ indifference curves. Therefore the interpretation of the area to the left of any of these Marshallian demand curves is identical to the case of the Hicksian demands, that is, the willingness to pay to face the lower price.

Abstract

There is a long history in economics of using market selection arguments in defence of rationality hypotheses. According to these arguments, rational investors drive irrational investors out of asset markets and profit maximizing firms drive non-maximizing firms out of goods markets. In this article we present the history of these arguments and discuss the literature that examines whether these arguments for market selection, and its impact on efficiency, are correct.

Keywords

rationality; market selection; Kelly rule; incomplete markets

Article

Realized positive profits, not maximum profits, are the mark of success and viability. It does not matter through what process of reasoning or motivation such success was achieved. The fact of its accomplishment is sufficient. This is the criterion by which the economic system selects survivors: those who realize positive profits are the survivors; those who suffer losses disappear. (Alchian, 1950, p. 213)

Most economic models make use of extreme rationality hypotheses: firms maximize profits with full knowledge of their technology and prices, and investors are subjective expected utility maximizers whose beliefs are correct. Surely some firms and some investors do not always behave as these models hypothesize, but does this matter for predictions of market outcomes? It could be that the aggregation that takes place in supply and demand results in prices and market quantities that agree with the predictions of models using extreme versions of rationality. It could be that, over time, firms and investors learn to behave as these models predict and so market outcomes converge to those predicted by the models. Finally, it could be that markets select for firms and investors who behave ‘as if’ they are
market competition and selection: The New Palgrave Dictionary of Economics

rational. This last defence of the use of rationality is the essence of the quote from Alchian (1950). There is a long history in economics of using market selection arguments in defence of rationality hypotheses. The early literature focused on selection for profit maximizing firms. Among its best-known proponents is Friedman (1953, p. 22): ‘The process of natural selection thus helps to validate the hypothesis (of profit maximization) or, rather, given natural selection, acceptance of the hypothesis can be based largely on the judgment that it summarizes appropriately the conditions for survival.’ Of course, even if the selection reasoning is correct, selection can only work over those types of behaviours that are present in the economy. If no firm maximizes profits, then no profit-maximizing firm can be selected. Alchian was acutely aware of this:

The pertinent requirement – positive profits through relative efficiency – is weaker than ‘maximized profits,’ with which, unfortunately, it has been confused. Positive profits accrue to those who are better than their actual competitors, even if the participants are ignorant, intelligent, skilful, etc. The crucial element is one's aggregate position relative to actual competitors, not some hypothetically perfect competitors. As in a race, the award goes to the relatively fastest, even if all the competitors loaf. (Alchain, 1950, p. 213)

Enke (1951) argued that, at least in competitive industries, the relatively fastest will in fact be profit maximizers, and so in this case selection will lead to the survival only of profit maximizing firms:

In the long run, however, if firms are in active competition with one another rather than constituting a number of isolated monopolies, natural selection will tend to permit the survival of only those firms that either through good luck or great skill have managed, almost or completely, to optimize their position and earn the normal profits necessary for survival. In these instances the economist can make aggregate predictions as if each and every firm knew how to secure maximum long-run profits. (Enke, 1951, p. 567)

Similar market selection arguments have been proposed to justify strong rationality hypotheses on the part of investors. Fama argues that:

dependency in the noise generating process would tend to produce ‘bubbles’ in the price series … If there are many sophisticated traders in the market, however, they may cause these ‘bubbles’ to burst before they have a chance to really get underway. (Fama, 1965, p. 38)

According to Fama, ‘A superior analyst is one whose gains over many periods of time are consistently greater than those of the market’. This is at least indirectly an argument for market selection and its affect on the efficiency of prices. Cootner was an early, clear proponent of this argument:

Given the uncertainty of the real world, the many actual and virtual traders will have many, perhaps equally many, forecasts … If any group of traders was consistently better
than average in forecasting stock prices, they would accumulate wealth and give their forecasts greater and greater weight. In this process, they would bring the present price closer to the true value. (Cootner, 1967, p. 80)

In this article we examine the more recent analyses of whether these arguments for market selection, and its impact on efficiency, are correct. We consider in turn, selection over firms and selection over investors.

Selection over firms

Alchain, Friedman and Enke argue that a profit dynamic will select for firms that, for whatever reason, maximize profits. Correspondingly, according to this argument, those that do not act as profit maximizers will be driven out of the market. But how is it that non-maximizers are driven out? The implicit idea is that, in the presence of maximizers, the non-maximizers experience losses that deplete their financial capital, which forces them out of the market. The literature has explored two avenues by which losses of financial capital could have this effect. One is that if the firm's operations are financed from retained earnings, then firms that consistently experience losses would eventually exhaust their retained earnings, causing them to vanish. A second argument is that unsuccessful firms will not be able to raise capital in the financial markets, and may not even be able to retain their initial capital. Thus, so this argument goes, the markets will punish unsuccessful firms, which will eventually vanish.

Winter (1964; 1971) and Nelson and Winter (1982) analyse a retained earnings dynamic. They argue that the retained earnings of profit maximizers will grow fastest, and thus these firms will eventually dominate the market. These authors construct a partial equilibrium model in which the ‘as if’ hypothesis of profit maximization describes the long-run steady state behaviour of firms. In their analysis, prices are fixed and all firms have access to the same technology. This structure leads to the existence of a uniformly most-fit firm, which is selected for by a retained earnings-based investment dynamic.

The early work on market selection was greatly concerned with the meaning of profit maximization when profits are random. Dutta and Radner (1999) directly take up the question of whether markets select for firms that maximize expected profits. Their answer is ‘no’: the decision rules that maximize the long probability of survival are not those that maximize expected profits. Dutta and Radner's firms are owned by investors who choose how much of the firm's earnings to reinvest in the firms and how much to withdraw as dividends. An expected profit maximizing firm is one that maximizes the expectation of present discounted value of dividends paid to its owners. This policy results in an upper bound on the retained earnings left in the firm, and from this level of retained earnings any firm can experience a string of losses that results in bankruptcy.

There are two parts to the argument for market selection of profit maximizers. First, there is the issue of whether the market selects for profit maximizers. Second, there is the issue of whether in the long run the economy behaves as if only profit maximizing firms exist. The Dutta and Radner analysis casts doubt about a positive answer to the first question in stochastic settings. Koopmans (1957) cast doubts about a positive answer to the second question even in a deterministic setting. According to his analysis, appealing to an external dynamic process to defend the profit maximization assumption is not a satisfactory way to proceed. Instead, he believed that the dynamic process itself should be modelled.
Nelson and Winter (1982, p. 58) were also aware that the co-evolution of firm behaviour and the economic environment resulting from a complete model of the dynamic process could pose problems for the evolutionary defence of profit maximization. They observed that among the ‘less obvious snags for evolutionary arguments that aim to provide a prop for orthodoxy’ is ‘that the relative profitability ranking of decision rules may not be invariant with respect to market conditions’. They do not, however, go on to provide a general equilibrium analysis of the consequences of replacing static profit maximization with a selection dynamic.

Blume and Easley (2002) showed that Koopman’s concern about the market selection dynamic in a general equilibrium setting is correct. They show that although only profit maximizers persist in any steady state of the retained earnings dynamic, the long run of the economy need not be well described by assuming that only profit maximizing firms exist. The difficulty arises because of the endogeneity of prices, which causes the relative profitability of firms to depend on the allocation of capital across the firms. As a result, the retained earnings dynamic need not settle down, and efficient firms can be driven out of the market by inefficient firms.

In addition to raising working capital through retained earnings, firms also enter the capital markets. Whether these markets reinforce the market selection hypothesis, as Friedman argues, or undermine it, depends on how well these markets function. If markets are complete (without the securities created by non-maximizing firms) and investors are expected utility maximizers with rational expectations, then investors would not allocate capital to non-maximizing firms. Such firms would never produce, and the selection hypothesis would be trivially, and instantly, correct. Alternatively, if some investors have incorrect expectations, then they could invest in non-maximizing firms. The fate of these firms depends on the fate of their investors. So, in this case, the question of selection for profit maximizing firms reduces to the question of selection for investors who act as expected utility maximizers with rational expectations.

Selection over investors

Friedman, Fama and Cootner argue that asset markets will select for rational investors, and that because of this selection, assets will eventually be priced efficiently. Two interesting approaches have been taken to the selection for rational investors question. First, suppose traders use a variety of portfolio rules. Is it the case that traders whose rules are not rational will lose their money to those who do act as if they are rational? Second, suppose that all traders are subjective expected utility maximizers. Is it the case that markets select for those whose expectations are correct, or most nearly correct? In order to pose these questions precisely rationality has to be defined (see rationality). The selection literature has asked about selection for a very strong form of rationality – expected utility maximization with correct expectations about the payoffs to assets. This is the interesting question because in economies populated by subjective expected utility maximizers whose beliefs are not tied down by a rational expectations hypothesis we have little to say about asset prices. The mere assumption that investors are subjective expected utility maximizers (in the sense of Savage, 1951) places no restrictions on the stochastic process of Arrow security prices (Blume and Easley, 2005).

Selection over rules
Consider an intertemporal general equilibrium economy with a collection of Arrow securities and one physical good available at each date. Suppose traders are characterized by their stochastic processes of endowments of the good and by portfolio and savings rules. A savings rule describes the fraction of wealth the trader saves and invests at each date given any partial history of states. Similarly, a portfolio rule describes the fraction of savings the trader allocates to each Arrow security. The savings and portfolio rules that rational traders could choose form one such class of rules; but other, non-rationally motivated rules are also possible.

Three questions arise about the dynamics of wealth selection in this economy. First, is there any kind of selection at all? Second, is it possible to characterize the rules which win? Third, if selection does take place, does every trader using a rational rule survive, and in the presence of such a trader do all non-rational traders vanish?

In repeated betting, with exogenous odds, the betting rule that maximizes the expected growth rate of wealth is known as the Kelly rule (Kelly, 1956). The use of this formula in betting with fixed, but favourable odds was further explored by Breiman (1961). In asset markets the ‘odds’ are not fixed; instead they are determined by equilibrium asset prices, which in turn depend on traders’ portfolio and savings rules. Nonetheless, the market selects over rules according to the expected growth rate of wealth share they induce. Blume and Easley (1992) show that if there is a unique trader using a rule that is globally maximal with respect to this criterion, then this trader eventually controls all the wealth in the economy, and prices are set as if he is the only trader in the economy. A trader whose savings rate is maximal and whose portfolio rule is, in each partial history, the conditional probability of states for tomorrow has a maximal expected growth rate of wealth share. This rule is consistent with the trader having logarithmic utility for consumption, rational expectations and a discount factor that is as large as any trader's savings rate. Thus, if this trader exists, he is selected for. However, rationality alone does not guarantee a maximal expected growth rate of wealth share. There are rational portfolio rules that do not maximize fitness (even controlling for savings rates), and traders who use these rules can be driven out of the market by traders who use rules that are inconsistent with rationality.

Amir et al. (2005) and Evstigneev, Hens and Schenk-Hoppe (2006) take an alternative approach to selection over rules in asset markets. They consider general one-period assets and ask if there are simple portfolio rules that are selected for, or are evolutionarily stable, when the market is populated by other simple (not explicitly price dependent) portfolio rules. In this research, either all winnings are invested, or equivalently, all investors are assumed to invest an equal fraction of their winnings. So selection operates only over portfolio rules. Amir et al. (2005) find that an investor who apportions his wealth across assets according to their conditional expected relative payoffs drives out all other investors as long as none of the other investors end up holding the market. This result is consistent with Blume and Easley (1992) as the log optimal portfolio rule agrees with the conditional expected relative payoff rule when only these two rules exist in the market. Hence, both these rules hold the market in the limit. Evstigneev, Hens and Schenk-Hoppe (2006) use notions of stability from evolutionary game theory to show that the expected relative payoffs rule is evolutionarily stable.

**Selection among subjective expected utility maximizers**
DeLong et al. (1990; 1991) analyse selection over traders who are subjective expected utility maximizers with differing beliefs. In an overlapping generations model they show (1990) that traders with incorrect beliefs can earn higher expected returns, because they take on extra risk. But as survival is not determined by expected returns, this result does not answer the selection question. DeLong et al. (1991) argue that traders whose beliefs reflect irrational overconfidence can eventually dominate an asset market in which prices are set exogenously. This result appears to contradict Alchian's and Friedman's intuitions. But, as prices are exogenous, these traders are not really trading with each other; if they were, then were traders with incorrect beliefs to dominate the market, prices would reflect their beliefs and rational traders might be able to take advantage of them.

In an economy with complete markets and traders who have a common discount factor, Alchian and Friedman's intuition is correct. Sandroni (2000) shows, in a Lucas trees economy with some rational-expectations traders, that if traders have a common discount factor, then all traders who survive have rational expectations. Blume and Easley (2006) show that this result holds in any Pareto optimal allocation in any bounded classical economy and thus for any complete markets equilibrium. To see why the market selection hypothesis is true for these economies suppose that states are iid and that traders have differing, fixed iid beliefs. Then each trader assigns zero probability to almost all the infinite sample paths that any other trader believes to be possible. Each trader would be willing to give up all his endowment on the sample paths he believes to be impossible in order to obtain more consumption on those he believes to be possible. Since markets are complete, these trades are effectively possible. But, if only one trader has correct beliefs, then only one trader puts positive probability on the infinite sample paths that actually occur. So only this trader will have positive consumption, and thus positive wealth, in the limit.

For bounded complete market economies there is a survival index that determines which traders survive and which vanish. This index depends only on discount factors, the actual stochastic process of states, and, traders’ beliefs about this stochastic process. Most importantly, for these economies, attitudes towards risk do not matter for survival. The literature also provides various results demonstrating how the market selects among learning rules. The market selects for traders who learn the true process over those who do not learn the truth, for Bayesians with the truth in the support of their prior over comparable non-Bayesians, and among Bayesians according to the dimension of the support of their prior (assuming that the truth is in the support).

In economies with incomplete markets, the market selection hypothesis can fail to be true. Blume and Easley (2006) show that if markets are incomplete, then rational traders may choose either savings rates or portfolio rules that are dominated by those selected by traders with incorrect beliefs. If some traders are irrationally optimistic about the payoff to assets, then the price of those assets may be high enough for rational traders to choose to consume more now, and less in the future. Their low savings rates are optimal, but as a result of their low savings rates the rational traders do not survive.

An alternative version of the market selection hypothesis is that asset markets select for traders with superior information. The research discussed above asks about selection over traders with different, but exogenously given, beliefs. Alternatively, if traders begin with a common prior and receive differential information they will have differing beliefs, but now they will care about each others’ beliefs. In this case, the selection question is difficult because the information that traders have will be reflected in prices. If the economy is in a fully revealing rational expectations equilibrium, then there is no
market competition and selection: The New Palgrave Dictionary of Economics

advantage to having superior information; see Grossman and Stiglitz (1980). So the question only makes sense in the more natural, but far more complex, case in which information is not fully revealed by market statistics. Figlewski (1978) shows that traders with information which is not correctly reflected in prices have an advantage in terms of expected wealth gain over those whose information is fully impounded in prices. But as expected wealth gain does not determine fitness this result does not fully answer the question. Mailath and Sandroni (2003) consider a Lucas trees economy with log utility traders and noise traders. They show that the quality of information affects survival, but so does the level of noise in the economy. Scuibba (2005) considers a Grossman and Stiglitz (1980) economy in which informed traders pay for information and shows that in this case uninformed traders do not vanish.

Conclusion

The modern literature has shown that the market selection hypothesis needs to be qualified. For some economies it acts much as the earlier writers conjectured; in others it does not select for profit maximizers or rational traders. Much work remains to be done, however. Blume and Easley (2006) and Sandroni (2000) mostly discuss selection in complete markets. Sandroni, though, points out that even when markets are incomplete, traders with log utility and rational expectations are favoured, while Blume and Easley construct some examples to show that the outcome of market selection can depend on market completeness. The connection between market structure and market selection is not well understood. The implications of market selection for asset pricing are known only for complete markets in the long run and some examples. Most economists’ intuition about market behaviour and asset pricing comes from the study of market models that allow little or no agent heterogeneity. Taking heterogeneity seriously and chasing down its implications for market performance promises to be a rich area for future research.

market failure

John O. Ledyard
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Market failure occurs when there are too few markets, non-competitive behaviour, or non-existence, leading to inefficient allocations. Many suggested solutions for market failure, such as tax-subsidy schemes, property rights assignments, and special pricing arrangements, are simply devices for the creation of more markets. This remedy can be beneficial but, if the addition of markets creates either non-convexities or thin participation, then adding markets will simply lead to market failure from monopolistic behaviour. Examples are natural monopolies and informational monopolies. To achieve a more efficient allocation of resources in the presence of such fundamental failures one must explore non-market alternatives.

Keywords

Article

The best way to understand market failure is first to understand market success, the ability of a collection of idealized competitive markets to achieve an equilibrium allocation of resources that is Pareto optimal. This characteristic of markets, which was loosely conjectured by Adam Smith, has received its clearest expression in the theorems of modern welfare economics. For our purposes, the first of these, named the first fundamental theorem of welfare economics, is of most interest. Simply stated it reads: (1) if there are enough markets, (2) if all consumers and producers behave competitively, and (3) if an equilibrium exists, then the allocation of resources in that equilibrium will be Pareto optimal (see Arrow, 1951; Debreu, 1959). Market failure is said to occur when the conclusion of this theorem is
false; that is, when the allocations achieved with markets are not efficient. Market failure is often the justification for political intervention in the marketplace (for one view, see Bator, 1958, section V). The standard argument is that if market allocations are inefficient, everyone can and should be made better off. To understand the feasibility and desirability of such Pareto-improving interventions, we must achieve a deeper understanding of the sources of market failure. Since each must be due to the failure of at least one of the three conditions of the first theorem, we will consider those conditions one at a time.

The first condition requires there to be enough markets. Although there are no definitive guidelines as to what constitutes ‘enough’, the general principle is that if any actor in the economy cares about something that also involves an interaction with at least one other actor, then there should be a market for that something; it should have a price (Arrow, 1969). This is true whether the something is consumption of bread, consumption of the smoke from a factory, or the amount of national defence. The first of these examples is a standard private good, the second is an externality, and the third is a public good. All need to be priced if we are to achieve a Pareto-optimal allocation of resources; without these markets, actors may be unable to inform others about mutually beneficial trades which can leave both better off.

The informational role of markets is clearly highlighted by a classic example of market failure analysed by Scitovsky (1954). In this example, a steel industry, which must decide now whether to operate, will be profitable if and only if a railway industry begins operations within five years. The railway industry will be profitable if and only if the steel industry is operating when the railway industry begins its own operations. Clearly each cares about the other and it is efficient for each to operate; the steel industry begins today and the railway industry begins later. Nevertheless, if there are only spot markets for steel, the railway industry cannot easily inform the steel industry of its interests through the marketplace. This inability to communicate desirable interactions and to coordinate timing is an example of market failure and has been used as a justification for public involvement in development efforts; a justification for national planning. However, if we correctly recognize that there are simply too few markets, we can easily find another solution by creating a futures market for steel. If the railway industry is able to pay today for delivery of steel at some specified date in the future then both steel and railway industries are able to make the other aware of their interests through the marketplace. It is easy to show that as long as agents behave competitively and equilibrium exists, the addition of futures markets will solve this type of market failure.

A completely different example of the informational role of markets arises when actors in the marketplace are asymmetrically informed about the true state of an uncertain world. The classic example involves securities markets where insiders may know something that outsiders do not. Even if it is important and potentially profitable for the uninformed actor to know the information held by the informed actor, there may not be enough markets to generate an efficient allocation of resources. To see this most clearly, suppose there are only two possible states of the world. Further, suppose there are two consumers, one of whom knows the true state and one of whom thinks each state is equally likely. If the only markets that exist are markets for physical commodities, then the equilibrium allocation will not in general be Pareto optimal. One solution is to create a contingent claims market. An ‘insurance’ contract can be created in which delivery and acceptance of a specified amount of the commodity is contingent on the true state of the world. Assuming both parties can, \textit{ex post}, mutually verify which is indeed the true state of the world, if both behave competitively and an equilibrium allocation exists, it will be...
Pareto optimal, given the information structure. A more general and precise version of this theorem can be found in Radner (1968).

Analysing this example further we note that in equilibrium the prices of commodities in the state that is not true will be close to or equal to zero, since at positive prices the informed actor will always be willing to supply an infinite amount contingent on the false state, knowing delivery will be unnecessary. If the uninformed actor is clever and realizes that prices will behave this way in equilibrium then he can become informed simply by observing which contingency prices are zero. If he then uses this information, which has been freely provided by the market, the equilibrium will be Pareto optimal under full information. In a very simple form, this is the idea behind rational expectations (see Muth, 1961). With clever competitive actors, it may not be necessary to create all markets in order to achieve a Pareto-efficient equilibrium allocation.

Completing markets seems to be an easy technique to correct market failure. The suggestions that taxes and subsidies (Pigou, 1932) or property rights reassignments (Coase, 1960) can cure market failure follow directly from this observation. However, an unintended consequence can sometimes occur after the creation of these markets. In some cases, adding more markets may cause conditions (2) and (3) of the first theorem to be false. Curing one form of market failure can lead to another. To understand how this happens and how the second condition requiring competitive behaviour can be affected, consider the informed consumer in our previous example. If he realizes that the uninformed consumer is going to make inferences based indirectly on his actions then he should not behave competitively because he could do better by pretending to be uninformed. He can, by strategically limiting the supply of information of which he is the monopoly holder, do better than if he behaved competitively. It is only his willingness to supply infinite amounts of the commodity in the false state that gives away his knowledge. Supplying only a little commodity contingent on that (false) state in return for a small payment today would not allow the uninformed agent to infer anything and would allow the informed agent to make a profit from his monopoly position. This is not very different from the standard example of a violation of condition (2), monopoly supply of a commodity.

A different example of this phenomenon of unintended outcomes arises when markets are created to allocate public goods. It is now well known that the introduction of personal, Lindahl prices to price individual demands for a public good does indeed lead to Pareto-optimal allocations if consumers behave competitively (see Foley, 1970). However, under this scheme, each agent becomes a monopsonist in one of the created markets and, therefore, has an incentive to understate demand and not to take prices as given. This is the phenomenon of ‘free riding’, often alluded to as the reason why the creation of markets may not be a viable solution to market failure. To understand why, let us now examine the second condition of the first theorem in more detail.

The second condition of the first theorem about market success is that all actors in the marketplace behave competitively. This means that each must act as if they cannot affect prices and, given prices, as if they follow optimizing behaviour. Consumers maximize preferences subject to budget constraints and producers maximize profits, each taking prices as fixed parameters. This condition will be violated when actors can affect the values that equilibrium prices take and in so doing be better off. The standard example of market failure due to a violation of this condition is monopoly, in which one actor is the sole supplier of an output. By artificially restricting supply, this actor can cause higher prices and make himself or herself better off even though the resulting equilibrium allocation will be inefficient.
those conditions under which agents find it in their interests to follow competitive behaviour. The work of Roberts and Postlewaite (1976) has established that if each agent holds only a small amount of resources relative to the aggregate available, then they will usually be unable to manipulate prices in any significant way and will act as price takers. It is the depth of the market that is important. This is also true when the commodity is information. If each agent is informationally small, in the sense that he either knows very little or what he does know is of little importance to others, then he loses little by behaving competitively (see Postlewaite and Schmeidler, 1986). On the other hand, if he is informationally important, as in the earlier example, he may have an incentive to behave non-competitively. The key is the size of the agent's resources, both real and informational, relative to the market.

The solution to market failure from non-competitive behaviour then seems to be to ensure that all agents are both resource and informationally small. Of course this must be accomplished through direct intervention as in the antitrust laws and the securities market regulations of the United States and may not be feasible. For example, it may not be possible to correct this type of market failure by simply telling agents to behave competitively. In such an attempt, one would try to enforce a public policy that all firms must charge prices equal to the marginal cost of output. But, unless the costs and production technology of the firm can be directly monitored, a monopolist can easily act as if he were setting price equal to marginal cost while using a false cost curve. It would be impossible for an outside observer to distinguish this non-competitive behaviour from competitive behaviour without directly monitoring the cost curve. If the monopolist were a consumer whose preferences were unobservable, then even monitoring would not help. In general, market failure from non-competitive behaviour is difficult to correct while still retaining markets. We will hint at some alternatives below.

Expansion of the number of markets can also lead to violations of the third condition of the first theorem. For illustration we consider three examples. The first and simplest of these is the case of increasing returns to scale in production. The classic case is a product that requires a fixed set-up cost and a constant marginal cost to produce. (More generally we could consider non-convex production possibilities sets.) If the firm acts competitively in this industry and if the price is above marginal cost the firm will supply an infinite amount. If the price is at or below marginal cost the firm will produce nothing. If the consumers’ quantity demand is positive and finite at a price equal to marginal cost, then there is no price such that supply equals demand. Equilibrium does not exist. The real implication of this situation is not that markets do not equilibrate or that trade does not take place, it is that a natural monopoly exists. There is room for at most one efficient firm in this industry. Again it is the assumption of competitive behaviour that is ultimately violated.

The next example, due to Starrett (1972), involves an external diseconomy. Suppose there is an upstream firm that pollutes the water and a downstream firm that requires clean water as an input into its production process. It is easy to show that if such a diseconomy exists and if the downstream firm always has the option of inaction (that is, it can use no inputs to produce no outputs at zero cost), then the aggregate production possibilities set of the economy when expanded to allow enough markets cannot be convex (see Ledyard, 1976 for a formal proof). If the production possibilities set of the economy is non-convex, then, as in the last example, it is possible that a competitive equilibrium will not exist. Expansion of the number of markets to solve the inefficiencies due to external diseconomies can lead to a situation in which there is no competitive equilibrium.
The last example, first observed by Green (1977) and Kreps (1977), arises in situations of asymmetric information. Recall the earlier example in which one agent was fully informed about the state of the world while the other thought each state was equally likely. Suppose preferences and endowments in each state are such that if both know the state then the equilibrium prices in each state are the same. Further, suppose that if the uninformed agent makes no inferences about the state from the other's behaviour then there will be different prices in each state. Then no (rational expectations) equilibrium will exist. If the informed agent tries to make inferences the prices will not inform him, and if the uninformed agent does not try to make inferences the prices will inform him. Further, it is fairly easy to show that if a market for information could be created (ignoring incentives to hide information) the resulting possibilities set is in general non-convex. In either case there is no equilibrium.

Most examples of non-existence of equilibrium seem to lead inevitably to non-competitive behaviour. In our example of non-existence due to informational asymmetries, it is natural for the informed agent to behave as a monopolist with respect to that information. In the example of the diseconomy, if a market is created between the upstream and the downstream firm, each becomes a monopoly. If there is a single polluter and many pollutees, the polluter holds a position similar to a monopsony. The non-existence problem due to the fundamental non-convexity caused by the use of markets to eliminate external diseconomies is simply finessed by one or more of the participants assuming non-competitive behaviour. An outcome occurs but it is not competitive and, therefore, not efficient.

Market failure, the inefficient allocation of resources with markets, can occur if there are too few markets, non-competitive behaviour, or non-existence problems. Many suggested solutions for market failure, such as tax-subsidy schemes, property rights assignments, and special pricing arrangements, are simply devices for the creation of more markets. If this can be done in a way that avoids non-convexities and ensures depth of participation, then the remedy can be beneficial and the new allocation should be efficient. On the other hand, if the addition of markets creates either non-convexities or shallow participation, then attempts to cure market failure from too few markets will simply lead to market failure from monopolistic behaviour. Market failure in this latter situation is fundamental. Examples are natural monopolies, external diseconomies, public goods and informational monopolies. If one wants to achieve efficient allocations of resources in the presence of such fundamental failures one must accept self-interested behaviour and explore non-market alternatives. A literature using this approach, sometimes called implementation theory and sometimes called mechanism design theory, was initiated by Hurwicz (1972) and is surveyed in Groves and Ledyard (1986). More recent results can be found at mechanism design and mechanism design (new developments).

Market institutions ensure that property rights are respected, that people can be trusted to live up to their promises, that externalities are held in check, that competition is fostered, and that information flows smoothly. Evidence is reviewed here on some market institutions: property rights and contracting with and without the law, and mechanisms to sustain information flow in markets.

In order to work as they should, markets need institutions. Defining the rules of the game, institutions consist of the constraints, formal and informal, on economic and political actors (North, 1991). Market institutions serve to limit transaction costs: the time and money spent locating trading partners, comparing their prices, evaluating the quality of the goods for sale, negotiating agreements, monitoring performance and settling disputes (McMillan, 2002).

The notion that institutions matter is as old as the study of economics. For markets to create gains from trade, as Adam Smith recognized, the state must define property rights and enforce contracts. That institutions matter is also one of the chief insights from modern economics. In the presence of informational asymmetries, markets can falter. If buyer and seller have different information about the item to be exchanged, a ‘lemons market’ may arise. Unable to distinguish high-quality goods, buyers may be unwilling to pay a price that elicits supply of anything other than low-quality items. Potential gains from trade go unrealized (Akerlof, 1970). When information is distributed unevenly – as is
ubiquitous in the real world of economics, even if most of the textbooks have yet to bring it on board – prices do not incorporate all relevant information, and so non-price information is needed (Spence, 1973; Rothschild and Stiglitz, 1976). Limiting the inefficiencies from informational asymmetries requires mechanisms for signalling and screening: devices like reputation, warranties and credentials, as well as in some cases government-set rules and regulations. A more nuanced view of market processes is called for than the institution-free textbook account of price equilibration via supply and demand. Evidence on the role of market-supporting institutions is accumulating. Much of the evidence comes from developing countries and countries in transition from communist central planning. Where markets work smoothly, in affluent countries, the market-supporting institutions are almost invisible. It is hard to find evidence of lemons markets in a country like the United States, because institutional solutions have evolved. By contrast, where markets work badly, in poor countries, the absence of institutions is conspicuous (Klitgaard, 1991). A few examples are given in what follows.

**Property rights and contracting**

Institutional innovation sometimes occurs even in affluent countries. An experiment in property rights has arisen in fisheries. Worldwide, fisheries are in crisis. Overfishing results from an externality: the costs of any one fisher's taking too many fish are mostly borne by others. Applying the idea of Ronald Coase (1960) of defining property rights to solve an externality, the New Zealand government has created, essentially, property rights in the fish. Fishers are assigned quotas that define, by species, their allowable fish catch. The quotas are tradable, so they end up with those fishers with the highest willingness to pay, which probably leads to an efficient allocation. Property rights in fish do not come for free, however, but require extensive, costly government monitoring (Grafton, Squires and Fox, 2000). Military aircraft patrol the oceans. Each step of every single fish's journey from landing to final sale is documented, with catch reports, buyers' receipts, cold-storage records and export invoices being collated. Fishery inspectors police breaches. The costs of overseeing the quotas have yielded a return, as fish stocks have been successfully conserved.

Another property-rights experiment has occurred in residential land. In cities in every developing country there are squatters, poor people living on land to which they hold no legal rights. Ad hoc property rights exist even in the absence of formal legal protections, as neighbourhood associations and the squatters themselves guard the land. However, the inability to appeal to the law brings some inefficiencies. Hernando de Soto (2000) argued that, if the impoverished squatters held land titles, they would acquire access to capital markets, because they would then have collateral to offer. In Peru, following de Soto's advocacy, over a million squatter households were granted title to the land they occupied. The effects of this huge inauguration of property rights showed up, unexpectedly, not in the capital market but in the labour market. Householders’ borrowing increased little, but hours worked outside the home by adult household members increased and hours worked by their children decreased (Field, 2003; Field and Torero, 2004). Without land titles, householders stayed at home to watch over their property, sending their children out to work. Holding land titles, they felt secure enough to enter the workforce. Establishing the market institution brought instant welfare gains. However, the gains came in an unforeseen form, illustrating the difficulty in general of anticipating the effects of institutional reform (McMillan, 2004).
With contracting, as with property rights, informal substitutes operate in the absence of formal institutions. Small firms make deals with each other and get finance, using personal networks and ongoing relationships to substitute for missing laws of contract and using retained earnings and trade credit to make up for a lack of access to financial markets (Fafchamps, 2004; McMillan and Woodruff, 2002). Large firms also can prosper without institutions, coping instead by cultivating favours from politicians. Where the lack of institutions shows up is for small firms wishing to grow. Needing to make large, discrete investments, they can no longer rely on retained earnings and trade credit, so they may be unable to grow if the financial market is underdeveloped. Needing to deal with increasing numbers of trading partners, they cannot continue to rely on personal connections but must start to use the law of contract. The firm-size distribution in a typical developing country shows a missing middle, with a lot of employment in tiny firms and quite a lot in large firms, but not much in mid-sized firms (Snodgrass and Biggs, 1996). The missing middle is a symptom of weak legal and regulatory institutions.

Information transmission

An archetypical lemons market existed in India in the 1970s (Klitgaard, 1991). Quality fresh milk was hard to find because vendors routinely watered it down. Buyers could not assess the milk's butterfat content, and so the low-quality milk drove out the high-quality milk. Launching a campaign against adulterated milk, the National Dairy Development Board provided inexpensive machines to measure butterfat content as the milk moved from farmer to wholesaler to vendor. It also set up payment schemes making the price of milk reflect its measured quality and created brand names to give buyers trust in what they were getting. As a result of this coordinated initiative, quality improved and consumption rose.

The loan market is impeded by information asymmetries: both adverse selection (a lender may find it hard to distinguish whether any given loan applicant is a good credit risk) and moral hazard (a borrower, having received a loan, may have an incentive to default). Since these transaction costs are proportionately larger for small than for large loans, small lenders often pay exorbitant interest rates or are frozen out of the loan market. In Bangladesh's Grameen Bank and other microcredit banks, tiny loans are made to poor people via groups of borrowers. Each group member is held responsible for any other member's loan. Being neighbours, the group members know each other's business better than any banker, can monitor each other's use of the loans and can invoke social sanctions to discipline defaulters. Group lending is an elegant solution to the loan market's informational asymmetries.

The equity market relies heavily on institutions. For shareholders, who lack information about the firm's affairs, evaluating managers is difficult, and so a lemons market may arise. In many countries, lax oversights allow controlling shareholders to expropriate minority shareholders (Johnson et al., 2000). If the rules governing the financial markets are inadequate, investors are reluctant to buy stocks because they are unwilling to trust managers, and so firms do not get the finance they need. A well-functioning equity market relies on a complex set of interrelated institutions, formal and informal, to foster information flow (Black, 2001). First, reputations for honest dealings must be built up by auditors, law firms, investment banks and the business press. Second, there are self-regulating private-sector bodies such as industry associations as well as the stock exchange, with its rules on listing firms' financial reporting and its sanction of delisting. Third, the equity market rests on state-provided mechanisms: not only laws requiring that investors receive accurate data, but also an activist regulator. The law's
transaction costs (Glaeser and Shleifer, 2003) mean that a regulator supplements the courts in setting and enforcing the rules of the game.

Conclusion

Market-supporting institutions ensure that property rights are respected, that people can be trusted to live up to their promises, that externalities are held in check, that competition is fostered and that information flows smoothly (McMillan, 2002). Without institutions, the promise of efficient markets goes unrealized.

Abstract

Market microstructure research uses the rules and trading protocols of markets to analyse price formation in asset markets. Microstructure research shows how markets provide liquidity and price discovery, and how prices come to reflect information. Of particular importance to this process is how market participants learn from market data. Microstructure researchers often consider issues related to market structure, in particular how changing features of the market affect the price process. Empirical microstructure research uses high-frequency data-sets, and develops statistical approaches to deal with such data.

Article

Market microstructure studies the behaviour and formation of prices in asset markets. Whereas economic analyses of price formation generally abstract from any particular price-setting mechanisms, market microstructure relies on the specific rules and protocols of markets to analyse how prices are determined. This focus on the microstructure of the market provides insights into how the design of markets affects the price process, detailing both how individual prices are determined and how those prices evolve over time. Such insights are useful for a wide range of issues in asset pricing, as well as for guiding econometric investigations of high frequency data. In addition, microstructure research analyses structural issues in securities trading, such as the role and function of exchanges, the optimal design of trading systems, and the optimal regulation of securities markets.
Fundamental to microstructure research is the realization that asset prices are set in actual markets, and not by fictional auctioneers. Thus, while the forces of supply and demand ultimately underlie all asset prices, the specific formation and evolution of prices is much more complex. Buyers and sellers, for example, need not arrive synchronously, making the determination of a market-clearing price at a point in time problematic. When traders do arrive at markets, they may also face a range of market frictions such as transactions costs, search costs and the like (see Stoll, 2001). Furthermore, the value of assets may change over time, with some traders potentially knowing more about future values than other traders. Markets facilitate the trading of assets by providing liquidity and price discovery, and how they do so depends on the rules and structure of the market (see O'Hara, 2003).

**Canonical models in microstructure**

Early microstructure models focused on the specific market structure found in organized stock markets. In such markets, a designated market-maker or specialist quotes prices to buy or sell units of the asset. By serving as counter-party to buyers and sellers, the market-maker solves the asynchronicity problem noted above by standing ready to provide liquidity on either side of the market. The market-maker earns the ‘spread’, or the difference between the price at which he buys shares (the bid) and the price at which he will sell shares (the ask). In return, however, the market-maker has to bear inventory risk, essentially going long when traders wish to sell, and short when traders wish to buy.

There is an extensive literature analysing the market-maker's pricing problem in the presence of inventory risk (for a review of models, see O'Hara, 1995). In general, such models assume risk-averse market-makers facing exogenous holding costs in a setting in which all agents are symmetrically informed and ‘true’ asset prices are assumed fixed or, at least, stationary processes. An important feature of the equilibrium is that there is no single price: the price the market-maker sets depends upon whether the trader wishes to buy or sell, and on how much he wishes to trade. Prices change over time in response to the specialist's inventory position, his market power and parameters relating to the supply and demand for the asset. Such inventory models have been extended to a wide variety of market settings such as foreign exchange, bond markets, and options and futures markets. Empirical analyses find substantial support for the predictions of inventory models.

An alternative class of microstructure models considers price-setting when some agents have better information about the asset's true value than do other agents. The impetus for such models was an early paper by Treynor (1971), who noted that traders arriving at the market included those who needed to trade for liquidity reasons, those with better information about the asset's true value, and those who thought they had better information but were in fact incorrect. Treynor conjectured that the market-maker's prices were a balancing act offsetting his losses to the informed traders with his gains from the liquidity and noise traders. Viewed from this perspective, a spread arises naturally in security markets, independent of any inventory or transactions costs explanations. Fisher Black (1986) expanded on this notion to highlight the important role played by noise or liquidity traders in allowing markets to become efficient.

An intriguing implication of this research is that, if some traders do have better information about the asset's true value, then the nature of the order flow can be informative as to future asset values. Consequently, the market-maker's price-setting problem evolves from being a simple balancing of
expected gains and losses to that of learning how to extract information from the order flow. With the market-maker drawing inferences from the order flow, this sets the stage for traders to consider the impact of their trades as well, particularly if they are attempting to profit on private information.

There are two general approaches to modelling price-setting in the presence of asymmetric information, sequential trade models and Kyle (1985) models. Glosten and Milgrom (1985) consider a risk-neutral market-maker facing known populations of informed and uninformed traders, where traders arrive sequentially to the market. The market-maker knows these population parameters, but does not know the identity of any individual trader. The market-maker does know, however, that traders informed of good news will all want to buy, while those informed of bad news will all want to sell. Consequently, the market-maker's conditional expectation of the asset's value also differs with trade direction, and it is these conditional expectations that become his bid and ask prices. Based on the trade that actually occurs, the market-maker updates his beliefs regarding the asset's value using Bayes’ rule. The continued one-sided trading of the informed traders eventually forces prices to the true equilibrium level.

Sequential trade models provide an elegant means to characterize the relation between trades and prices on a tick-by-tick basis. Because the market-maker learns from trades, the evolution of prices depends on the order flow, as does the size and movement of the spread. More complex analyses demonstrate a role for other market information in affecting price behaviour. Trade size, for example, may be informative as informed traders prefer to trade larger rather than smaller amounts (Easley and O'Hara, 1987). The time between trades may also have information content as a signal of the existence of new information, and this, in turn, can impart information content to volume (Easley and O'Hara, 1992). Trade location, trade in correlated assets, and alternative order types can also have information content. Because of their tick-by-tick focus, sequential models are particularly useful for guiding empirical analysis of microstructure data, an issue we will return to shortly.

An alternative modelling approach is a Kyle (1985) model. Kyle models focus on the dual problems facing the market-maker, who must figure out what the informed traders know, and the informed trader, who wishes to exploit his private information for profit. The Kyle model uses a batch-auction framework in which the market-maker sees the aggregated trades of both the informed traders and the noise or liquidity traders, and based on this order flow he sets a single price. The market-maker conjectures a trading strategy for the informed trader that is linear in the asset's true value, while the informed trader conjectures a pricing strategy for the market-maker that is linear in the total order flow. In equilibrium, both conjectures must be correct, a feature typical of rational expectations equilibrium models. As in sequential trade models, the market-maker's price reflects his conditional expected value for the asset, this conditional expectation changes as he learns from the order flow, and prices eventually adjust to true values. Back and Baruch (2004) demonstrate conditions under which the Kyle and Glosten–Milgrom models essentially converge.

An important feature of Kyle models is their ability to characterize the trading strategy of the informed trader. The optimal strategy for the informed trader is essentially to hide his trades in the noise trade, and he varies his trades over time in response to the market-maker's growing precision of his beliefs about the asset's true value. Holden and Subrahmanyam (1992) show that, if there are many informed traders, then their combined trading actions force prices almost instantaneously to true values, a result again reminiscent of rational expectations models. A wide range of research has considered variants of the Kyle model allowing for different types of information structures, for uninformed traders to also act...
strategically, and for the market-maker to have differential information. These two asymmetric information-based modelling approaches allow researchers to address a broad range of issues in the trading of financial assets, and are particularly useful in demonstrating how markets perform their price discovery function. Because market-makers are risk neutral and unconstrained as to their inventory holdings, liquidity issues in these models reflect more difficulties induced by the potential information content of trades, rather than the risk-bearing considerations that arise in inventory models. As both effects are likely to be present in actual markets, a wide range of research has investigated empirically how spreads and price changes are influenced by information, inventory, and the fixed costs of making markets.

**Research directions in microstructure research**

The growth of financial asset markets worldwide, as well as the increasing availability of high frequency microstructure data from a wide array of markets, has allowed microstructure researchers to investigate a broad range of issues, both empirical and theoretical. I highlight here a few areas that are of particular importance.

**Econometrics of high-frequency data**

Microstructure data allows researchers to analyse the evolution of prices and market data on a second-by-second basis. Indeed, most microstructure data sets include millions of observations, raising a range of econometric issues. Of particular importance are the periodicity of the data, biases introduced by market structure protocols, optimal statistical models for evaluating the behaviour of prices and spreads, and data sampling issues. Hasbrouck (2006) discusses each of these topics.

Because prices arise only when there are trades, price data is not spaced uniformly throughout the trading day. This introduces a censored sampling problem as prices can be thought of as draws from the true asset value distribution, but where the timing of the draws may not be independent of evolution of the value process itself. Engle and Russell (1998) exploit this insight to develop the auto-conditional duration (ACD) model to analyse the evolution of intra-day volatility. A related problem is sampling across assets, as non-synchronicity of trading may result in price observations that lag true value innovations across stocks. A number of authors have considered the implications of non-synchronous trading for cross-sectional econometric analyses.

A variety of authors also consider the time-series properties of microstructure data, with a particular focus on decomposing price movements into those associated with the value process and those reflecting noise arising from the microstructure such as tick size constraints, bid/ask bounce, price continuity rules, and so on. These econometric issues are particularly important for asset pricing research.

**Asset pricing – liquidity and information risk**

Microstructure models analyse the liquidity and price discovery roles markets play in asset pricing. Recent research has focused on whether these two market roles also affect asset returns. Amihud and Mendelson (1986) first suggested that liquidity could influence asset returns by affecting an investor's
overall cost of trading. Numerous empirical researchers have investigated whether spreads, a proxy for these liquidity costs, are related to asset returns, but the empirical evidence has been mixed. More recent research by Pastor and Stambaugh (2004) using lagged volume measures of liquidity provides stronger evidence, and the authors propose a liquidity factor to explain asset returns. One reason why this effect may arise is commonality in liquidity. Chordia, Roll and Subrahmanyam (2000) find that liquidity measures appear to vary systematically across stocks, and these effects may be time-varying. Other researchers have found similar commonality effects in bond market liquidity measures.

A second research stream considers the price discovery process, and whether investors require higher returns to hold stocks for which a greater fraction of the available information is private rather than public. Easley, Hvidkjaer and O'Hara (2002) derive measures of information-based trading using a structural microstructure model, and demonstrate that asset returns are explained by these information measures. What generates this effect is the inability to diversify optimally, as uninformed traders always lose to informed traders, who are better able to shift their portfolio weights to reflect true values. Empirical research supports a distinct role for both liquidity and information risk in affecting asset returns.

Electronic markets and trading systems

Microstructure models have typically analysed price-setting on a centralized market with a designated market-maker (or makers). While such a setting corresponds well to an exchange or dealer market, it is less applicable to the wide variety of electronic markets now used to trade many financial assets. Of particular importance are electronic trading systems which rely on the aggregation of limit orders to effectuate trades. Orders to buy and sell at a specific price and quantity are collected in the ‘book’, with price and time priority rules dictating how such orders are handled. At any point in time, a spread exists between the highest (lowest) price at which someone is willing to buy (sell) the asset. In such systems, trades arise when orders cross, imparting an importance to the order decisions of individual traders. Traders face complex decision problems in placing orders due to the uncertainty of execution of any order. Of particular concern is that uninformed traders may face an adverse selection problem in that their trades are more likely to execute when there is new information, causing them to buy when there is bad news and sell when there is good news. This difficulty is further compounded by trading protocols that allow limit orders to ‘sweep the book’ and thereby trigger the execution of many individual orders as the opposite side of a large order. There is a substantial literature looking at the behaviour of such electronic markets, but the complexity of these markets leaves many important issues yet to be resolved.

Market structure

Microstructure research is traditionally concerned with issues related to the design and structure of markets. The rise of new markets and trading technologies has raised a plethora of market structure issues. Of particular interest to many researchers are questions relating to transparency, or what information is available to traders and when can they see it. Bond markets, for example, were traditionally opaque, but new reporting rules have increased their transparency. Numerous authors have investigated how this has changed the liquidity and efficiency of the bond market. Option markets
traditionally faced little competition, but the development of a national options market in the United States, along with the rise of electronic competitors, has changed this market structure. Regulatory changes in the United States and Europe have also dramatically affected market structure in equities, raising questions as to the efficacy of these new rules. Finally, the markets themselves are evolving from member-owned cooperatives to publicly traded firms, raising a host of issues relating to corporate governance and self-regulation. Microstructure research provides a means to evaluate the economic impact of these changes and to suggest alternative structures for the trading of financial assets.

The concept of market period was introduced by Marshall to define markets according to the time period over which they extended. It was thus an additional classification of markets to that of location or space (Principles, V.i.6). This distinction became the modern textbook one between the short period and the long, reducing Marshall's more complex three-period classification. As he put it,

we shall find that if the period is short, the supply is limited to the stores which happen to be at hand; if the period is long, the supply will be influenced, more or less, by the cost of producing the commodity in question; and if the period is very long, this cost will in its turn be influenced, more or less, by the cost of producing the labour and material things required for producing the commodity.

Hence the short run is that period for which stocks are constant, the long run that period where price is determined by the costs of production (but factors are constant) and the very long run that period where all factors vary.

The Marshallian market period was, as Hicks pointed out (1965, ch. 5) one of the ways in which Marshall used his ‘static method’. For in the short period, Hicks goes on to say, Marshall could treat the industry as if it were in static equilibrium. Capital, fixed in the short period, is like land in Ricardo, and it earns a rent. In the longer run, the static method breaks down, as capital becomes variable, like labour.

The concept of Marshallian short period has been used extensively in the theory of the firm, in terms of short- and long-run equilibria, and the defining of cost curves according to this classification. Harrod, in 1934, linked this Marshallian concept with the new theory of imperfect competition developed by Joan
market period: The New Palgrave Dictionary of Economics

Robinson (and Chamberlin), to look at the process of imperfect competition and the impact of entry on short- and long-run profit maximization.

The Marshallian short run concept was taken over into macroeconomics by Keynes as one of three components of Marshall's theory which he used to construct the *General Theory* (the others were partial equilibrium and thus exogenous expectations, and the representative firm aggregate which Keynes took over as the economy). However the Keynesian use of market period was not universally adopted in macroeconomics and it is Hicks's much more restrictive concept used in the IS–LM framework which is now much more familiar. The Hicksian ‘week’ is a market period in which fundamentally it is stocks that are constant, while the Keynesian ‘year’ allows for an element of ‘user cost’ whereby the utilization of capital affects the future demand for capital.

The Hicksian week and the concept of temporary equilibrium associated with it were first set out by Hicks in the middle chapters of *Value and Capital* in 1939, and were subsequently revised in an important, somewhat neglected essay entitled ‘Methods of Dynamic Analysis’ in 1956, reprinted in *Money, Interest and Wages* (1982). These concepts formed part of an attempt to construct a theory of dynamics, going beyond Marshall's static analysis. The alternative extreme hypothesis of allowing all factors to vary is a longer-run theory, and forms the basis of general equilibrium and growth theory. Both the Hicksian and Keynesian theories attempt to construct an intermediary period, and for each the corresponding problems were to decide which factors are to be allowed to vary, which to stay constant and what process of adjustment to vary, which to be employed by firms. But once these theoretical assumptions have been made, the individual periods become discrete rather than continuous (as in the longer-run case). Thus a theory of dynamics based on the Hicksian week requires an additional theory by which to link the discrete periods together to form a continuous model. We need to know how to get from one period to another. Both Keynes and Hicks resorted in one way or another to a link via expectations, though both provided what now appear to be inadequate explanations of their formation. The modern new classical theory of macroeconomic equilibrium avoids the short and the long run distinction by appealing both to the perfectibility of markets per se, and to a theory of expectations which is itself based on perfect markets. Thus although the rational expectations approach ‘solves’ the problem of linking market periods, it does so in a way which avoids rather than solves the problems of market period analysis. Perfect markets do not have dynamics with limited time horizons and rigidities and thus, in the rational expectations perfect foresight model, there is really no need for market period analysis. It is clear however that market imperfections in real variables and expectations do exist, and hence that short-run temporary equilibria cannot easily be linked together.

market power and collusion in laboratory markets

Douglas D. Davis
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Despite the robust tendency of laboratory markets to generate competitive outcomes, some market designs deviate persistently from competitive predictions. This article discusses the primary drivers of supra-competitive prices that have been observed in market experiments.

Article

The robustness of competitive market predictions stands as one of the most impressive results in experimental economics. Laboratory markets regularly generate competitive outcomes in environments populated by just two or three sellers. However, as in natural contexts, competitive outcomes do not always emerge. This article reviews results of laboratory markets in which price increases are driven by factors such as the exercise of unilateral market power or by collusion.

Before reviewing the main concepts and contributions in this area, I offer two observations. First, laboratory methods represent an important but limited complement to existing empirical tools for investigating market performance. Given the stark simplicity and limited duration of laboratory markets, experimentalists can aspire to say little about specific naturally occurring markets. Experiments can, however, provide important insights into the behavioural relevance of theories upon which antitrust policies are based. Second, the trading rules defining negotiations and contracting can exert first-order effects on market competitiveness. For example, markets organized under the double auction trading rules used in many financial exchanges, are much more robustly competitive than markets organized under the posted-offer trading rules used in most retail exchanges: duopoly or even monopoly sellers are less able to increase market prices in double-auction than in posted-offer markets (Davis and Holt, 1993, chs 3, 4; Holt, 1995). Indeed, one of the motivating factors in the emerging field of institutional design was an interest in developing institutional rules that promoted efficient market outcomes.

For specificity I focus here on results from posted-offer markets, primarily because posted-offer markets allow a particularly intuitive illustration of the factors affecting market competitiveness. However, a host of other trading institutions exist, ranging from single and multi-unit auctions, to multi-sided computerized ‘smart’ markets, and again to institutions that exist primarily as theoretical constructs, such as quantity-setting Cournot mechanisms. The competitive implications of each of these institutions must be evaluated independently.

Posted-offer markets and unilateral market power

Unilateral market power is perhaps the most frequently observed reason why prices in laboratory markets deviate from competitive predictions. This market power exists when one or more sellers, acting on their own, find it profitable to raise prices above the competitive level. The supply and demand structures shown in the two panels of Figure 1 illustrate how capacity restrictions can create market power. In each panel, the market consists of three sellers, S1, S2 and S3, each of whom offers four units for sale, under the conditions that two units cost $2.00 and two units cost $3.00. A buyer will purchase a fixed number of units (seven in the left panel or ten in the right panel) at prices less than or equal to $6.00.

Figure 1
Supply and demand arrays for markets without and with unilateral market power
Exchange in these markets proceeds in a number of trading periods. At the outset of each period, sellers simultaneously make price decisions. Production is ‘to order’ in the sense that sellers incur costs only for the units that actually sell. Once all sellers post prices, a simulated fully revealing buyer makes all possible purchases, starting with the least expensive units first. In the case of a tie, the buyer rotates purchases among the tied sellers.

In the market shown in the left panel of Figure 1 the buyer will purchase at most seven units. Given an aggregate supply of 12 units, sellers in this market have no market power: at any common price above $3.00, each seller can increase sales from an expected 2.33 units to four units by posting a price just slightly below the common price. For any vector of heterogeneous prices above $3.00 only the seller posting the lowest price will sell all four units. The seller posting the second highest price will sell three units, while the high-pricing seller will sell nothing. The unique Nash equilibrium for the stage game has each seller posting the competitive price of $3.00, selling 2.33 units in expectation and earning $2.00.

Expanding demand to ten units, as shown in the right panel of Figure 1, limits excess supply, and thus creates market power. Given that the highest price seller is now certain to sell at least two units, the competitive price of $3.00 is no longer a Nash equilibrium for the stage game. At a common price of $3.00 each seller sells 3.33 units (in expectation) and earns $2.00. By posting a price of $6.00, any seller can sell two units and increase earnings to $8.00. A common price of $6.00 is not an equilibrium for the stage game, since any seller would find that deviating from $6.00 increases sales to four units. Sellers have similar incentives to undercut any common price down to a minimum \( p_{\text{min}} = 4.50 \), where the profits from selling four units as the lowest pricing seller equals earnings at the limit price. The equilibrium for this game involves mixing over the range from $4.50 to $6.00. As shown in the figure, the unique symmetric equilibrium is $4.71.

An extensive series of experiments show that sellers respond to unilateral market power by raising prices. Further, power drives pricing outcomes more powerfully than do changes in the number of sellers. For example, when they reallocated units among five sellers to create market power, Davis and Holt (1994) observed substantial price increases. However, reducing the number of sellers from five to three in a way that held market power conditions fixed, Davis and Holt observed only modest additional price increases. Market power of the sort illustrated in the right panel of Figure 1 has wide applications, ranging from distortions in markets for emissions trading (Godby, 2000) and for electricity transmission (Rassenti, Smith and Wilson, 2003), to price stickiness in the face of aggregate demand shocks (Wilson, 1998).

 Tacit collusion 

Experimentalists have also observed supra-competitive prices in repeated market games where sellers have no market power. This tacit collusion has been observed most frequently in duopolies (for example, Alger, 1987; Fouraker and Seigel, 1963). However, tacit collusion has also been observed in thicker markets where sellers possess no market power. For example, Cason and Williams (1990) observe persistently high prices in a four-seller design similar to that shown as the left panel of Figure 1. Experimentalists often measure tacit collusion as the difference between observed prices and prices consistent with the Nash equilibrium for the market analysed as a stage game. Importantly, other than exceeding equilibrium price predictions, tacitly collusive laboratory outcomes typically exhibit no obvious signs of coordinated activity. Tacit collusion may coexist with market power. For example, prices in the market power sessions reported by Davis and Holt (1994) were significantly above prices consistent with the equilibrium mixing distribution. In this context, the difference between mean observed prices and the mean of the equilibrium mixing distribution may be reasonably taken as a
measures of tacit collusion.
Tacit collusion is not yet well understood, and isolating the causes of tacit collusion represents an important project for future experimental work. Price signalling activity at least partially explains tacit collusion (for example, Durham et al., 2004). However, evidence suggests that more than price signals and responses may be at play. Dufwenberg and Gneezy (2000) report an experiment where duopolists deviate from the static Nash (competitive) prediction for a game, even when sellers are rematched into different markets after each decision. In such a context price signalling is not possible.

Explicit collusion

Given opportunities to explicitly discuss pricing, laboratory sellers quite persistently organize profit-increasing cartels (Isaac, Ramey and Williams, 1984). However, a capacity to monitor agreements and prevent secret discounts appears critical to the success of these arrangements (Davis and Holt, 1998). Given the illegality of explicit agreements, the more interesting questions regarding explicit collusion concern the capacity of authorities to detect such arrangements through the actions of sellers in the market (Davis and Wilson, 2002).

Other factors affecting pricing

A host of experimental studies indicate that standard ‘facilitating practices’ can contribute to price increases. Experimental studies where supra-competitive prices have been attributed to facilitating practices include ‘most favoured nation’ and ‘meet-or-release’ clauses (Grether and Plott, 1984), non-binding price signals (Holt and Davis, 1990) and multi-market competition (Phillips and Mason, 1991).
Buyer behaviour can also affect market outcomes. When buyer decisions are simulated, details of the purchasing rules can have a large effect on prices (Kruse, 1993). Powerful human buyers can substantially undermine both market power and tacit collusion (Ruffle, 2000). However, the use of real rather than simulated buyers appears to generate more competitive prices even when the human buyers engage in no strategic behaviour (Coursey et al., 1984).

Finally, information conditions and even sellers’ expectations can significantly affect pricing outcomes. For example, Huck, Norman and Oechssler (2000) report that information regarding underlying supply and demand conditions facilitates the exercise of predicted market power (markets are drawn to static Nash predictions). However, information on rival sellers’ profits made markets more competitive in a market where the high-profit seller has the highest market share, so imitation by others will tend to expand quantity and reduce price. Also, in a Cournot context, Huck et al. (2007) report that seller aspirations for increased profits helped consolidated sellers maintain prices substantially above static Nash levels.

market price

G. Vaggi
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Cantillon, R.; competition; market price; natural price

Article

The market price, or market value, is defined as the actual price paid for a commodity during a certain period of time, and may be contrasted with the natural or normal price, which is determined by the long-term forces and the permanent causes of the value of commodities (see natural price). The distinction between market price and the intrinsic value of a good can be traced back to the origins of economic science. Before Adam Smith, Richard Cantillon had already analysed the causes which influence the temporary value of a commodity (Hollander, 1973, p. 41).

Many different causes can affect the market price of a commodity and it is difficult to explain the day-to-day changes in its value. However, economic theory has generally singled out the relationship between the demand for a product and its supply on the market as the main force determining the market value. For Smith, the existence of a positive difference between the effectual demand for a commodity and the quantity of it which has been produced and brought to the market leads to a high market price vis-à-vis the natural value, and vice versa. But if there is free competition between producers, market prices cannot be too different from natural prices for a long period of time. Market competition forces lead to the gravitation of market prices around the natural prices. Therefore in classical political economy the two concepts are carefully listed. In particular, the market price is continuously brought towards the natural price.

The concept of market price is an important feature of Adam Smith's description of the competitive mechanism and the way in which it leads to a uniform rate of profit in all sectors of the economy. For instance, when the supply of a commodity falls short of its effectual demand the market price is higher than the natural one, because of the competition between the buyers who are eager to purchase that good (Smith, 1776, pp. 73–4). Either one or more of the three component elements of value – wages, profits and rent – is paid at a rate higher than the natural rate. In a freely competitive economy producers compare their rate of profit with profit rates earned in other activities. Thus entrepreneurs invest their
capital in the sectors which yield the highest rates or profit. This leads to an increase in the output of the commodities whose market prices are higher than natural ones, and vice versa a decrease when market prices are lower than natural values. Therefore the concept of market price is part of Smith's explanation of the changes in output which occur from one production period to another in each sector.

Given the natural price, and the corresponding level of effectual demand, the increase in output leads to a market situation in which more consumers (willing to pay for the good at its natural price) can be satisfied. There is less competition than before between the consumers, and the market price tends to move towards the natural price. Again, the entrepreneurs compare market prices and profit rates in all sectors of the economy and capital will move if the rate of profit is not uniform. Only when all the demand is matched by an equal supply at a market price level which equals the natural one will competition stop; in this situation the market price is exactly the right amount to pay all the components of price at their natural values. The market price depends on excess demand (or supply) on the market at any moment in time, but cannot be too far away from the natural price for a long period of time, because competition tends to bring it towards this level.

Alfred Marshall's distinction between the market and normal value of commodities is similar to Adam Smith's. Normal value is related to the cost production of commodities, while market prices are mainly influenced by utility and demand (Marshall, 1920, pp. 289–90). Marshall also believes that it is difficult to work out a precise theory to determine the market values of commodities; they are affected by too many factors. Marshall argues that there are long and short period forces acting on prices. But he is much more sceptical than Smith about the existence of a precise mechanism, namely competition, which should prevent short-term market prices from moving too far away from the normal price of commodities.

market structure

John Sutton
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The term ‘market structure’ relates to the number and size distribution of firms in a market. Markets dominated by a few large firms are said to be ‘concentrated’. This article offers a brief review of the modern literature that sets out to explain differences in concentration levels across different industries.

Keywords

advertising; barriers to entry; endogenous sunk costs; first mover advantages; Herfindahl index; integer effects; k-firm concentration ratio; learning; market structure; mergers; minimum efficient scale; monopolistic competition; monopoly; multi-stage games; network effects; oligopoly; perfect competition; rate of return; research and development; scale economies

Article

Why is the world market for large commercial jet aircraft dominated by just two firms, while oil tankers are produced by a large number of firms spread over many countries? This is the kind of question addressed in the literature on ‘market structure’, a field once seen as a rather arcane area, in which explanatory theories were weak and in which discussion tended to focus on rival interpretations of ‘statistical regularities’ reported in empirical studies. The most famous of these ‘regularities’ related to a supposed link, across different industries, between the degree to which the industry was dominated by a few large firms (‘concentration’), and some average measure of the rate of return (profit) on fixed assets enjoyed by firms in the industry. (Popular summary measures of concentration include the ‘k-firm concentration ratio’, that is, the share of industry sales revenue accounted for by the top k firms, and the Herfindahl index, defined as the sum of squares of all firms’ market shares). Now the presence of a (positive) relation of this kind would raise the question, ‘why do industries with high rates of profit not attract entry, to the point where such differences are eroded?’ This question was countered in the older literature, following Bain (1956), by appealing to the supposed existence of ‘barriers to entry’ in various
industries. These barriers fell into three categories. The first related to factors intrinsic to the industry’s methods of production (‘scale economies’). If the average cost of production falls sharply as output rises to a certain level, then we might regard that level as a ‘minimum efficient scale’, and postulate that the industry is large enough to accommodate only a small number of firms of this size. This point was, and remains, uncontroversial. The second category related to institutional barriers associated with legal or regulatory impediments, or poor access to financial markets, and so on, but, while barriers of this category may be important in some industries and for some countries, they are probably of secondary relevance to the general run of industries in market economies. The third type of barrier related to the role played by advertising and R&D, and it is here that some serious difficulties arise, a point to which we turn in what follows.

The series of ideas just set out came to be known as the Bain paradigm, or the Structure–Conduct–Performance paradigm. Expressed briefly, this view held that a more concentrated structure, however sustained, allowed firms to operate less intensive forms of price competition (‘conduct’), and this in turn led to high profits (‘performance’). This view was seriously undermined in the 1980s as a result of two developments in the literature. The first of these developments was empirical: it became clear, in the light of new empirical studies, that the claim for a positive relationship between concentration and profitability was not well-founded. (For a review of the evidence, see Schmalensee, 1989.) The second development was theoretical: it was clear that any successful explanation of differences in concentration across industries could not rely solely on ‘scale economies’ and ‘institutional barriers’; the role played by advertising and R&D in raising the stakes required of entrants to an industry seemed crucial. But here a problem arises: the levels of advertising and R&D, unlike the degree of scale economies, are matters that are under the control of the firms themselves. The levels of expenditure firms undertake in these areas are ground out as part of the competitive process – and so we cannot treat their levels as a given, and claim that, when we observe a high ratio of advertising and/or R&D to industry sales revenue, this constitutes a ‘barrier to entry’ that explains the industry's high level of concentration. Rather, an explanation of market structure must explain both the level of concentration and the levels of advertising and R&D intensity. The ‘given’ that distinguishes one industry from another must not be the observed (or ‘equilibrium’) level of advertising or R&D, but rather the underlying (industry-specific) relationship between any firm's level of spending on these fixed outlays and the resulting benefit (‘perceived product quality’, say, or, more generally, any effect leading to an outward shift in the firm's demand schedule or a fall in its unit cost of production).

These problems with the older literature led from the late 1980s onwards to the development of a new literature on market structure. (See, for example, Dasgupta and Stiglitz, 1980; Shaked and Sutton, 1986; Sutton, 1991; 1998. A full technical review of the literature will be found in Sutton, 2007.) The point of departure of this literature lies in modelling the evolution of structure by reference to a ‘free entry’ model, in which any one of a number of potential entrants is free to enter the industry, and to choose its level of outlays on advertising, R&D, and so on, in the light of the choices made by its rivals.

The modern game-theoretic literature

The models used in the modern literature take the form of ‘multi-stage games’. In the simplest example, a firm decides, at stage 1, to enter (and pay some positive, minimal, entry fee whose size is a given, and
which can, for example, be interpreted as the cost of building a production plant of ‘minimum efficient scale’). At stage 2, each firm, knowing the number of firms that have entered, chooses its level(s) of advertising and/or R&D. Its choices will depend inter alia on the (industry-specific) degree of effectiveness of these expenditures in influencing consumer demand for its product(s). In ‘commodity’ type industries, where this effectiveness is very low, these outlays will be close to zero. Finally, in stage 3, firms compete in price, taking as given the attributes of their respective products, and they realize corresponding levels of (gross) profits. (It is always assumed that firms have constant marginal costs of production, and that they face downward-sloping demand schedules.)

The central idea that emerges from these (‘endogenous sunk costs’) models is as follows: as the size of the market increases (in the sense of having a larger number of consumers, so that each firm's demand schedule shifts outwards) the industry may adjust to this in two ways: the number of firms may rise (‘entry’), and/or the spending level per firm on advertising, R&D, and so on, may rise – because, in the absence of a proportional rise in the number of firms, each firm now enjoys a higher level of demand, and so the marginal return it gains from being able to charge a given price premium for a higher-quality product rises (‘escalation’). Now the degree to which one or other of these effects operates depends inter alia on the effectiveness of advertising and/or R&D. It also depends on the degree to which high-quality products can draw customers away from rival products of a lower quality. Suppose, for example, that products differ not only in quality, but in other attributes also, and that customers differ in their preferences over these latter attributes. Then it will be correspondingly harder for a firm that raises its ‘perceived quality’ level to attract sales from rivals. An example may be helpful here: consider, for instance, the market for flowmeters. These devices are used to measure the rate of flow of liquids, and they come in a large number of types. An increase in R&D spending by a producer of ‘electromagnetic’ flowmeters will have only a limited impact in drawing consumers away from ‘ultrasonic’ flowmeters, since the latter type of meter has attributes that makes it better suited than the electromagnetic type in certain applications. By way of contrast, consider the case of the (civil) aircraft industry, as it developed since the late 1920s. At that period, there were many types of plane in operation (monoplanes/biplanes, metal/wood construction, land/seaplanes, and so on). Yet all makers faced a market where all buyers (airlines) sought to achieve the same objective: to minimize the carrying cost per passenger mile. As soon as it became clear which type of design best achieved this single aim, plane-makers converged on the solution (an all metal monoplane with a cantilever wing design, following the Douglas DC3). Thereafter, technical developments were focused on pushing forward the performance of this type of plane, and, as plane-makers escalated their efforts in this direction, the stakes required to keep up with rival firms’ innovations rose, and there was a ‘shake-out’ of all but a handful of firms. This story was repeated at the dawn of the jet age in the 1950s. Here a growing world market led, not to the entry of new plane-makers, but to an increasing flow of development outlays by the surviving firms, so that only Boeing and Airbus remain in the wide-body commercial jet business today. (For the details of this story, and the rise of Airbus, see Sutton, 1998, ch. 15.)

Where does this leave us? The kind of market profiles that emerge are these: (a) those with high R&D outlays and high global concentration (for example, wide-body commercial jets); (b) those with high R&D outlays, low concentration and a fragmented set of distinct product categories (for example, flowmeters); and (c) those with low R&D spending, where, once the size of the market is large, the level of concentration may become arbitrarily low.

Within advertising-intensive industries, a simpler picture emerges. Here, the fact that a firm can use a
Single brand to span a range of product types in a market means that we can, with few exceptions, define markets in a way that avoids the complication posed by the presence of sub-markets for distinct product types, of the kind we encountered in the flowmeter example above. Here, the theory leads to a very simple prediction: if we take a cross-section of markets of different sizes (by looking, say, at a single industry across a number of countries of different sizes), then we will find a sharp difference in the market size–concentration relationship as between the ‘advertising-intensive’ industries and a control group of industries in which advertising plays an insignificant role. In the latter group, very low levels of concentration may be reached as market size increases. In the former group, concentration levels will necessarily remain above some critical level in all countries, no matter how large the size of the country (the ‘non-convergence’ property). This prediction, and related predictions of the theory, have been widely tested over the past decade and appears to be closely in line with what is found in the data (for a review, see Sutton, 2007).

One further comment is called for in relation to this prediction: what is predicted is not an actual or equilibrium level of concentration, but rather a lower bound to the level of concentration that can emerge under given circumstances. It is intrinsic to models of this kind that a range of different outcomes is possible, depending on such factors as the form of the entry process (simultaneous, sequential, and so on). The most graphic illustration of this point comes from thinking about the pattern of ownership of plants spread over some geographic region large enough to support many plants. There will be a ‘fragmented’ equilibrium in which every plant is owned by a different firm, and there will be other equilibria in which the number of plants will remain (roughly) the same, but several of these plants will be owned by the same firm. In other words, a range of outcomes can arise as equilibria, depending on the form of the entry process and the nature of price competition, and the theoretical focus of interest lies in asking, not about the actual outcome, but about the range of possible outcomes, or, more specifically, about the lower bound to the level of concentration that can emerge.

Extensions: learning effects and network externalities

Two further (‘dynamic’) mechanisms play a role in explaining high levels of concentration. First, if each firm’s unit cost level falls over time as a function of its cumulated volume of output to date, then an early entrant may build a dominant market position by setting an initial low price – possibly below its current unit variable cost of production – with a view to achieving a high output volume, and so a relatively low level of unit cost in the future. In a small number of industries – aircraft, semiconductors and chemical fibres – this effect is quite large.

Second, if the attractiveness of a firm’s product to new consumers increases with the number of consumers it has supplied in the past, then again a firm may use an initial low price to build up its early client base and so stimulate future demand (Katz and Shapiro, 1985). Examples of such effects abound in the information technology sector: as an item of hardware becomes more widely owned, more firms in the software industry will find it attractive to develop dedicated software for it, thus reinforcing its initial popularity.

What both these examples have in common with the endogenous sunk cost models described earlier becomes clear once we interpret the ‘planned losses’ incurred in the initial phase as a fixed outlay – analogous to an outlay on R&D or advertising – which yields a payoff in the later phase, either through lower unit costs or increased demand. The novel element which arises in these ‘learning’ or ‘network
effects’ models is that these effects can be cumulative over time, and so a small initial disparity in the costs or sales of two firms may in principle become amplified over time.

Structure, conduct and performance revisited

What does this imply for the Structure–Conduct–Performance paradigm? If high concentration is merely the natural outcome of the competitive process, should we still see high concentration in an industry as an indication that policy intervention might be warranted?

At a conceptual level, what remains is this: it is still true within the modern ‘free entry’ models discussed above that structure affects conduct. It is also true that conduct affects performance; but now there is a feedback loop through which high levels of profit may attract new entry, that is, structure is not a given, but is now determined as part of the market process. One consequence that emerges from this is that there is no simple and general link, of the kind central to the old literature, between high concentration and high profitability: it is possible, for example, to have industries with widely different levels of concentration that exhibit no difference in their rates of return on investment. High (‘supernormal’) profits can, however, arise in these ‘free entry’ models, through a number of channels. Most notably, they may arise because of asymmetries in the entry process (‘first mover advantages’): an early entrant to the market may build up a level of investment in R&D, for example, and so enjoy both a high market share and a high rate of return on its investments, so that the industry-wide levels of concentration and profitability are relatively high. A second channel relates to the important but neglected role of ‘integer effects’, that is, if there is room in market at equilibrium for only a small number of entrants, then it may be, for example, that two firms can both make supernormal profits, but the entry of a third firm would drive the profit rate below a normal rate of return, so further entry does not occur. Finally, and most importantly, variations in productivity (unit costs) across firms associated with non-imitable advantages can lead to positive (supernormal) profits for (all) intra-marginal firms – a free entry condition implies ‘zero profits’ only for the marginal entrant (Demsetz, 1973).

One key issue remains: what of comparisons between alternative forms of market structure within any one industry? This is the question that lies at the heart of competition policy regarding mergers. As we have seen, the normal workings of the competitive process fix a lower bound to the level of concentration that must come about under free competition. This bound can, in the case of some industries, be very high in absolute terms, even in a large market; but in other industries it will be very low. Above this bound, varying levels of concentration can emerge since various patterns of market structure can be sustained as equilibria (as in the example of geographically dispersed plants mentioned above). What remains true of the Structure–Conduct–Performance story is that these different market structures may have different welfare properties; a proposed merger that moves us towards a more concentrated structure which will lead to reduced consumer welfare will be subject to the traditional objections. On the other hand, it may be that a merger arises merely as a response to changes in external conditions, and represents a shift away from a form of market structure that constituted an equilibrium outcome under the previous setting, but is no longer sustainable as an equilibrium in this changed environment. Distinguishing between these two possibilities in any specific instance is one of the (many) challenges in dealing with merger cases.

Why does it matter?
The traditional rationale for studying market structure was based on its link to profitability and to social welfare. There is, however, another line of argument that has gained considerable force as a result of the empirical success of the modern free entry models in explaining cross-industry differences in concentration. This line of argument rests on the claim that the success of these models provides convincing, though indirect, evidence for the workings of some key competitive mechanisms that appear to operate in a more or less uniform way across a wide range of industries.

To place this in perspective, it is worth noting that the conventional wisdom in economics from the 1950s to the late 1980s was deeply pessimistic in respect of models that lay between the two polar cases of perfect competition or (Chamberlinian) monopolistic competition, on the one hand, and monopoly on the other. This pessimism was typically expressed in the observation, ‘with oligopoly, anything can happen’. The new game-theoretic literature of the 1980s formalized oligopoly theory using the Nash equilibrium concept, and offered it as a general framework within which perfect competition and monopoly appeared as special (limiting) cases. While this new literature appeared to some critics to simply reinforce the negative view of oligopoly theory, the successful application of these game-theoretic models to the task of ‘explaining market structure’ suggests that the early pessimism is unwarranted: it seems that these models capture at least some ‘robust’ competitive mechanisms that operate in a more or less uniform way across the general run of industries.

marketing boards

Christopher B. Barrett and Emelly Mutambatsere
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Marketing boards (state-controlled or state-sanctioned entities legally granted control over the purchase or sale of agricultural commodities) flourished in the 20th century. Since the mid-1980s they have declined in number under pressure from domestic liberalization and from international trade rules that increasingly cover agriculture. Where reforms have been widespread and successful, marketing boards have vanished or retreated to providing public goods, such as strategic grain reserves or insurance against extraordinary price fluctuations. Elsewhere, the weaknesses of private agricultural marketing channels have been revealed by the rollback of marketing boards, often leading to calls for reinstatement of powerful marketing boards.

Article

Marketing boards are state-controlled or state-sanctioned entities legally granted control over the purchase or sale of agricultural commodities. They can be divided into two broad categories. Monopolistic marketing boards that create a single-commodity seller are found mainly in developed countries. Monopsonistic marketing boards concentrating buyer-side market power in one institution were commonplace for many years in developing countries. Monopolistic marketing boards were typically established with the main objective of maintaining or raising and stabilizing farm prices and incomes in an administratively practical and politically acceptable manner. By contrast, monopsonistic
marketing boards were typically established to give the state control over commodity prices – normally for the benefit of foreign and urban buyers – and capacity to tax agriculture so as to subsidize industrialization.

Marketing boards in developed countries

Marketing boards are state-sponsored trading enterprises legally invested with monopoly powers to organize the marketing of agricultural commodities. These statutory entities typically operate under direct or indirect producer control. Among the earliest boards were the New Zealand Meat Producers Board and the New Zealand Dairy Board, each established in 1922, the Australia Queensland Sugar Board of 1923, and the Australia Wheat Board, formed in 1939. In Australia, marketing boards used import protection and home consumption price schemes to stabilize producer prices. They initially received financial support from the state, although such support later declined as the focus of the boards changed. A number of state and commonwealth-level marketing boards were later established, with varying degrees of authority and responsibilities in the marketing of agricultural products such as wool, dairy, meat, wine and brandy, honey and horticultural products. The marketing boards in New Zealand evolved in a similar manner, with regulatory authority in export marketing and licensing but no direct financial support from the state. These boards, involved in the marketing of dairy, apple and pear, kiwi fruit, horticulture, meat and wool products, all used activities such as single-desk selling, price pooling, revenue pooling and preferential financing to seek higher producer prices.

The earliest major marketing schemes in Britain were the milk, potatoes and bacon marketing boards formed under the British Marketing Acts of 1931 and 1933. These acts enabled producers to set up marketing schemes that had the legislative power to ensure conformity by all producers. The core purpose of the marketing boards was to maintain or raise producer prices of basic agricultural commodities through acreage restrictions, direct or indirect limits on saleable quantities, and price discrimination, with higher prices in sheltered markets and lower prices in exposed ones. In addition, monopolies of processed products were legalized, leading to the organization of processor and distributor schemes. The marketing boards thus held the monopoly power to control supply, the terms of sale and the channels and conditions of sale (Bauer, 1948). By 1948 marketing boards had spread to include all major agricultural commodities. In Canada, marketing boards were also formed in response to the price fluctuations of the Great Depression. The Dominion Marketing Board, a federal agency established under the National Farm Products Act of 1934, exercised extensive market power over the sale of regulated products, transferable to provincial-level producer-organized boards. The Agricultural Marketing Acts of 1940 and 1956 delineated the powers of regulation and market control activities for the established and new federal and provincial marketing boards. The result was marketing boards with diverse market powers and scope of operations across provinces, and across boards within the same province. Some marketing boards act only in a supervisory capacity, whereas others wield more extensive powers in market regulation and control. Activities generally range from negotiating minimum prices, regulating quantity and quality of marketed products, collecting and distributing payments, as well as grading and quality control.

Several common features distinguish marketing boards in developed countries from those found in developing nations. First, marketing boards in developed countries tend to be specialized in both scale and scope of operations. For example, New Zealand currently runs strictly export monopolies, such as
the Dairy Board, that have control over the country's agricultural exports but negligible influence over domestic production, sales, imports or tariff rates.

Second, marketing boards in developed countries tend to subsidize farmers at the expense of consumers, as evidenced by their mandate to maintain high producer prices for farmers through limited supply. One result is that marketing boards in developed countries have tended to generate windfall profits for the owners of farm land and other sector-specific assets in agriculture.

Third, and following directly from their role in subsidizing farmers, state trading enterprises tend to encourage and support cartels at producer, processor and distributor levels. Developed country agricultural marketing boards have been a major issue in international trade because historically they dominated certain markets. For example, McCalla and Schmitz (1982) estimated that 95 per cent of world wheat trade in 1973–7 involved a state marketing board on at least one side of the transaction. Because marketing boards enjoy greater flexibility than private traders in pricing – for example, they can commonly delay payments to producers, pool payments so as to reduce producer price risk, and can practise discriminatory pricing among export or import markets – their operations are closely scrutinized by the World Trade Organization for prospectively anti-competitive practices.

Marketing boards in developing countries

Marketing boards in developing countries were typically begun during colonial times for purposes distinct from those of their counterpart marketing boards in developed economies. And they have followed a somewhat different trajectory from those of marketing boards in developed countries. European colonial powers formed marketing boards in large measure to facilitate the export of agricultural commodities to Europe and to stabilize prices faced by colonial elites (for food crops) and metropolitan buyers (for export crops). Post-independence governments generally maintained marketing boards because these were considered simpler to manage and more efficient in conducting organized trade than the traditional, decentralized private sector. More compellingly, marketing boards provided a convenient way for the governments to maintain control over the marketing of strategic commodities, such as the food staples and important export crops (Lele and Christiansen, 1989). The marketing boards system was most prevalent in the anglophone African and South Asian countries, but widespread as well in francophone and lusophone African countries and in Asia and Latin America.

Marketing boards were both state-owned and state-funded, based on centralized decision making systems. They possessed the sole legal authority to purchase commodities from farmers and to engage in trade. Through the boards, governments typically fixed official producer prices for all controlled commodities, often in a pan-seasonal and pan-territorial manner whereby a single price was set for the whole marketing season and for all regions of the country. Marketing boards provided a guaranteed market for the farmers, absorbing all marketed surplus at the official producer prices, and maintaining extensive buying networks and storage facilities throughout the production regions. Pan-seasonal and pan-territorial pricing practices eliminated any opportunities for arbitrage, discouraging private investment in commodity storage or transport capacity, and reinforcing the government's control over the marketing channel. Unlike marketing boards in developed countries, producer sales into the network were rarely rationed, because the marketing boards' objective was normally to increase supply and lower prices for consumers, as opposed to controlling supply for the benefit of producers.

Two features of the export crop marketing boards – as distinct from those handling staple food
commodities – are worth noting. First, the marketing boards held the sole legal rights in commodity export, and had a mandate to generate income for the state. Therefore, storage costs were maintained at low levels through selling policies such as rapid evacuation and forward selling. In addition, local producer prices were typically set at levels lower than the international free-on-board prices, through price fixing or overvalued exchange rates. Essentially, export crop marketing boards were used as a means to tax agriculture in order to develop the industrial sector in these agrarian economies. The taxes were often quite severe. In Tanzania, for example, local producer prices for coffee and tobacco fell to 23 per cent and 15 per cent of international prices, respectively, by the mid-1980s.

Second, because export crop marketing boards served foreign demand, no price controls existed on the selling end. Marketing boards could trade on an open market for the highest possible selling prices. However, because most of the former European colonies enjoyed preferential access to European markets under the Lomé Convention, most commodities were sold to Europe. In addition, some export crops enjoyed commodity price stabilization through international commodity agreements such as the International Coffee Agreement or the International Rubber Agreement. In those cases where a country enjoys world market power, a state marketing board can, at least in theory, increase prices and thereby extract consumer surplus from foreign buyers to benefit the exporting country, including its producers. This is one of the concerns surrounding state trading enterprises within global trade policy fora.

Even though the export crop marketing boards were generally established first, in most developing countries staple food commodity marketing boards became at least as significant a part of the parastatal system. For food commodities, government control extended to every stage of the market chain, to include farm gate, wholesale and retail price controls. In-country commodity movement was restricted, especially the movement of strategic food commodities, and private trade was either illegal or legal only by licence. To achieve food security objectives, food subsidies were generally offered, mostly implicitly, in the form of fixed consumer prices set at levels lower than the market price. Although farm prices were generally set at a below-market level as well, the government often offered implicit subsidies to farmers, through price stabilization operations, and input and credit subsidies administered through the marketing boards (Lele and Christiansen, 1989). Moreover, pan-territorial pricing typically implied subsidies for farmers in more remote smallholder regions. In some countries and for some crops, these arrangements likely stimulated greater crop production than would have occurred under open market arrangements. Grain marketing boards commonly also handled the strategic food reserves for emergency situations, and had the responsibility to import food in shortage seasons. These parastatals therefore held most of their nations’ inter-seasonal and inter-annual grain storage capacity, a legacy that would affect inter-seasonal commodity price movements after the liberalization of commodity marketing systems in the 1980s and 1990s. Although processing was not their core business, marketing boards, in some cases, were also involved in preliminary processing, such as milling rice or maize, or in licensing and monitoring the processing industry activities. This underscores an important difference from developed country marketing boards: the breadth of commodity marketing boards’ mandate in most developing countries.

Over time, the fiscal sustainability of marketing boards in developing countries became questionable. The broad range of marketing operations handled by marketing boards and the politically charged manner in which these operations were typically handled led to massive inefficiencies and deficits that cash-strapped central governments had an increasingly difficult time covering. The subsidies embedded in grains pricing systems, coupled with heavy overhead costs associated with high administrative,
transportation and storage costs, soon created huge tax burdens. In an attempt to ensure food security, the state would generally increase producer prices with less than proportional increases in consumer prices, taking on responsibility for a significant share of the marketing costs associated with moving food from farm to table. The pan-territorial pricing system meant higher transportation and handling costs in moving commodities from some remote areas, and the management of large volumes of commodities in storage was costly. In addition, the monitoring of private trade was not only costly but generally ineffective, especially for food commodities in shortage seasons, when parallel markets flourished to meet local demand. In Mali, for example, even though private cereals trade was illegal before 1981, only 30–40 per cent of total grain trade was actually handled by the state trading agency, OPAM (Dembélé and Staatz, 2002). On the international market, marketing boards faced decreasing real commodity prices for export crops, further undermining their sustainability.

By the end of the 1970s budget deficits resulting from the management and mismanagement of parastatals had reached astronomical levels in most countries. In Mali, OPAM's annual deficit reached US$80 million by 1980, three times the board's annual grain sales. In Tanzania, the National Marketing Corporation's overdrafts were about $250 million in 1993, against total state expenditures on agriculture of $12 million. The National Cereals and Produce Board (NCPB) of Kenya accumulated an estimated loss of about $300 million by 1993, in contrast with central government expenditure on agriculture of $33 million (Staatz et al., 2002; Lele and Christiansen, 1989). These patterns were by no means exclusive to Africa. Indonesia's price stabilization scheme for rice, managed by the National Logistics Supply Organization (BULOG), also proved a high price to pay for self-sufficiency, as did the Food Corporation of India.

In addition to budgetary complications, marketing boards also faced organizational challenges. Their susceptibility to bureaucracy and corruption increased both the inefficiency in their operations and the transactions costs for farmers and consumers. For example, Arhin, Hesp and van der Laan (1985) argue that by the mid-1970s the Ghana Cocoa Marketing Board had become little more than an instrument of the government for the purpose of mobilizing political support for the incumbent government. Mounting deficits, poor management and the perverse incentives created by anti-competitive behaviour brought marketing boards and price stabilization systems under attack, based in part on seminal research into the welfare effects of government interventions to stabilize commodity prices (Newbery and Stiglitz, 1981). These deficit problems, coupled with the new economic insights, triggered widespread agricultural market reforms in the 1980s and 1990s throughout the developing world, implemented mainly but not exclusively, in the context of structural adjustment programmes (SAPs) of the World Bank and the International Monetary Fund.

Agricultural marketing reforms generally aimed to reduce the role of the public sector in marketing and to encourage private sector participation so as to let markets allocate scarce goods more efficiently. Marketing boards experienced major reforms under these programmes, comprising the elimination of price controls, termination of farm input and consumer food subsidies, removal of marketing boards’ monopsony power and deregulation of private trade. In many cases, marketing boards were privatized or at least commercialized, the latter referring to cases where marketing boards remained government owned, but with autonomous decision-making power and an explicit objective to maximize profits. The logic was that, by removing political interference in the marketing process, market forces would lead to efficient resource allocation and price discovery. Market deregulation was thus expected to improve marketing efficiency by reducing transactions costs, increasing producer prices, thus inducing increased
production and potentially also lowering consumer prices.
The response of the market was immediate and quite dramatic in many cases. Entry into formerly controlled agricultural markets was massive in most countries, although with continued bottlenecks in functions requiring significant capital outlays, such as bulk inter-seasonal storage and long-haul motorized transport, entry was typically restricted to niches with low entry barriers (Barrett, 1997). Nonetheless, formal and informal private traders became a significant part of the marketing channel, performing most of the trade activities that the marketing boards previously performed.

In spite of widespread liberalization, marketing operations for most ‘strategic’ food and export crops changed little. Newly privatized or commercialized marketing boards were often replaced with ‘new’ marketing boards that were initially intended to provide public goods, but eventually and predictably became involved in crop marketing. In Zambia, for example, the government-owned Food Reserve Agency (FRA) that replaced the National Agricultural Marketing Board (NAMBOARD) in 1995, charged with maintaining the strategic grain reserve and acting as a buyer of last resort for smallholder farmers, in time took up prior NAMBOARD responsibilities such as fertilizer distribution. Moreover, some of the commercialized marketing boards did not significantly change their pricing systems and continued to use the power of the state to remain dominant players in the current market system. In Indonesia for example, even though the market was opened to private traders, BULOG remained a price leader by operating a major buffer stock, purchasing rice when rice prices fell below a stated floor price and releasing stocks when prices rose above a price ceiling. Similarly, in the Kenyan maize sector the NCPB continued to intervene directly in markets to support maize prices; and in Malawi ADMARC remains the dominant maize buyer and distributor of inputs. Zimbabwe went so far as to reinstate the monopsony power of the Grain Marketing Board and its pre-reform operations. Not surprisingly, the budget deficit of these marketing boards actually increased after reforms.

These trends reflect governments’ reluctance to relinquish control over marketing board operations, particularly the setting of prices for key food and export crops, given political sensitivity to these issues. As it turned out, such concerns were not completely unwarranted. In many developing countries the legacy of private underinvestment in storage and transport capacity, inadequate commercial trading skills in the nascent private sector, combined with limited access to finance, restricted entry into key niches of the marketing channel. These market conditions facilitated the emergence of new monopolies, often substituting private for public market power. Problems of weak contract enforcement, unreliable physical security and underdeveloped communications and transport infrastructure often impeded business expansion, market integration and price transmission. Despite increased private investment in transportation and storage infrastructure after reforms, the weaknesses of the existing systems implied considerable business risk. Consequently, private traders did not fully or quickly fill the voids left by the withdrawal of the marketing boards from core commodity market intermediation functions. Price volatility increased sharply in many countries. Moreover, farmers’ access to seasonal credit dropped significantly as market liberalization ended formerly monopsonistic marketing boards’ willingness to extend seasonal credit to growers that were collateralized by future sales. Reduced credit often led to fewer purchased inputs and lower crop output. In an attempt to restore market stability and production volumes, states often suspended or reversed reforms, reinstating price controls and trade restrictions, thereby further exacerbating instability and undermining investor confidence. The result has been incomplete reforms in most developing countries, where private sector involvement remains pervasive but small-scale and weak, while unprofitable commercialized marketing boards remain prominent and
prone to government interference.

**The current state of play**

Far fewer marketing boards exist than previously. Because they reduce or eliminate competition, marketing boards are widely believed to induce inefficiency in marketing and sluggishness in price discovery. Therefore, government involvement in agricultural marketing has been weakening in both developed and developing countries since the mid-1980s, a result of the adoption of more liberal domestic economic policies, coupled with global pressure to conform to international trade rules steadily expanding their coverage of agriculture. The monopoly or monopsony powers of all but a few marketing boards have been lifted, and the marketing and processing activities of the boards have been streamlined. Where reforms have been widespread and successful, marketing boards have vanished or retreated to providing public goods, such as strategic grain reserves or insurance against extraordinary price fluctuations. Where reforms have been halting or unsuccessful, the weaknesses of private agricultural marketing channels have been laid bare by the rollback of marketing boards.

Marketplaces

Winifred B. Rothenberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Marketplace’ was defined by the great 18th century jurist, William Blackstone, as ‘a spot of ground set apart by custom for the sale of particular goods.’ The definition is striking in its simplicity, but the simplicity is deceptive, for each word should give us pause. If a marketplace is a ‘spot’ it is both bounded and of little consequence. Having said it was a ‘spot’, ‘of ground’ would seem to be redundant were it not that this, the market as a place located in space is the feature that over time will change the most. ‘Set apart’ underscores the irreconcilability of Commerce and Community, and, by implication, bestows upon Community the greater authenticity. ‘Sale’—legally to divest a seller—presupposes a body of legal rules protecting title and the alienability of title, at least to ‘particular goods’. And ‘particular goods’, in turn, implies the inalienability of title to other goods. Finally, there is ‘custom’. In Blackstone’s syntax, custom’s role appears limited to the setting of the spot. But when Commerce threatens to overwhelm the barriers that Community has erected against it, it will be custom that writes the regulations into law. ‘Marketplace’ is not at all ‘simple,’ and reckoning with it in one or another of the protean forms it has assumed over the millennia deserves to engage, as indeed it has, the attention of archaeologists, historians, anthropologists, sociologists, and economists.

Marketplaces in the long-run

The history of marketplaces is traced here as a sequence of pivotal events that began at least 60,000
years ago when, archaeologists suggest, the earliest appearance of trade in Europe can be inferred from the discovery of made objects -- amber, mollusc shells and worked stone -- that had been moved to sites hundreds of kilometers from their sources. But the origins of trade may extend back even further in time, for ‘the archaeological record does not reveal any time in the history of man in Europe in which there was no movement of “manufactured” objects’ (Grantham, 1997, p. 18).

A giant leap takes us to Mesopotamia 10,000 years ago. Having by now collected abundant evidence of the deleterious effect of settled agriculture on human health in the Neolithic, it has been suggested by some paleopathologists that the Agricultural Revolution – the sedentary cultivation of grain, sugar, flax, wool, sisal, jute and hemp – may have been driven less by the quest for food security than by the high value these staple crops could earn in trade.

Study of the 4,000 year-old Heqanakht Papyri reveals Heqanakht himself to have been ‘obsessed’ with running his farm to make a profit and augment his wealth, and the economy of Pharaonic Egypt to have been one not of priestly redistribution, as had been thought, but of private property, money prices, cash crops, rental land, wage labour and marketplaces (Allen, 2002).

Ten centuries before the Christian era, the marketplaces rimming the Aegean Basin were specializing in the export of high-value wines, olives and oil to trade for imports of grains, raw materials and slaves from the ‘barbarians’ north of the Mediterranean.

In the eighth and seventh centuries BC, Phoenicia's legendary traders integrated the markets of the eastern and western Mediterranean; the Etruscans made contact with the Celts; and the merchants of India reached the northwest coast of England.

In the Bible, The Book of Ezekiel, written, it is thought, in the sixth century BC, describes in chapters 26–27 the prosperous city of Tyre whose marketplaces overflowed with an abundance of fir trees from Senir, cedars from Lebanon, ivory benches from the isle of Chittim, fine linen from Egypt, silver, iron, tin and lead from Tarshish, emeralds, purple, coral, agate and fine linen from Syria, wheat from Minnith, honey, oil and balm from Pannag, wine and white wool from Helbon, lambs, rams and goats from Arabia, spices from Sheba and Ra-amah, and skilled artisans, laborers seafaring men, and merchants from all over the eastern Mediterranean.

Most exotic of all were the marketplaces that grew up along the Silk Road, established by the Han Dynasty in the second century BC as China's only link to the West. Along much of its length, the Silk Road was less a ‘road’ than a hazardous path around the world's most unlivable desert, through the world's most inaccessible mountain passes, over the world's highest peaks, and among the world's most isolated and hostile peoples. The Road started in what is now Xian on China's northwest border, and made its way west through Kazakhstan, Kyrgyzstan, Uzbekistan, Tajikistan, and Afghanistan, encircling the Hindu Kush, until crossing the Black Sea, it ended in Roman Syria – which is as much as to say, in Venice! The market-places of this commerce were the oases of central Asia and the fabled ‘Arabian Nights’ cities they became: Xian, Islamabad, Tehran, Kashi, Samarkand, Bukhara, Kabul, Kandahar, Tashkent, Aleppo, Lahore, Baghdad, Ankara, Istanbul. For 15 centuries, caravans of up to 1,000 camels each made the journey from oasis to oasis for months on end, under armed guard, bearing gold, metals, ivory, precious stones, myrrh, frankincense, ostrich eggs, horses, glass, silks, porcelain, guns, powder, jade, bronzes, lacquer – and the great religious civilizations of Buddhism and Islam.

On the European end of the Silk Road great ‘diaspora networks’ were founded by Greek, Armenian and Jewish merchant families of the eastern Mediterranean, who traded a world away with the diaspora networks of India, China, Japan and Indonesia (McCabe, Harlaftis and Minoglou, 2005).
In time, the Romans would discover the secret of making silk, Europeans would find a sea route to China, the Silk Road with its storied past would disappear beneath the sand, the Mongol hordes would burst out of the East, and Europe would reap the whirlwind. In the Black Death that ravaged the continent between 1348 and 1351, Europe lost as much as 40 per cent of its population.

To a demographic event so catastrophic no system, no institution, no mode of production could remain impervious. Especially transformed were Europe's labour markets. In England, those who survived the Black Death lived to enjoy ‘the sole golden age of the English peasantry’ (Hatcher 1987, p. 281). The Statute of Artificers notwithstanding, the general response of the manorial economy to the desperate scarcity of labour, the abundance of abandoned land, and rising prices in grain markets was to relax feudal constraints on the mobility of labour, to raise nominal wages, lower rents, and make concessions on customary dues and obligations. In a word, peasants under villein tenure were able to secure copyhold and leasehold tenancies. By the 17th century, England had become ‘a peasant-free zone’ (R.M. Smith in Scott, 1998, p. 346).

In Russia, in stunning contrast, the response to depopulation was the establishment of serfdom. In the face of acute labour scarcity and expanding grain markets, the Boyars demanded tighter and tighter legal restrictions on the mobility of peasants until, by an Act of the Duma in 1649, serfs and their households were made the personal property of the lord -- effectively slaves (Domar, 1970, pp. 13–32).

Thus, ‘peasant’ in the European context came to be a status that defies definition: some were well on the way to yeomanry by 1600, others were only a technicality away from a heritable condition of slavery.

**Marketplaces and peasants**

From the 14th century to the 18th, the history of marketplaces is linked to the history of peasants, as that of peasants is to marketplaces. In Brueghel's exuberant paintings of peasants tumbling about in overflowing marketplaces the link has become an icon of Flemish art. ‘Historically, peasants only exist when markets exist, even if they do not fully participate in them’ (Scott, 1998 p. 2).

Having for well over a century minutely observed a vast number of peasant societies, the characteristics of peasant markets, and the behaviour of peasants with respect to them, it has been anthropology, rather than economics, that has become, to use Grantham's phrase (1997, p. 19), ‘the referent social science’ of the peasant economy. Peasant villages, whether in Indo-China, West Africa, the Stone Age, or – improbably – colonial New England, are said to have this in common: that the village marketplace is ‘embedded in’ the social fabric of the community; the rules governing it, and the motivations of buyers and sellers and borrowers and lenders transacting in it are subordinate to and constrained by the non-market values of the ambient culture, and stand as epicentres of resistance to the encroachment of the ‘disembedded’, proto-capitalist, dynamic, hegemonic Market, with a capital M.

Influential as this model has been, there is a counter-narrative, accepted even by some anthropologists. Thus, for example, among the Panajachelenos of the Guatemalan highlands, ‘Commerce is the breath of life’ (Tax, 1963, p. 132). According to Sol Tax, both men and women spend more time buying and selling and talking about buying and selling than doing anything else. When they have nothing to sell, they buy something in a cheap market and carry it to a dear one to sell. The Maoris of New Zealand, the Ifugao of the Philippines, the Senegambian, Afikpo, Esusu, Yoruba, Hausa, Tiv and Dahomean peoples of West Africa, the northeastern Malays, the Javanese and the Trobriand Islanders have all been found to
engage in price- and quantity-bargaining, to ‘seek maximal advantage’ in marketplace transactions (Firth and Yamey, 1964), and to exhibit in their market-dependence the same U-shaped relationship to their disposable assets as is associated with risk-averse behaviour in developed economies.

A case in point is a new study of African markets by Marcel Fafchamps (2004) who argues that sub-Saharan Africa today is decisively ‘market-oriented’. The development of Africa, Fafchamps insists, has been impeded not by the cultural incongruity of markets, or the absence of markets, or the lack of a market mentalité, but by the accommodation that traders in sub-Saharan markets have had to make to the ubiquity of market imperfections. In the absence of well-defined property rights, intermediary institutions, notaries public and contract enforcement, the sole bar against asymmetric information, adverse selection and moral hazard has been what might be called ‘insider trading’: repeated transactions among networks of friends and relations bound to one another by webs of trust. In the context of sub-Saharan Africa these webs, although intimate, are not cooperative, says Fafchamps, but strategic; the object is not to avoid the discipline of the market but more nearly to satisfy its assumptions.

Few peasant economies fit the ‘moral economy’ model (Rothenberg, 1992, chap. 2). And those that do may, like 15th-century French villages, have been torn by strife, the collective experience ‘rubbed raw’ (Hoffman, 1996, p. 77) by the face-to-face pursuit of what Avner Offer (1997) has called ‘regard’.

But the principal critique of a non-market model is that it is a steady-state model, and that has tended to impart a Durkheimian steady-state bias to peasant studies. It is a bias very much ‘at home’ with a methodology in anthropology itself in which scrutiny ever closer is leveled at subjects ever narrower -- from tribe, to village, clan, household, extended family, nuclear family, gender -- thereby surrendering to economists the trade among groups and the articulation between marketplaces that generates growth. It is in regulating that process that the community asserts its dominion over what Braudel (1982, p. 58) has called ‘the insidious tentacles of the economy’.

Regulating the marketplace

Such interventions have a very long history, coming down to us, Blackstone thought, from Saxon times when no title to goods valued above 20 pence could change hands without witnesses. But such impediments to trade could not have persisted were it not for law. It is the province of any law worthy of the name to recognize in ‘You have got what belongs to me’ its sphere of action (Pollock and Maitland, 1895 p. 33), and nowhere more urgently than at the point of transferring the ownership of chattels by sale. For what but law can distinguish sale from theft, right from use, ownership from possession, dominium from seisin?

As the frequency of trade increased in the 13th century, exchange in an open market established by royal grant – a ‘market ouvert’ – sufficed, in lieu of witnesses, to divest a seller. With outdoor marketplaces came rules, regulations and ordinances establishing, locating, restricting, and supervising open markets, covered markets, fairs, merchant courts and piepoudre courts for itinerant merchants; appointing ringers of opening and closing bells, monitors of weights and measures, collectors of fees and fines, inspectors of quality, enforcers of Just Prices, and wardens to patrol the perimeters of the marketplace. This regulatory ‘apparatus’ was brought to the American colonies and given the force of law in the municipal marketplaces of all large towns in Massachusetts and throughout the colonies.

‘The Laws and Liberties of Massachusetts’, codified between 1641 and 1691, declared the taking of
excessive wages by mechanics and day labourers and the charging of unreasonable prices by shopkeepers and merchants punishable by double restitution or imprisonment. They set the weight of the pennyloaf of white bread, and authorized the selection of two able persons annually to enter into the houses of all bakers ‘as oft as they see cause’ to inspect and weigh all bread found there on pain of forfeiture. Two persons were appointed annually to ascertain the range of prevailing wheat prices each month and set the price at which bakers shall bake their bread. ‘The Laws and Liberties’ also set the days of the week when a marketplace shall be kept in Boston, Salem, Lynn and Charlestown, set the times of the ringing of the opening and closing bells, forbade all trade outside the perimeter of the marketplace, and set the two days a year when Boston, Salem, Watertown and Dorchester shall have fairs (Cushing, 1976).

In 1737, Faneuil Hall, Boston's beleaguered marketplace, was besieged by farmers from the surrounding hinterland who ‘donned the livery of heaven’ (disguised themselves as clergy) and burned it to the ground (Brown, 1900, chap. 8). By the early 1820s, the regulated ‘market ouvert’ and the legal doctrine of implied contract expressed by it were abandoned in favour of the rule of *caveat emptor*. Contract, not Community, would come increasingly to regulate markets.

**Marshallian markets: the marketplace after 1900**

With the publication of Alfred Marshall's *Principles of Economics* in 1900, economics became the referent social science of markets. It may therefore come as something of a surprise to discover that in this, the urtext of economics, marketplaces have vanished! Marshall's definition of a market is of an abstraction, outside of spatial coordinates, oblivious of cultural context, and functioning homeostatically in accordance with laws of its own making. ‘The distinction of locality is not necessary,’ he wrote. ‘Economists understand by the term “Market” not any particular market-place in which things are bought and sold, but the whole of any region in which buyers and sellers are in such free intercourse with one another that the prices of the same good tend to equality easily and quickly’ (Marshall, 1890, p. 324).

Thus, the market is not a place but a *process* that expands in space and unfolds in time, driven by the pace at which different prices for the same good converge toward a single price. Called the Law of One Price, that convergence is the unintended consequence of arbitrage between buyers seeking cheap markets and sellers seeking dear markets.

But as long as a wedge between ‘cheap’ and ‘dear’ markets persists, that is, as long as the convergence process is incomplete, marketplaces remain significant, not as ‘spots of ground’ but as transitional nodes of price-formation that become ‘folded in’ as the market process advances along its dendritic expansion-path. The story we have followed for 60,000 years has not, even in a Marshallian sense, become irrelevant.

At the same time, economics itself, as the referent social science of markets, is expanding its narrow field of vision beyond its Marshallian boundaries in an attempt to comprehend the wider social and psychological foundations of economic behaviour. I am reminded of the earthquake of 8 October 2005 which struck high up in the Kashmiri Himalayas. Within a week of the catastrophe, survivors set up a village marketplace (BBC News). Seventy-three thousand had been killed, three million were made homeless, none had necessities, none had surpluses, but within days they made a marketplace.

markets

Geoffrey M. Hodgson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Until recently, and despite strong interest in market outcomes, economists have paid relatively little attention to the institutional structure of markets. This article considers the historical evolution of markets and poses some dilemmas concerning their definition. Several alternative definitions are considered, involving different degrees of historical specificity. It is argued that developments in economics and elsewhere since the 1980s point to a more nuanced view of markets, involving a recognition of different types of market mechanisms and institutions. These developments include work in experimental economics and auction theory. A definition of markets is offered that is consistent with these developments.

Article

Markets dominate modern life, and economists have for long been concerned about market prices, but, despite this ongoing preoccupation, until recently there has been little discussion of the nature and operation of markets themselves.
No fewer than three Nobel Laureates in economics have noted this paradox. George Stigler (1967, p. 291) wrote: ‘The efficacy of markets should be of great interest to the economist: Economic theory is concerned with markets much more than with factories or kitchens. It is, therefore, a source of embarrassment that so little attention has been paid to the theory of markets and that little chiefly to speculation.’ Stigler made a plea for the theoretical study of markets, which for a long time went unheard.

Ten years later Douglass North (1977, p. 710) similarly remarked: ‘It is a peculiar fact that the literature on economics and economic history contains so little discussion of the central institution that underlies neoclassical economics – the market’. Another 11 years had passed when Ronald Coase (1988, p. 7) observed that ‘in modern economic theory the market itself has an even more shadowy role than the firm’. Economists are interested only in ‘the determination of market prices’ whereas ‘discussion of the market place itself has entirely disappeared’.

Economists have had little to say about the nature of markets, other than classifying them by their degrees of competition and their numbers of buyers and sellers. Beyond this, the institutional aspects of markets have been widely neglected. For much of the 20th century there has been little discussion of how specific markets are structured to select and authenticate information, and of how specific prices are actually formed. Furthermore, ‘the market’ was treated as a relatively homogeneous and undifferentiated entity, with little consideration of different market mechanisms and structures. When market mechanisms were addressed this was typically confined within the framework of general equilibrium theory, with relatively little attention to the institutional details and alternative market structures.

Inspection of standard economics textbooks confirms these observations. While market outcomes such as prices are always central to the discussion, there is generally little consideration of the detailed rules and mechanisms through which prices are formed, and the concept of the market itself often goes undefined. Indeed, there is an entry on markets in neither the massive 1968 edition of the Encyclopaedia of the Social Sciences nor the otherwise comprehensive 1987 edition of The New Palgrave: A Dictionary of Economics.

Three questions arise. First, what briefly is the nature of markets and how can the market be defined? Second, why has the specific anatomy of markets been neglected by economists? Third, what recent developments in economics and elsewhere help to remedy the deficiency? After a brief historical discussion this article addresses these questions.

**Historical background**

Goods have changed hands within human societies for hundreds of thousands of years. However, much of this internal circulation was powered by custom and tradition. Transfers of goods often involved ceremony and personal, reciprocal actions. These personal and kin-based exchanges contrast with the organized and competitive pecuniary ambiance of modern markets. Ceremonial transfers involved ‘the continuous definition, maintenance and fulfilment of mutual roles within an elaborate machinery of status and privilege’ (Clarke, 1987, p. 4). Most of this internal circulation of goods was devoid of any conception of the voluntary, contractual transfer of ownership or property rights. These reciprocal transfers of goods were more to do with the validation of custom and social rank.

Something more akin to trade existed at least as far back as the last ice age. However, this trade was
largely peripheral and occurred at the meeting of different tribal groups. As Max Weber (1927, p. 195) attested, it did not take place ‘between members of the same tribe or of the same community’ but was ‘in the oldest social communities an external phenomenon, being directed only towards foreign tribes’. This contention that trade began externally and between communities rather than within them has withstood subsequent scholarly examination. Trade was typically a collective and inter-social enterprise between one tribe and another.

With the rise of the ancient civilizations, both external and internal trade increased substantially. The development of money and coinage facilitated its expansion. A definable internal commodity market (or agora), with multiple buyers and sellers, first appeared in a designated open space in Athens in the sixth century BC (Polanyi, 1971; North, 1977). The agora opened frequently and had strict trading rules. At around the same time there existed an annual auction market on Babylonia: young women were put on display and male bidders competed for marriage rights (Cassady, 1967). Nevertheless, some scholars have warned against the view that these ancient civilizations were generally and predominantly market economies (Finley, 1962; Polanyi, Arensberg and Pearson, 1957). By contrast, researchers such as Peter Temin (2006) have argued that the Roman Empire in particular contained developed and interlocking markets with variable prices, albeit without a highly developed banking system and with a relatively limited market for capital.

European and Mediterranean trade contracted after the fall of the Roman Empire. When commerce began to develop again in medieval times, internal markets then had a limited role in the medieval economy. ‘Strange though it may seem’, wrote the historian Henri Pirenne (1937, p. 140), ‘medieval commerce developed from the beginning not of local but of export trade.’ Although there are likely to have been other earlier organized markets in England, systematic evidence of the king enforcing his right to license all markets and fairs does not appear until the 13th century.

Markets for slaves existed in classical antiquity and persisted in some regions until the modern era. By contrast, feudal serfs were not owned as chattels, but they did not enjoy the right to choose their masters. Feudal institutions, driven by traditional obligations rather than voluntary contract, meant that the hiring of labourers was marginalized and markets for wage labourers were rare. With the decline of bonded labour, which began as early as the 14th century in England, employment contracts were limited largely to casual labourers, alongside a large number of self-employed producers and others in peasant family units. In England it was not until about the 18th century that a class of potentially mobile wage labourers emerged who constituted the most important source of labour power. Organized markets for employees, involving labour exchanges or employment agents, did not become prominent until the 19th century.

To turn to capital markets, an early market for debts was the French courrrier de change in the 12th century. In the 13th century, after the development of a banking system in Venice, trade began in government securities in several Italian cities. In 1309 a ‘Beurse’ was organised in Bruges in Flanders, named after the Van der Beurse family, who had previously hosted regular commodity exchanges in their residence. Soon after, similar ‘Beurzen’ opened in Ghent and Amsterdam. In 1602 the Dutch East India Company issued the first shares on the Amsterdam Bourse or Stock Exchange. The London Stock Exchange, founded in 1801, traces its origins to 1697 when commodity and stock prices began to be published in a London coffee house. The origins of the New York Stock Exchange go back to 1792, when 24 stockbrokers organized a regular market for stocks in Wall Street. Accordingly, developed capital markets first appeared in the Netherlands in the 17th century and later spread to other countries.
Overall, in the last 400 years markets have expanded enormously in scope, volume and economic importance. Markets have come to pervade internal as well as external trade and to dominate the global economic system. The modern era of globalization is often identified with the growth of global commodity and financial markets since the middle of the 19th century.

This brief historical sketch is background for the task of defining markets. At least three options emerge, involving different degrees of historical specificity. The broadest definition would be to use the term 'market' to refer to all forms of transfer of goods or services between persons, including the age-old customary or ceremonial transfers within tribes and households, exchanges of property between tribes, and modern organized markets with multiple buyers and sellers. We consider this option and some more restrictive alternatives next.

The nature of markets

The Austrian school economist Ludwig von Mises (1949) is exceptional among economists in devoting a lengthy chapter to 'the market'. He sees the market economy as 'the social system of the division of labour under private ownership of the means of production' (1949, p. 257). He explicitly excludes economies under social or state ownership of the means of production from this category, but nevertheless regards such systems as strictly 'not realizable'. Consequently, the historical and territorial boundaries of his concept of the market depend very much on what is regarded as 'private ownership'. He associates private ownership with the rise of civilization, and defines ownership in terms of full control of the services that derive from a good, rather than in legal terms. Together these specifications amount to a definition of the market that embraces all forms of trade or exchange that involve private property, defined loosely as assets under private control.

Although von Mises associates secure private property and exchange with the rise of civilization, these terms are defined in a manner that does not exclude their application to earlier periods of human history. It then becomes problematic whether or not ceremonial transfers and ritualistic gift-giving are regarded as 'exchanges' of 'property' and whether or not these activities come within the sphere of 'the market'. Essentially, the historical compass of the latter term depends very much on what we mean by notions such as exchange and property.

In downplaying the legal aspects of property and exchange, von Mises also fails to probe the nature of the rights that form part of the exchange. Instead he sustains the notion that uncoerced and informed consent by the parties to the transaction is a sufficient basis to constitute the contractual and property rights involved. A problem with this idea is that mutual individual consent itself requires a legislative and institutional framework to legitimize, scrutinize and protect those individual rights. The importance of this legal and constitutional framework is widely recognized, including by other Austrian theorists such as Friedrich Hayek (1960). Several historical cases of the spontaneous evolution of systems of enforced property rights do exist, but they generally rely on reputational and other monitoring mechanisms that are more difficult to sustain in large-scale, complex societies (Sened, 1997).

An alternative intellectual tradition places more emphasis on the legal and statutory basis of individual rights. This approach pervaded the 19th-century German Historical School and their predecessors such as Karl Heinrich Rau, and continued into the 20th century in the original American Institutionalist School, particularly in the writings of John Rogers Commons. Both Rau and Commons (1924) argued...
that exchange is more than a voluntary and reciprocal transfer of resources: it also involves the contractual interchange of statutory property rights. For them, exchange had to be understood and analysed in terms of the key institutions that are required to sustain it. This narrower and more legalistic understanding of private property and contractual exchange confine them both in longevity and scale. Statutorily endorsed property rights, applied to moveable goods and services, were not codified until the ancient civilizations. In feudal times, much of the transfer of goods and services was achieved by custom or coercion rather than by contract and consent. Indeed, economic historians such as North (1981), who attempt to explore the origins of modern markets and commodity exchange, generally focus on the late medieval or early modern period as the era in which well-defined individual property rights began to spread widely from specific parts of the world.

A second important dilemma emerges. This is whether the market is regarded as coextensive with the exchange of private property per se or whether it is given an even narrower meaning and used to refer to forms of organized exchange activity. Two major factors lead us to consider an even narrower meaning for the term.

The first consideration is the commonplace use of the term ‘market’ itself and its equivalent in other languages. The word ‘market’ originally appeared as a noun to describe a specific place where people gathered and exchanges of a particular kind took place. The first market in Athens in the sixth century BC had rules concerning who could buy or sell, what could be bought or sold, and how trading should take place. In medieval England markets were permitted by royal charters and located in specific towns. In Europe and elsewhere in the last 300 years organized town and village markets have become commonplace. There are also permanent buildings that function as ‘exchanges’ for agricultural products, minerals, financial stocks, and so on. Although it has acquired additional meanings, the noun ‘market’ still refers to a place or gathering where trade is organized.

The second issue is the existence of a well-researched form of exchange that takes place in different contexts and involves different considerations. In three seminal and influential works, George B. Richardson (1972), Victor P. Goldberg (1980) and Ronald Dore (1983) point out that many real-world commercial transactions do not take place in the competitive arena of a market. Instead they involve firms in ongoing contact, which exchange relevant information before, during and after the contract itself. The relationship is durable and the contract is often renewed. This is most often described as ‘relational exchange’. A question in the derivative literature is to examine the reason for the mutual choice of an ongoing exchange relationship rather than the more competitive institution of the market. Among the explanations is the importance of establishing ongoing trust in circumstances of uncertainty where product characteristics are complex, relatively unique or involve continuous potential improvements. Whatever the reason for its existence, such relational contracting is very different from the more anonymous exchanges in organized markets. Relational exchanges are nevertheless still contractual exchanges of property rights, in their fullest and most meaningful sense. If they are distinguished by definition from market exchanges, then not all exchanges take place in markets. Furthermore, the exchange of goods or services that are strictly unique may be regarded as a non-market phenomenon, even if the exchange is not relational. The term ‘market’ is thus reserved for forms of exchange activity with many similar exchanges involving multiple buyers or sellers.

In part, it is the degree of organization of exchange activity that makes markets different from relational exchange. In financial markets, for example, there are typically strict rules concerning who can trade and how trading should be conducted. In such relatively volatile markets, specific institutions sift
information and present it to traders to help the formation of price expectations and norms. Market institutions in other contexts monitor the quality of goods and the instruments of weight and measure. Within these structures, trading networks emerge on the basis of business connections and reputations. Modern telecommunications mean that a market does not have to be organized in a specific location. Either bidders can communicate with the market centre over long distances, as with many financial markets, or the market place can itself disappear, as in the case of Internet-based markets, such as eBay. The latter case nevertheless remains a market, because it is an organized (virtual) forum, subject to specific procedures and rules.

We thus arrive at a definition of a market in the following terms. Markets involve multiple exchanges, multiple buyers or multiple sellers, and thereby a degree of competition. A market is defined as an institution through which multiple buyers or multiple sellers recurrently exchange a substantial number of similar commodities of a particular type. Exchanges themselves take place in a framework of law and contract enforceability. Markets involve legal and other rules that help to structure, organize and legitimize exchange transactions. They involve pricing and trading routines that help to establish a consensus over prices, and often help by communicating information regarding products, prices, quantities, potential buyers or possible sellers. Markets, in short, are organized and institutionalized recurrent exchange.

Of course, it is often difficult to draw the line between organized and relational exchange. There are many possible intermediate cases. However, such difficulties are typical when dealing with highly varied phenomena and are commonplace in some other sciences, notably biology. Similar difficulties exist in distinguishing other economic forms, such as making the important distinction between employment contracts and contracts for services. Nevertheless, such distinctions are important. The difficulty of defining a species does not mean that species should not be defined.

The operation of the law of one price is often taken as an indication of the existence of a market. Of course, imperfect information and quality variations can explain variations within a market from a single price. Nevertheless, the organized competition of the market and its associated information facilities are necessary institutional conditions for any gravitation by similar commodities to a single price level. Taking stock, we may contrast the narrower definition of the market given above – as an institution with multiple buyers or multiple sellers, and recurrent exchanges of a specific type of commodity – with the much broader definitions raised earlier. These differences in definition do not simply affect the degree of historical specificity of ‘market’ phenomena, they also sustain different theoretical frameworks and promote different questions for research. Some explanations for this divergence arise in the next section.

Why have economists neglected the institutional character of markets?

For much of the 20th century, the institutional character of markets has been neglected by economists because institutions generally have been neglected. The exceptions consist of economists who placed a special emphasis on institutions. The institutional character of markets was emphasised by German historical economists such as Gustav Schmoller and Werner Sombart in the 19th century (Hodgson, 2001). The British dissident economist John A. Hobson (1902, p. 144) wrote: ‘A market, however crudely formed, is a social institution’. Likewise, for the American institutionalist John Maurice Clark (1957, p. 53): ‘the mechanism of the market, which dominates the values that purport to be economic, is
not a mere mechanism for neutral recording of people's preferences, but a social institution with biases of its own'. Coase, North and others have effectively revived an interest in the institutional structure of markets that was eclipsed by developments in mainstream economics during much of the 20th century. A further clue to help explain why generations of economists have neglected the institutional character of markets lies in the preceding section, where the problem of defining the boundaries of key concepts such as property, exchange and market was raised. Many economists have maintained that the principles of the subject should be as universal as possible – like physics – to the extent that substantial consideration of historically or nationally specific institutional structures is lost. The idea that economics should be defined as a general ‘science of choice’ (Robbins, 1932) is part of this tradition. Consequently, terms such as property, exchange and market are given a wide meaning. Accordingly, many forms of human interaction have been regarded as ‘exchange’ and the summation of such ‘exchanges’ as ‘markets’. In these terms, there is little difficulty in applying these concepts to many different types of system, from tribal societies through classical antiquity to the modern capitalist world. Consequently, the idea of the market assumes a de-institutionalized form, as if it was the primeval and universal ether of all human interactions. Whenever people gather together in the name of self-interest, then a market somehow emerges in their midst. The market springs up simply as a result of these spontaneous interactions: it results neither from a protracted process of multiple institution-building nor from the full development of a historically specific commercial culture. Incidentally, many sociologists have also assumed a de-institutionalized concept of the market. This is partly the result of the influence of a notion, promoted by Talcott Parsons and others, that sociology should also aspire to a high degree of historical generality. It is also a result of the influence of Marxism within sociology. Despite its emphasis on historical specificity, Marxism also treats markets as uniform entities, ultimately permeated by just one specific set of pecuniary imperatives and cultural norms. From the 1940s to the 1970s, general equilibrium theory provided the framework in which economists attempted to understand the functioning of markets in wide-ranging terms. Even here, however, some significant attention had to be paid to institutional mechanisms and structures. Something special like the ‘Walrasian auctioneer’ had to be assumed in order to make the model work (Arrow and Hahn, 1971). Some elemental institutional structures had to be brought in to make the model function in its own terms. The limits to this project of theoretical generalization became more apparent in the 1970s, when it was shown that few general conclusions could be derived. In particular, Hugo Sonnenschein (1972) and others demonstrated that within general equilibrium theory the aggregated excess demand functions can take almost any form (Rizvi, 1994).

The existence of ‘missing markets’ always poses a problem for the general equilibrium approach: a complete set of markets for all present and future commodities in all possible states of the world is typically assumed as a basis for general clearance in all markets. However, if market institutions are themselves scarce and costly to establish, then some may be missing for that reason. Furthermore, while capitalism has historically promoted market institutions, modern developed capitalism prohibits several types of market, such as markets for slaves, votes, drugs, or futures markets for labour. In so far as capitalism makes such prohibitions, ‘missing markets’ are inevitable within capitalism. The technical problems exposed by Sonnenschein and others led economists to shift their attention away from general equilibrium theory. Instead, game theory became the cutting edge of theoretical analysis. By its nature, game theory tends to lead to less general propositions and points instead to more specific rules and institutions. As game theory became fashionable in the 1980s, it became a theoretical tool in
the ‘new institutionalist’ revival in economic theory.

The revival of the notion of markets as institutions

At least three further developments helped to promote the study of markets as social institutions. First, the basic theory of auctions emerged in the 1970s and 1980s (McAfee and McMillan, 1987; Wolfstetter, 1996). It was assumed from the outset that participants in an exchange did not have complete information, and on this basis it was shown that choices concerning auction forms and rules could significantly affect market outcomes. These ideas assumed centre stage in the 1990s with the use by governments of auction mechanisms in electricity and telecommunications deregulation, most notably in the selling of the electromagnetic spectrum for telecommunications services, and subsequently with the growth of auctions on the Internet (McAfee and McMillan, 1996).

A second and closely related development was the rise of experimental economics, which began to be recognized as an important subdiscipline in the 1980s. Modern experimental economists, in simulating markets in the laboratory, have found that they have had also to face the unavoidable problem of setting up its specific institutional structure. Simply calling it a market is not enough to provide the experimenter with the institutionally specific structures and procedural rules. As leading experimental economist Vernon Smith (1982, p. 923) wrote: ‘it is not possible to design a laboratory resource allocation experiment without designing an institution in all its detail’. Work within experimental economics has underlined the importance of these specific rules, by showing that market outcomes are sometimes relatively insensitive to the information processing capacities of the agents involved, because particular constraints govern the results (Gode and Sunder, 1993).

In reality, each particular market is entwined with other institutions and a particular social culture. Accordingly, there is not just one type of market but many different markets, each depending on its inherent routines, cultural norms and institutional make-up. Differentiating markets by market structure according to textbook typology – from perfect competition through oligopoly to monopoly – is not enough. Institutions, routines and culture have to be brought into the picture. Experimental economists have discovered an equivalent truth in laboratory settings, and have learned that experimental outcomes often depend on the tacit assumptions and cultural settings of participants. Different types of market institution are possible, involving different routines, pricing procedures, and so on. This has been acknowledged by a growing number of economists, as the notion of a single universal type of market has lost credibility (McMillan, 2002).

Third, these theoretical developments were dramatized by events. Following the collapse of the Eastern bloc in 1989–91, a number of economists presumed that many markets would emerge spontaneously in the vacuum created by the breakdown of central planning. This view turned out to be mistaken, as capital and other markets were slow to develop and their growth was thwarted by the lack of an appropriate institutional infrastructure. Several formerly planned economics slipped back into recession. Critics such as Coase (1992, p. 718) drew attention to the necessary institutional foundations of the market system: ‘The ex-communist countries are advised to move to a market economy … but without the appropriate institutions, no market of any significance is possible’.

While sociologists, like economists, had previously paid relatively little attention to market institutions, the revitalization of the sub-discipline of economic sociology led to a series of studies by sociologists of...
financial and other markets (Abolafia, 1996; Baker, 1984; Burt, 1992; Fligstein, 2001; Lie, 1997; Swedberg, 1994; White, 1981; 1988). These works show how specific networks and social relationships between actors structure exchanges, and how cultural norms govern market operations and outcomes. Similar considerations have emerged in empirical and simulation work by economists that stresses the importance of learning and previous experience in trading partner selection and in the decision to accept a transaction (Kirman and Vignes, 1991; Härdle and Kirman, 1995).

Taken as a whole, these literatures testify to a much more nuanced conception of market phenomena. As a result of all these developments, the treatment by economists and others of markets began to change. Both economists and sociologists are now paying detailed attention to the nature of specific market rules and mechanisms. A milestone paper by Alvin Roth (2002) challenges the view of a single universal theory of market behaviour. While those economists who had paid attention to different market mechanisms had typically been preoccupied with a search for ‘optimal’ rules and institutional forms, gradually this has become a will-o’-the-wisp with the realization that typical assumptions in the emerging literature concerning cognitive and information impairments have made this search difficult or impossible (Lee, 1998; Mirowski, 2007).

Nevertheless, while the search for optimal institutional blueprints is intractable, these theoretical developments have begun to provide an analytical framework within which the limits and potentialities of different types of market mechanism can be appraised. An outcome is to abandon the former widespread notion – shared by all kinds of theorists from Marxists to the Austrian School – that ‘the market’ is a singular type of entity entirely understandable in terms of the same principles or laws. While Hayek and his followers should be given inspirational credit for their emphasis on the informational limitations inherent in all complex economic systems, they stressed that markets are the most effective processors of information while downplaying or ignoring the differences between various types of market.

In this context, markets reappear as varied and historically specific phenomena. The general equilibrium approach has been overshadowed by an array of theoretical and empirical methodologies, including game theory, agent-based modelling, laboratory experimentation and real-world observation.

**Conclusions**

A number of options for defining a market have been outlined here. The broadest option is to regard the market as the universal ether of human interaction, depending on little more than the division of labour. A second option is to regard the market as synonymous with commodity exchange, in which case it dates at least as far back to the dawn of civilization.

By contrast, several considerations militate in favour of a narrower definition, and recent developments in economic theory point in this direction. In the narrower sense, markets are organized exchange. Where they exist, markets help to structure, organize and legitimize numerous exchange transactions. Pricing and trading procedures within markets help to establish a consensus over prices, and communicate information regarding products, prices, quantities, potential buyers or possible sellers. Variation in market rules and procedures means that markets differ substantially, especially when we consider markets in different cultures. The markets of 2,000 years ago were very different from (say) the electronic financial markets of today. In the real world, and even in a single country, we may come
across many different examples of the market. The market itself is neither a natural datum nor an ubiquitous ether, but is itself a social institution, governed by sets of rules restricting some and legitimizing other behaviours. Furthermore, the market is necessarily entwined with other social institutions, such as in many cases the local or national state. It can emerge spontaneously, but it can also be promoted or guided by conscious design.

A clear implication of this argument is that the unnuanced but familiar pro- and anti-market policy stances are both insensitive to the possibility of different types of market institution. Instead of recognizing the important role of different possible cultures and trading customs, both the opponents and the advocates of the market have focused exclusively on its general features. Thus, for instance, Marxists have deduced that the mere existence of private property and markets will themselves encourage acquisitive, greedy behaviour, with no further reference in their analysis to the role of ideas and culture in helping to form the aspirations of social actors. This is the source of their ‘agoraphobia’, or fear of markets. Obversely, overenthusiastic advocates of the market claim that its benefits stem simply and unambiguously from the existence of private property and exchange, without regard to possible variations in detailed market mechanism or cultural context. As strange bedfellows, both Marxists and some market advocates have underestimated the degree to which all market economies are unavoidably made up of densely layered social institutions.

Abstract

MCMC methods, an important class of Monte Carlo methods, have played a major role in the growth of Bayesian statistics and econometrics. In an MCMC simulation, one samples a given distribution (say the posterior distribution in a Bayesian model) by simulating a suitably constructed Markov chain whose invariant distribution is the target distribution. The Metropolis–Hastings algorithm and its special case, the Gibbs sampler, are two common ways of devising an MCMC simulation. We discuss how these methods originate, discuss implementation issues and provide examples. The use of MCMC methods in Bayesian prediction and model choice problems is also discussed.

Keywords

autocorrelation; Bayesian econometrics; Bayesian prior–posterior analysis; Bayesian statistics; invariance; latent variables; marginal likelihood; Markov chain Monte Carlo methods; model choice; prediction; proposal densities; reversibility; transition density

Article

1 Introduction

Markov chain Monte Carlo methods, popularly called MCMC methods, are a class of Monte Carlo methods for sampling a given univariate or multivariate probability distribution (the target distribution). These methods play a central role in the theory and practice of modern Bayesian methods where they are used for the numerical calculation of quantities (such as the moments and quantiles of posterior and predictive densities) that arise in the Bayesian prior–posterior analysis. They have transformed the fields of Bayesian statistics and econometrics.

Suppose that in a given Bayesian model the prior density is \( \pi(\theta) \) and the sampling density or likelihood function is \( f(\gamma|\theta) \), where \( \gamma \) is a vector of observations and \( \theta \in \mathcal{Y} \) is an unknown parameter. In the Bayesian context, inferences about \( \theta \) are based on the posterior density \( \pi(\theta|\gamma) \propto \pi(\theta) f(\gamma|\theta) \). Now suppose that one is interested in finding the mean of the posterior density

\[
E(\theta|\gamma) = \int \theta \pi(\theta|\gamma) d\theta
\]

but that the integral cannot be computed analytically. In that case one can compute the integral by Monte Carlo sampling methods. The general idea is to calculate the integral from a sample
that is drawn from the posterior density. This sample can be used to estimate the posterior mean and other features of the posterior density. For instance, the posterior mean can be estimated by the average of the sampled draws, and the quantiles of the posterior density by the quantiles of the sampled output.

The requisite sampling of the target density is made possible by MCMC methods. In a MCMC simulation, one samples the target density in an indirect way: by simulating a suitably constructed Markov chain whose invariant distribution is the target density. Then the draws beyond some chosen burn-in period are taken as a (correlated) sample from the target density. The defining feature of Markov chains is the property that the conditional density of \( \theta^{(j)} \) (the \( j \)th element of the sequence) conditioned on the entire preceding history of the chain depends only on the previous value \( \theta^{(j-1)} \). Denote this conditional density, the transition density of the Markov chain, by \( p(\theta^{(j-1)}, \cdot | y) \). Then, in the MCMC framework, a sample is produced by simulating the transition density as

\[
\theta^{(1)} \sim p(\theta^{(0)}, \cdot | y); \theta^{(j)} \sim p(\theta^{(j-1)}, \cdot | y),
\]

If we let the first \( n_0 \) cycles represent the burn-in phase, for some choice of \( n_0 \), the draws

\[
\theta^{(n_0+1)}, \theta^{(n_0+2)}, \ldots, \theta^{(n_0+M)}
\]

are treated as those from \( \pi(\theta | y) \). Even though the sampled variates are correlated, laws of large numbers for Markov sequences can be used to show that, under regularity conditions, the sample average of any integrable function \( g(\theta) \) converges to its posterior expectation:

\[
M^{-1} \sum_{j=1}^{M} g(\theta^{(j)}) \rightarrow \int g(\theta) \pi(\theta | y) \, d\theta,
\]

as \( M \) becomes large.

There are two common ways of constructing a transition density \( p(\theta^{(j-1)}, \cdot | y) \) whose limiting distribution is the required target density. One way is by a method called the Metropolis–Hastings (M–H) algorithm, which was introduced by Metropolis et al. (1953) and Hastings (1970). Key references about this method are Tierney (1994), and Chib and Greenberg (1995). A second approach is by the so-called Gibbs sampling algorithm. This method was introduced by Geman and Geman (1984), Tanner and Wong (1987) and Gelfand and Smith (1990), and was the impetus for the current interest in Markov chain sampling methods. A summary of many aspects of MCMC methods is contained in Chib (2001) while textbook accounts include Gilks, Richardson and Spiegelhalter (1996), Chen, Shao and Ibrahim (2000), Liu (2001) and Robert and Casella (2004).
Suppose that we are interested in sampling the target density \( \pi(\theta | y) \), where \( \theta \) is a vector-valued parameter and \( \pi(\theta | y) \) is a continuous density. The idea behind the M–H algorithm is to simulate a proposal value \( \theta' \) from a transition density \( q(\theta, \theta' | y) \) that is convenient to stimulate but does not necessarily have the correct limiting distribution and then to subject the proposal value to a specific randomization to ensure that the resulting Markov chain has the correct limiting distribution.

To define the M–H algorithm, let \( \theta^{(j-1)} \) be the current value. Then the next value \( \theta^{(j)} \) is produced by a two-step process consisting of a ‘proposal step’ and a ‘move step’.

- **Proposal step**: Sample a proposal value \( \theta' \) from \( q(\theta^{(j-1)}, \theta' | y) \) and calculate the quantity

\[
\alpha(\theta^{(j-1)}, \theta' | y) = \min \left( 1, \frac{\pi(\theta' | y)}{\pi(\theta^{(j-1)} | y)} \frac{q(\theta, \theta^{(j-1)} | y)}{q(\theta', \theta^{(j-1)} | y)} \right)
\]

- **Move step**: Let \( \theta^{(j)} = \theta' \) with probability \( \alpha(\theta^{(j-1)}, \theta' | y) \); remain at the current value \( \theta^{(j-1)} \) with probability \( 1 - \alpha(\theta^{(j-1)}, \theta' | y) \).

In terms of nomenclature, the source density \( q(\theta, \theta' | y) \) is called the candidate generating density or proposal density, and \( \alpha(\theta^{(j-1)}, \theta' | y) \) the acceptance probability or, more descriptively, the probability of move. Note also that the function \( \alpha(\theta^{(j-1)}, \theta' | y) \) in this algorithm can be computed without knowledge of the norming constant of the posterior density \( \pi(\theta | y) \). In addition, if the proposal density is symmetric, satisfying the condition \( q(\theta, \theta' | y) = q(\theta', \theta | y) \), then the acceptance probability reduces to \( \pi(\theta' | y) / \pi(\theta^{(j-1)} | y) \); hence, if \( \pi(\theta') = \pi(\theta^{(j-1)} | y) \), the chain moves to \( \theta' \), otherwise it moves to \( \theta^{(j-1)} \) with probability given by \( \pi(\theta' | y) / \pi(\theta^{(j-1)} | y) \). The latter is the algorithm of Metropolis et al. (1953).

**Remark 1**: Derivation of the M–H algorithm: A question of some interest is the justification of this two-step approach. This question was tackled by Chib and Greenberg (1995) who derived the method from the logic of reversibility. A Markov transition density \( \rho(\theta, \theta' | y) \) is said to be reversible for \( \pi(\theta | y) \) if the following condition holds for every \( (\theta, \theta', y) \) in the support of the target distribution:

\[
\pi(\theta | y) \rho(\theta, \theta' | y) = \pi(\theta' | y) \rho(\theta', \theta | y).
\]

The reversibility condition is important because reversible chains are invariant. Invariance refers to the property that

\[
\pi(\theta' | y) = \int \rho(\theta, \theta' | y) \pi(\theta | y) \, d\theta
\]

which means that, if the transition density is invariant for the target density, then, once convergence is achieved, a subsequent value \( \theta' \) drawn from the transition density is also from the target density. To see that reversibility implies invariance one simply integrates both sides of (3) over \( \theta' \). This leads to the invariance condition since \( \int \rho(\theta, \theta' | y) \, d\theta' = 1 \).
by virtue of being a transition density. Now consider the Markov chain induced by the proposal density $q(\theta, \theta' | y)$. Because this was formulated without the reversibility condition in mind it is unlikely to satisfy reversibility. Suppose that for a pair of points $(\theta, \theta')$ it is true that

$$\pi(\theta | y) q(\theta, \theta' | y) > \pi(\theta' | y) q(\theta', \theta | y),$$

which means informally that the process moves from $\theta$ to $\theta'$ too frequently and too rarely in the reverse direction. This situation can be corrected by reducing the flow from $\theta$ to $\theta'$ by introducing probabilities $\alpha(\theta, \theta' | y)$ and $\alpha(\theta', \theta | y)$ of making the moves in either direction so that

$$\pi(\theta | y) q(\theta, \theta' | y) \alpha(\theta, \theta' | y) = \pi(\theta' | y) q(\theta', \theta | y) \alpha(\theta', \theta | y).$$

One now sets $\alpha(\theta', \theta | y)$ to be as high as possible, namely, equal to 1. Solving for $\alpha(\theta, \theta' | y)$ one then gets

$$\alpha(\theta, \theta' | y) = \frac{\pi(\theta | y) q(\theta, \theta' | y)}{\pi(\theta' | y) q(\theta', \theta | y)}.$$

Because one started from (5) this is clearly less than 1. On the other hand, if the inequality in (5) were reversed, the same argumentation leads to the conclusion that $\alpha(\theta, \theta' | y) = 1$.

Thus, on combining these two cases we reproduce the expression of $\alpha(\theta, \theta' | y)$ given in (2).

**Remark 2:** Transition density of the M–H chain: The transition density of the M–H chain has two components – one for the move away from $\theta$ and given by $q(\theta, \theta' | y)$ and one for the probability of staying at $\theta$ given by $r(\theta | y) = 1 - \int \alpha(\theta, \theta' | y) q(\theta, \theta' | y) \, d\theta'$. In particular,

$$p_{M-H}(\theta, \theta' | y) = \alpha(\theta, \theta' | y) q(\theta, \theta' | y) + \delta_{\theta}(\theta') r(\theta | y),$$

where $\delta_{\theta}(\theta')$ is the Dirac-function at $\theta$ defined as $\delta_{\theta}(\theta') = 0$ for $\theta' \neq \theta$ and $\int \delta_{\theta}(\theta') \, d\theta' = 1$. It is easy to check that the integral of the transition density over all possible values of $\theta$ is 1, as required.

**Remark 3:** Convergence properties: The theoretical properties of the M–H algorithm (in particular the ergodic behaviour of the chain from an arbitrarily specified initial value) depend crucially on the nature of the proposal density. One requirement is that the proposal density be everywhere positive in the support of the posterior density, which means that the M–H chain can make a transition to any point in its support in one step. Further discussion of the conditions is given in Tierney (1994) and Robert and Casella (2004).

**Remark 4:** Mixing: The sampled values from the M–H algorithm (as from any Markov chain) are correlated. The goal in any particular application is to ensure that the serial correlation is not excessive. One diagnostic to check for the degree of serial correlation in the sampled draws is the autocorrelation time or inefficiency factor of each component $\theta_k$ of $\theta$ defined as
\[
\alpha_k = \left[ 1 + 2 \sum_{s=1}^{M} \left( 1 - \frac{s}{M} \right) \rho_{ks} \right],
\]

where \( \rho_{ks} \) is the sample autocorrelation at lag \( s \) from the \( M \) sampled draws \( \theta_{k}^{(r_0+1)}, \ldots, \theta_{k}^{(r_0+M)} \). One can interpret this quantity in terms of the \textit{effective sample size}, or ESS, defined for the \( k \)th component of \( \theta \) as

\[
\text{ESS}_k = \frac{M}{\tilde{a}_k}.
\]

With independent sampling the autocorrelation times are theoretically equal to 1, and the effective sample size is \( M \). When the inefficiency factors are high, the effective sample size is much smaller than \( M \).

\subsection*{2.1 Choice of proposal density}

One family of candidate-generating densities is given by \( q(\theta', \theta | y) = q(\theta' - \theta) \). The candidate \( \theta' \) is thus drawn according to the process \( \theta' = \theta + z \), where \( z \) follows the distribution \( q \), and is called the \textit{random walk M–H chain}. The random walk M–H chain is quite popular in applications. One has to be careful in setting the variance of \( z \) because if it is too large the chain may remain stuck at a particular value for many iterations, while if it is too small the chain will tend to make small moves and move inefficiently through the support of the target distribution.

Another possibility is to let \( q(\theta, \theta' | y) = q(\theta' | y) \), an \textit{independence M–H chain} in the terminology of Tierney (1994). One way to implement such chains is by tailoring the proposal density to the target at the mode by a multi-variate normal or multivariate-t distribution with location given by the mode of the target and the dispersion given by inverse of the Hessian evaluated at the mode (Chib and Greenberg, 1994; 1995).

Yet another way to generate proposal values is through a Markov chain version of the accept–reject method (Tierney, 1994; Chib and Greenberg, 1995). To explain this method, suppose \( c > 0 \) is a known constant and \( h(\theta) \) a source density. Let \( C = \{ \theta : \pi(\theta | y) \leq ch(\theta) \} \) denote the set of value for which \( ch(\theta) \) dominates the target density. Given \( \theta^{(j-1)} = \theta \) the next value \( \theta^{(j)} \) is obtained as follows. First, a candidate value \( \theta' \) is obtained, independent of the current value \( \theta \), by applying the accept–reject algorithm with \( ch(\cdot) \) as the ‘pseudo-dominating’ density. The candidates \( \theta' \) that are produced under this scheme have density

\[
q(\theta' | y) \propto \min \left\{ \frac{\pi(\theta' | y)}{c h(\theta')}, 1 \right\}.
\]

Then, the M–H probability of move is given by

\[
\alpha(\theta, \theta' | y) = \begin{cases} 
1 & \text{if } \theta \in C \\
1 / w(\theta) & \text{if } \theta \not\in C, \theta' \in C \\
\min \left\{ w(\theta') / w(\theta), 1 \right\} & \text{if } \theta \not\in C, \theta' \not\in C 
\end{cases}
\]

where \( w(\theta) = c^{-1} \frac{\pi(\theta | y)}{h(\theta)} \).

\subsection*{2.2 Example}

To illustrate the M–H algorithm, consider the binary response data in Table 1, on the occurrence or non-occurrence of infection following birth by Caesarean section. The response variable \( y \) is 1 if the Caesarean birth resulted in an infection, and zero if not. There are three covariates: \( x_1 \), an indicator of whether the caesarean was non-planned; \( x_2 \), an indicator of
whether risk factors were present at the time of birth; and \( x_3 \), an indicator of whether antibiotics were given as a prophylaxis. The data in the table contains information from 251 births. Under the column of the response, an entry such as 11/87 means that there were 98 deliveries with covariates \((1, 1, 1)\) of whom 11 developed an infection and 87 did not. Suppose that the probability of infection for the \(i\)th birth \((i \leq 251)\) is

\[
\Pr(y_i = 1 | x_i, \beta) = \Phi(x'_i \beta),
\]

(7)

where \( x_i = (1, x_{i1}, x_{i2}, x_{i3})' \) is the covariate vector, \( \beta = (\beta_0, \beta_1, \beta_2, \beta_3) \) is the vector of unknown coefficients, \( \Phi \) is the cdf of the standard normal random variable and \( I_4 \) is the four-dimensional identity matrix. The target posterior density, under the assumption that the outcomes \( Y = (y_1, y_2, \ldots, y_{251}) \) are conditionally independent, is

\[
\pi(\beta | y) \propto \pi(\beta) \prod_{i=1}^{251} \Phi(x'_i \beta)^{y_i} \{1 - \Phi(x'_i \beta)\}^{1 - y_i}
\]

where \( \pi(\beta) \) is the density of the \( N(0, 10I_4) \) distribution.

To define the Chib and Greenberg (1994) tailored proposal density, let

\[
\tilde{\beta} = (-1.093022, 0.607543, 1.197543, -1.904739)'
\]
be the maximum likelihood estimate and let

\[
V = \begin{pmatrix}

0.062292 & -0.016803 \\
0.080788
\end{pmatrix}
\]

be the symmetric matrix obtained by inverting the negative of the Hessian matrix (the matrix of second derivatives) of the log-likelihood function evaluated at \( \hat{\beta} \). To generate proposal values, we use a multivariate-t density with 15 degrees of freedom, location given by \( \hat{\beta} \) and dispersion given by \( V \). The M–H algorithm is run for 5,000 iterations beyond a burn-in of 100 iterations. The prior–posterior summary is reported in Table 2. It contains the first two moments (the mean and the standard deviation) of the prior and posterior and the 2.5th (lower) and 97.5th (upper) percentiles of the marginal densities of \( \beta \).

In addition, we plot in Figure 1 the four marginal posterior densities. These are derived by smoothing the histogram of the simulated values with a Gaussian kernel. In the same plot we also report the autocorrelation functions (correlation against lag) for each of the sampled parameter values. The serial correlations decline quickly to zero indicating that the algorithm is mixing well.

Figure 1
Caesarean data with tailored M–H algorithm: marginal posterior densities (top panel) and autocorrelation plot (bottom panel)
2.3 Multiple block M–H algorithm

When the dimension of $\theta$ is large it is often necessary to divide the parameters into smaller groups or blocks and then to sample the blocks in turn. For simplicity suppose that two blocks are adequate and that $\theta$ is written as $\langle \theta_1, \theta_2 \rangle$, with $\theta_k \in \Omega_k \subseteq \mathbb{R}^{d_k}$. To sample these blocks let

$$q_1(\theta_1, \theta_1' | y, \theta_2); q_2(\theta_2, \theta_2' | y, \theta_1),$$

denote the two proposal densities, one for each block $\theta_k$, where the proposal density $q_k$ may depend on the current value of the remaining block. Also, define

$$\alpha(\theta_1, \theta_1' | y, \theta_2) = \min \left\{ \frac{\pi(\theta_1', \theta_2 | y) q_1(\theta_1', \theta_1 | y, \theta_2)}{\pi(\theta_1, \theta_2 | y) q_1(\theta_1, \theta_1' | y, \theta_2)}, 1 \right\},$$

and

$$\alpha(\theta_2, \theta_2' | y, \theta_1) = \min \left\{ \frac{\pi(\theta_1, \theta_2' | y) q_2(\theta_1, \theta_2 | y, \theta_1)}{\pi(\theta_1, \theta_2 | y) q_2(\theta_1, \theta_2' | y, \theta_1)}, 1 \right\},$$

as the probability of move for block $\theta_k$ conditioned on the other block. Then, in what may be called the multiple-block M–H algorithm, one updates each block using an M–H step with the above probability of move, given the most current value of the other block. The method can be extended to several blocks in the same way.

Remark 5: An important special case arises if each proposal density is the full conditional density of that block. Specifically, if we set

$$q_1(\theta_1, \theta_1' | y, \theta_2) \propto \pi(\theta_1', \theta_2 | y), \quad q_1(\theta_1', \theta_1 | y, \theta_2) \propto \pi(\theta_1, \theta_2 | y),$$

and

$$q_2(\theta_2, \theta_2' | y, \theta_1) \propto \pi(\theta_1, \theta_2' | y), \quad q_2(\theta_2', \theta_2 | y, \theta_1) \propto \pi(\theta_1, \theta_2 | y),$$

then an interesting simplification occurs. The probability of move (for the first block) becomes
and similarly for the second block, implying that, if proposal values are drawn from their full conditional densities, then the proposal values are accepted with probability one. This special case is called the Gibbs sampling algorithm.

3 The Gibbs sampling algorithm

The Gibbs sampling was introduced by Geman and Geman (1984) in the context of image processing and then discussed in the context of missing data problems by Tanner and Wong (1987). It was brought into prominence by Gelfand and Smith (1990) who demonstrated its use in a range of Bayesian problems.

3.1 The algorithm

Suppose that the parameters are grouped into two \( p \) blocks \( \{\theta_1, \theta_2, \ldots, \theta_p\} \) with the associated set of full conditional distributions

\[
\pi(\theta_1, \theta_2 | y, \theta_3) - \min \left( 1, \frac{\pi(\theta_1', \theta_2' | y) \pi(\theta_1', \theta_3 | y)}{\pi(\theta_1, \theta_2 | y) \pi(\theta_1', \theta_3 | y)} \right) = 1,
\]

where each full conditional distribution is proportional to \( \pi(\theta_1, \theta_2, \ldots, \theta_p | y) \). Then, one cycle of the Gibbs sampling algorithm is completed by simulating \( \{\theta_k\}_{k=1}^p \) from these distributions, recursively refreshing the conditioning variables.

3.2 Sufficient conditions for convergence

Under rather general conditions, the Markov chain generated by the Gibbs sampling algorithm converges to the target density as the number of iterations become large. Formally, if we let \( p_G(\theta, \theta' | y) \) represent the transition density of the Gibbs algorithm and let \( p_G^{(M)}(\theta_0, \theta | y) \) be the density of the draw \( \theta' \) after \( M \) iterations given the starting value \( \theta_0 \), then

\[
\| p_G^{(M)}(\theta(0), \theta' | y) - \pi(\theta' | y) \| \to 0, \quad \text{as} \quad M \to \infty.
\]

Roberts and Smith (1994) (see also Chan, 1993) have shown that this convergence occurs under the following weak conditions: (i) \( \pi(\theta | y) > 0 \) implies there exists an open neighbourhood \( N_0 \) containing \( \theta \) and \( \varepsilon > 0 \) such that, for all \( \theta' \in N_\varepsilon \), \( \pi(\theta' | y) > \varepsilon > 0 \); (ii) \( \int \pi(\theta | y) d\theta_k \) is locally bounded for all \( k \), where \( \theta_k \) is the \( k \)th block of parameters; and (iii) the support of \( \theta \) is arc connected.

4 MCMC sampling with latent variables
MCMC sampling can involve not just parameters but also latent variables. This idea was called data augmentation by Tanner and Wong (1987) in the context of missing data problems. To fix notations, suppose that \( z \) denotes a vector of latent variables and let the modified target distribution be \( \pi(\theta, z | y) \). If the latent variables are tactically introduced, the conditional distribution of \( \theta \) (or sub-components of \( \theta \)) given \( z \) may be easy to derive. Then, a multiple-block M–H simulation is conducted with the blocks \( \theta \) and \( z \) leading to the sample

\[
\left\{ \theta^{(r_0 + 1)}, z^{(r_0 + 1)} \right\}, \ldots, \left\{ \theta^{(r_0 + M)}, z^{(r_0 + M)} \right\} \sim \pi(\theta, z | y),
\]

where the draws on \( \theta \), ignoring those on the latent data, are from \( \pi(\theta | y) \), as required.

To demonstrate this technique in action, consider the probit regression example discussed in Section 2.2. Albert and Chib (1993) introduced a technique for this and related models that capitalizes on the simplifications afforded by introducing latent data into the sampling. The Albert–Chib method has found wide use and has made possible the routine analysis of models for categorical responses. To begin, let

\[
z \mid \theta \sim N(x_i^\prime \theta, 1),
\]

\[
y_i = I[z_i > 0], \quad i \leq n,
\]

\[
\theta \sim N_{\chi}(\theta_0, E_0).
\]

This specification is equivalent to the probit model since \( \Pr(y_i = 1 \mid x_i, \theta) = \Pr(z_i > 0 \mid x_i, \theta) = \Phi(x_i^\prime \theta) \). Now the MCMC sampling is based on the full conditional distributions

\[
\theta | y, \{z_i\}; \quad \{z_i\} | y, \theta,
\]

which are both tractable. In particular, the distribution of \( \theta \) conditioned on the latent data becomes independent of the observed data and has the same form as in the Gaussian linear regression model with the response data given by \( \{z_i\} \) and is multivariate normal with mean \( \hat{\theta} = B (B_0^{-1} \hat{\theta}_0 + \sum_{i=1}^{n} x_i z_i) \) and variance matrix \( B = (B_0^{-1} + \sum_{i=1}^{n} x_i x_i^\prime)^{-1} \). Next, the distribution of the latent data conditioned on the data and the parameters factor into a set of \( n \) independent distributions with each depending on the data through \( y_i \).
\[(z_i | y_i, \beta) \overset{d}{=} \prod_{i=1}^{n} z_i | y_i, \beta,\]

where the distribution \(z_i | y_i, \beta\) is the normal distribution \(z_i | \beta\) truncated by the knowledge of \(y_i\); if \(y_i = 0\), then \(z_i \leq 0\) and if \(y_i = 1\), then \(z_i > 0\). Thus, one samples \(z_i\) from \(\mathcal{N}(-\infty, 0)(x_i | \beta, 1)\) if \(y_i = 0\) and from \(\mathcal{N}(0, \infty)(x_i | \beta, 1)\) if \(y_i = 1\), where \(\mathcal{N}(\mu, \sigma^2)\) denotes the \(N(\mu, \sigma^2)\) distribution truncated to the region \((a, b)\).

We apply this method to the example considered in Section 2.2 above and report the results in Figure 2. We see the close agreement between the two sets of results.

Figure 2
Caesarean data with Albert–Chib algorithm: marginal posterior densities (top panel) and autocorrelation plot (bottom panel)
5 Strategies for improving mixing

In practice, while implementing MCMC methods it is important to construct samplers that mix well, where mixing is measured by the autocorrelation time, because such samplers can be expected to converge more quickly to the invariant distribution.

5.1 Choice of blocking

As a general rule, sets of parameters that are highly correlated should be treated as one block when applying the multiple-block M–H algorithm. Otherwise, it would be difficult to develop proposal densities that lead to large moves through the support of the target distribution.

Blocks can be combined by the method of composition. For example, suppose that \( \theta_1, \theta_2 \) and \( \theta_3 \) denote three blocks and that the distribution \( \theta_1 | Y, \theta_3 \) is tractable (that is, can be sampled directly). Then, the blocks \( (\theta_1, \theta_2) \) can be collapsed by first sampling \( \theta_1 \) from \( \theta_1 | Y, \theta_2 \) followed by \( \theta_2 \) from \( \theta_2 | Y, \theta_1, \theta_3 \). This amounts to a two-block MCMC algorithm. In addition, if it is possible to sample \( (\theta_1, \theta_2) \) marginalized over \( \theta_3 \) then the number of blocks is reduced to one. Liu (1994) discusses the value of these strategies in the context of a three-block Gibbs MCMC chain. Roberts and Sahu (1997) provide further discussion of the role of blocking in the context of Gibbs Markov chains used to sample multivariate normal target distributions.

5.2 Tuning the proposal density

The proposal density in an M–H algorithm has an important bearing on the mixing of the MCMC chain. Chib and Greenberg (1994; 1995), Tierney (1994), Tierney and Mira (1999) and Liu (2001) discuss various possibilities for formulating proposal density that can be helpful in a variety of problems.

6 Prediction and model choice

In some settings, for example in models for time series data, an important goal is prediction. In the Bayesian context, a future observation \( y_f \) is predicted through the (predictive) density defined as

\[
    f(\cdot | y) = f(\cdot | y, \theta) \pi(\theta | y) d\theta,
\]

where \( f(\cdot | y, \mathcal{M}, \theta) \) is the conditional density of \( y_f \) given \( (Y, \theta) \). In general, the predictive density is not available in closed form. It can be shown, however, that, if one simulates
for each sampled draw \( \theta^{(j)} \) from the MCMC simulation, then the collection of simulated values \( \{ y^{(1)}, \ldots, y^{(M)} \} \) is a sample from \( f(y | \theta) \). This simulated sample can be summarized in the usual way.

MCMC methods have also been widely applied to the problem of the model choice. Suppose that there are \( K \) possible models \( \mathcal{M}_1, \ldots, \mathcal{M}_K \) for the observed data defined by the sampling densities \( \{ f(y | \theta, \mathcal{M}_k) \} \) and proper prior densities \( \{ p(\theta | \mathcal{M}_k) \} \) and the objective is to find the evidence in the data for the different models. In the Bayesian approach this question is answered by placing prior probabilities \( \Pr(\mathcal{M}_k) \) on each of the \( K \) models and using the Bayes calculus to find the posterior probabilities \( \{ \Pr(\mathcal{M}_1 | y), \ldots, \Pr(\mathcal{M}_K | y) \} \) conditioned on the data but marginalized over the unknowns \( \theta \). Specifically, the posterior probability of \( \mathcal{M}_k \) is given by the expression

\[
\Pr(\mathcal{M}_k | y) = \frac{\Pr(\mathcal{M}_k) m(y | \mathcal{M}_k)}{\sum_{j=1}^{K} \Pr(\mathcal{M}_j) m(y | \mathcal{M}_j)} \propto \Pr(\mathcal{M}_k) m(y | \mathcal{M}_k) \quad (k \leq K)
\]

where \( m(y | \mathcal{M}_k) \) is the marginal likelihood of \( \mathcal{M}_k \).

A problem in estimating the marginal likelihood is that it is an integral of the sampling density over the prior distribution of \( \theta \). Thus, MCMC methods, which deliver sample values from the posterior density, cannot be used to directly average the sampling density. One method for dealing with this difficulty is due to Chib (1995). The starting point is the expression

\[
m(y | \mathcal{M}_k) = \frac{f(y | \theta, \mathcal{M}_k) p(\theta | \mathcal{M}_k)}{\pi(\theta | y, \mathcal{M}_k)}
\]

which is an identity in \( \theta \). From here an estimate of the marginal likelihood on the log-scale is given by

\[
\log \hat{m}(y | \mathcal{M}_k) = \log f(y | \theta^*_k, \mathcal{M}_k) + \log p(\theta^*_k | \mathcal{M}_k) - \log \hat{\pi}(\theta^*_k | y, \mathcal{M}_k)
\]

where \( \theta^*_k \) denotes an arbitrarily chosen point and \( \hat{\pi}(\theta^*_k | y, \mathcal{M}_k) \) is the estimate of the posterior density at that single point. To estimate the posterior ordinate one utilizes the Gibbs output in conjunction with a decomposition of the ordinate into marginal and conditional components. Chib and Jeliazkov (2001) extend this approach for output produced by the M-H algorithm while Basu and Chib (2003) show how the method can be applied in semiparametric models.

In some cases one is interested in a large number of candidate models, each with parameters \( \theta_k \). In such cases one can get information about the relative support for the contending models from a model space-parameter space MCMC algorithm. In these algorithms, the models are represented by a categorical variable \( \mathcal{M} \) which is then sampled along with the parameters of each model. The posterior distribution of \( \mathcal{M} \) is computed as the frequency of times each model is visited. Methods for doing this have been proposed by Carlin and Chib (1995) and Green (1995). Both methods are closely related as shown by Dellaportas, Forster and Ntzoufras (2002) and Godsill (2001). Related methods for the problem of variable selection have also been developed starting with George and McCulloch (1993).

Markov equilibria in macroeconomics

Dirk Krueger and Felix Kubler
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We review the recent literature in macroeconomics that analyses Markov equilibria in dynamic general equilibrium model. After defining the Markov equilibrium concept we first summarize what is known about the existence and uniqueness of such equilibria in models where sequential equilibria can be obtained by solving a suitable social planner problem. We then discuss the existence problems of Markov equilibria in models where equivalence of equilibrium allocations and solutions to social planner problems cannot be established and review techniques the literature has developed to deal with the existence problem, as well as recent applications of these techniques in macroeconomics.

Article

We say that a dynamic economy has a Markovian structure (or is Markovian, for short) if the stochastic processes that specify the fundamentals of the economy (such as endowments, preferences and technologies) are Markov processes. Note that deterministic economies are special cases in which the stochastic processes for the fundamentals have degenerate distributions. In many applications attention is restricted to first-order Markov processes in which the probability distributions over fundamentals today are functions exclusively of their values yesterday.
In dynamic economies sequential equilibria are sequences of functions mapping histories of realizations of the stochastic process of the fundamentals into allocations and prices such that all agents in the economy maximize their objectives, given prices, and all markets clear. Under fairly mild conditions (that is, convexity and continuity assumptions on the primitives) such equilibria exist. However, in order to characterize and compute equilibria it is often useful to look for equilibria of a different form. Recursive Markov equilibria can be characterized by a state space, a policy function and a transition function. The policy function maps the state today into current endogenous choices and prices, and the transition function maps the state today into a probability distribution over states tomorrow (see, for example, the definition in Ljungqvist and Sargent's 2000 textbook). In most of this survey we will use the terms ‘Markov equilibria’ and ‘recursive Markov equilibria’ interchangeably; however, below we also consider Markov equilibria which are not recursive and refer to these as ‘generalized Markov equilibria’. This characterization leaves open, of course, what the appropriate state variables are that constitute the state space.

Most simply, the state space would consist of the set of possible exogenous shocks governing endowments, preferences and technologies. But, other than in exceptional cases (see, for example, Lucas's 1978 asset pricing application where asset prices are solely functions of the underlying shocks to technology), such a strongly stationary Markov equilibrium does not exist.

In addition to the exogenous shocks, endogenous variables have to be included in the state space to assure existence of a Markov equilibrium. We define as the minimal state space the space of all exogenous shocks and endogenous variables that are payoff-relevant today, in that they affect current production or consumption sets or preferences (see Maskin and Tirole, 2001).

We call Markov equilibria with this minimal state space ‘simple Markov equilibria’. In the remainder of this article we want to discuss what we know about the existence and uniqueness of such Markov equilibria, both in general and for important specific examples. As it turns out, when equilibria are Pareto efficient, and thus equilibrium allocation can be determined by solving a suitable social planner problem, simple Markov equilibria can be shown to exist under fairly mild conditions. We therefore discuss this case first. On the other hand, when equilibria are not Pareto efficient – for example, when markets are incomplete or economic agents behave strategically – forward-looking variables often have to be included for a Markov equilibrium to exist; therefore, simple Markov equilibria in the sense defined above do not exist in general. We discuss this case in Section 2.

1 Markov equilibria in economies where equilibria are Pareto optimal

In this section we discuss the existence and uniqueness of simple Markov equilibria in economies whose sequential market equilibrium allocations can be determined as solutions to a suitable social planner problem. In these economies the problem of proving the existence of a Markov equilibrium reduces to showing that the solution of the social planner can be written as a time-invariant optimal policy function of the minimal set of state variables, as defined above.

This is commonly done by reformulating the optimization problem of the social planner as a functional equation and showing that the optimal Markov policy function generates a sequential allocation which solves the original social planner problem; this is what Bellman (1957) called the principle of optimality. This principle can be established under weak conditions (see Stokey, Lucas and Prescott, 1989).
Equipped with this result, the existence of a Markov equilibrium then follows from the existence of a solution to the functional equation associated with the social planner problem. If the functional equation can be shown to be a contraction mapping (sufficient conditions for this were provided by Blackwell, 1965), then it follows that there exists a unique value function solving the functional equation and an optimal policy correspondence. In addition, the contraction mapping theorem also gives an iterative procedure to find the solution to the functional equation from any starting guess, which is helpful for numerical work.

Under weaker conditions other fixed-point theorems may be employed to argue at least for the existence (if not uniqueness) of a solution to the functional equation, with associated optimal Markov policy correspondence. In order to establish that the policy correspondence is actually a function (and thus the Markov equilibrium is unique), in general strict concavity of the return function needs to be assumed. Stokey, Lucas and Prescott (1989) provide a summary of the main results in the general theory of dynamic programming.

This technique of analysing and computing dynamic equilibria in Pareto optimal economies is now widely used in macroeconomics. Its first application can be found in Lucas and Prescott (1971) in their study of optimal investment behaviour under uncertainty. Lucas (1978) used recursive techniques to study asset prices in an endowment economy and showed that the Markov equilibrium has a particularly simple form. Kydland and Prescott (1982) showed how powerful these techniques are for a quantitative study of the business cycle implications of the neoclassical growth model with technology shocks to production. The volume by Cooley (1995) provides a comprehensive overview over this line of research.

2 Generalized Markov equilibria

In models where the first welfare theorem is not applicable (for example, models with incomplete financial markets or with distorting taxes), in models where there are infinitely many agents (such as overlapping generations models) or in models with strategic interaction the existence of simple Markov equilibria (that is, Markov equilibria with minimal state space) cannot be guaranteed. See Santos, 2002; Krebs, 2004; Kubler and Schmedders, 2002; and Kubler and Polemarchakis, 2004, for simple counterexamples. An important exception is Bewley-style models with incomplete markets where simple recursive Markov equilibria exist; see, for example, Krebs, 2006. The functional equations characterizing equilibrium have no contraction properties, and more general fixed-point theorems than the contraction mapping theorem, such as Schauder's fixed-point theorem, cannot be applied because it is difficult to guarantee compactness of the space of admissible functions. Coleman (1991) is an important example where existence can be shown. However, his results rely on monotonicity conditions on the equilibrium dynamics which are not satisfied in general models.

In the applied literature a solution to this problem was suggested early on. For example Kydland and Prescott (1980) analyse a Ramsey dynamic optimal taxation problem. To make the problem recursive they add as a state variable last period's marginal utility. On the theoretical side Duffie et al. (1994) were the first to rigorously analyse situations where recursive equilibria may fail to exist in general equilibrium models. Kubler and Schmedders (2003) and Miao and Santos (2005) refine their approach and make it applicable for computations. Miao and Santos (2005),
also give a clear explanation of how this approach relates to the work by Abreu, Pearce and Stacchetti (1990). We now present their basic idea.

Consider a Markovian economy where a date-event (or node) can be associated with a finite history of shocks, $s^t = (s_0, ..., s_t)$. The shocks follow a Markov chain with support $S = \{1, ..., 5\}$. Denote by $z(s^t)$ the vector of all endogenous variables at node $s^t$. Typically this would include the vector of household asset holdings across individuals and the capital stock at the beginning of the period, but also prices and endogenous choices at note $s^t$, as well as shadow variables such as Lagrange multipliers. A competitive equilibrium is a process of endogenous variables $\{z(s^t)\}$ with $z(s^t) \in \mathcal{Z} \subseteq \mathbb{R}^M$, which solve the optimization problems of all agents in the economy, and clear markets. The set $\mathcal{Z}$ denotes the set of all possible values of the endogenous variables.

We focus on dynamic economic models where an equilibrium can be characterized by a set of equations relating current-period exogenous and endogenous variables to endogenous and exogenous variables next period. It is straightforward to incorporate inequality constraints into this framework. For expositional purposes we focus on equations. Examples of such equations are the Euler equations of individual households, first order conditions of firms, as well as market-clearing conditions for all markets. We assume that such a set of equations characterizing equilibrium is given and denote it by

$$h(\hat{s}, \hat{z}, z_1, ..., z_5) = 0.$$

The arguments $(\hat{s}, \hat{z})$ denote the exogenous state variables and endogenous variables for the current period. Note that the endogenous variables might contain variables which were determined in the previous period, such as the capital stock and individuals’ assets. The variables $(z_s)_{s=1}^S$ denote endogenous variables in the subsequent period, in states $s = 1, ..., 5$, respectively. We refer to $h(\cdot) = 0$ as the set of ‘equilibrium equations’.

As explained above, to analyse Markov equilibria one needs to specify an appropriate state space. We assume that the equilibrium set $\mathcal{Z}$ can be written as the product $\mathcal{Y} \times \hat{\mathcal{Z}}$, where $\mathcal{Y}$ denotes the set into which the endogenous state variables fall. In the neoclassical growth model, $\mathcal{Y}$ would consist of the set of possible values of the capital stock; in models with heterogeneous agents one would need to add the set of possible wealth distributions across agents. Unfortunately, as the references cited above show, a recursive Markov equilibrium with this state space may not exist. We therefore require a more general notion of Markov equilibrium for these types of economies.

A generalized Markov equilibrium consists of a (non-empty valued) ‘policy correspondence’, $P$, that maps the state today into possible endogenous variables today, and a ‘transition function’, $F$, that maps the state and endogenous variables today into endogenous variables next period. Formally, the maps

$$P: S \times \mathcal{Y} \Rightarrow \hat{\mathcal{Z}} \quad \text{and} \quad F: \text{graph}(P) \rightarrow \mathcal{Z}^5$$

should satisfy that for all shocks and endogenous variables in the current period, \((\hat{s}, \hat{z}) \in \text{graph}(P)\), the transition function prescribes values next period that are consistent with the equilibrium equations, that is,

\[ h(\hat{s}, \hat{z}, F(\hat{s}, \hat{z})) = 0, \]

and lie in the policy correspondence, that is,

\[ (s, F(s, \hat{s})) \in \text{graph}(P) \text{ for all } s \in S. \]

It follows that a generalized Markov equilibrium is recursive, according to our earlier definition, if the associated policy correspondence is single valued. It is simple if the state space is the natural minimal state space.

It is easy to see that Markov equilibria are in fact competitive equilibria in the usual sense. Duffie et al. (1994) show that, under mild assumptions on the primitives of the model, generalized Markov equilibria exist whenever competitive equilibria exist. The basic idea of their approach is very similar to backward induction, using critically a natural monotonicity property of the inverse of the equilibrium equations. (See their original paper, Kubler and Schmedders (2003), or Miao and Santos (2005), for details.)

For practical purposes it is of course crucial that the chosen state space is relatively small and that the Markov equilibrium is recursive. In an asset pricing model with heterogeneous agents, Kubler and Schmedders choose the state space to consist of the beginning-of-period wealth distribution, but can show the existence only of a generalized Markov equilibrium. One cannot rule out the possibility that the equilibrium is not recursive; the same value of the state variables might occur with different values of the endogenous variables. The counter-examples to existence mentioned above show that this is precisely the problem. If for given initial conditions there exist multiple competitive equilibria, the one that realizes is pinned down by lagged variables. Without ruling out multiplicity of equilibria, it does not seem possible to prove the existence of recursive equilibria with the natural state space.

Miao and Santos (2005) enlarge the state space with the shadow values of investment of all agents and prove that with this larger state space a recursive Markov equilibrium exists. The basic insight of their approach is that one needs to add variables to the natural state space that uniquely select one out of several possible endogenous variables.

The main practical problem with the approach originated by Duffie et al. (1994) and refined by Miao and Santos (2005) is that it provides a method to construct all Markov equilibria. There might exist some recursive equilibria for the natural (minimal) state space, but this approach naturally solves for all other recursive Markov equilibria as well. Datta et al., 2005, provide ideas for solving for the one Markov
equilibrium with minimal state space. In many recent applications of recursive methods to macroeconomics the focus of researchers studying non-optimal economies is to find a recursive equilibrium with minimal state space. Notable examples in which even this natural state space is large are Rios-Rull (1996), Heaton and Lucas (1996) and Krusell and Smith (1998). They mark the boundary of economies that currently can be analysed with recursive techniques. In dynamic endowment economies with either informational frictions or limited enforceability of contracts, constrained-efficient (efficient, subject to the informational or enforcement constraints) consumption allocations usually display a high degree of dependence on past endowment shocks, even though the natural state space contains only the current endowment shock. Therefore, Markov equilibria with minimal state space do not exist. However, using ideas by Spear and Srivastava (1987) and Abreu, Pearce, and Stacchetti (1990), the papers by Atkeson and Lucas (1992) and Thomas and Worrall (1988) demonstrate that nevertheless the constrained social planner problem has a convenient recursive structure if one includes promised lifetime utility as a state variable into the recursive problem. This approach or its close alternative, namely, to introduce as an additional state variable Lagrange multipliers on the incentive or enforcement constraints (as in Marcet and Marimon, 1998), has seen many applications in macroeconomics, since it facilitates making a large class of dynamic models with informational or enforcement frictions recursive and hence tractable. Miao and Santos (2005) show how such problems with strategic interactions can be incorporated into the framework above. In optimal policy problems in which the government has no access to a commitment technology, a discussion has emerged about the desirability of a restriction to Markov policies with minimal state space. Such restrictions rule out reputation if one confines attention to smooth policies. See Phelan and Stacchetti (2001) and Klein and Rios-Rull (2003) for examples of the two opposing views on this issue. However, as Krusell and Smith (2003) argue, if one allows discontinuous policy functions reputation effects can be generated even with Markov policies. (While Krusell and Smith discuss optimal decision rules in a consumption–savings problem with quasi-geometric discounting, their results carry over to optimal policy problems without commitment on the part of the policymaker.)

Markov processes

Daniel W. Stroock
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In this article the theory of Markov processes is described as an evolution on the space of probability measures. Following a brief historical account of its origins in physics, a mathematical formulation of the theory is given. Emphasis has been placed on the ergodic properties of Markov processes, and their presence is checked in a simple example.

Keywords

Boltzmann, L.; Brownian motion; ergodic theory; Gibbs, G.; Markov processes; Markov property; Newton's equation; probability; statistical mechanics; Wiener process

Article

Unless one is clairvoyant, the only temporally evolving processes which are tractable are those whose future behaviour can be predicted on the basis of data which is available at the time when the prediction is being made. Of course, in general, the behaviour of even such an evolution will be impossible to predict. For example, if, in order to make a prediction, one has to know the detailed history of everything that has happened during the entire history of the entire universe, one's chance of making a prediction may be a practical, if not a theoretical, impossibility. For this reason, one tries to study evolutions mathematically with models in which most of the distant past can be ignored when one makes predictions about the future. In fact, many mathematical models of evolutions have the property that, for the purpose of predicting the future, the past becomes irrelevant as soon as one knows the present, in which case the evolution is said to be a 'Markov process', the topic at hand, after Andrei Andreyevich Markov (1856–1922).

The components of a Markov process are its state space $\mathcal{S}$ and its transition rule $T$. Mathematically, $\mathcal{S}$ is just some non-empty set, which in applications will encode all the possible states in which the evolving system can find itself, and $T : \mathcal{S} \to \mathcal{S}$ is a function from $\mathcal{S}$ into itself which gives the transition rule. More precisely, if now the system is in state $x$, it will be next in state $T(x)$, from which it will go to $T^2(x) = T(T(x))$, and so on. (Here we are thinking of time being discrete. Thus, 'next' means after one unit of time has passed.)

To give a sense of the sort of reasoning required to construct a Markov process, consider a (classical) physical particle whose motion is governed by Newton's equation $\ddot{\mathbf{r}} = m \mathbf{a}$ ("force equals mass times acceleration"). At least in theory, Newton's equation says that, on the assumption that one knows the mass of the particle and the force field $\mathbf{F}$ which acts on it, one can predict where the particle will be in the future as soon as one knows what its position and velocity are now. On the other hand, knowing only its present position is not sufficient by itself. Thus, even though one may care about nothing but its position, in order to produce a Markov process for a particle evolving according to Newton's equation it is necessary to adopt the attitude that the state of the particle consists of its position and velocity, not just its position alone. Of course, in that velocity is the derivative of position, the two are so inextricably intertwined that one might be tempted to concentrate on position on the grounds that one will be able to compute the velocity whenever necessary. However, this tack destroys the Markov property,
Markov processes: The New Palgrave Dictionary of Economics

naturally, there is no way of computing the velocity of a particle ‘now’ if all one knows is its position ‘now’. For this reason, physicists consider the state of a particle to be a composite of its position and velocity, and the resulting state space \( \mathbb{R}^6 = \mathbb{R}^3 \times \mathbb{R}^3 \) (three coordinates for position and three for velocity) they call the phase space of the particle.

The same point may be clearer in the following example. Suppose that one has an evolution on a state space \( \mathbb{S} \) which proceeds according to the rule that, if the present state is \( x_n \) and the preceding state was \( x_{n-1} \), then the next state will be

\[
x_{n+1} = T(x_{n-1}, x_n).
\]

This is not a Markov process. Nonetheless, it can be ‘Markovized’. Indeed, replace the original state space by \( \tilde{\mathbb{S}} = \mathbb{S} \times \mathbb{S} \), the set of ordered pairs \( (x, y) \) with \( x \) and \( y \) from \( \mathbb{S} \), and define

\[
\tilde{T}((x, y)) = (y, T(x, y)).
\]

It is then an easy matter to check that, if the original system was in state \( x_{n-1} \) at time \( -1 \) and state \( x_0 \) at time 0, then its state at time \( n \geq 1 \) will be \( x_n \), the second component of the pair \( (x_{n-1}, x_n) = \tilde{T}^n((x_1, x_0)) \).

The moral to be drawn from these examples is that the presence or absence of the Markov property is in the eye of the beholder. That is, a change of venue (the state space) can make the Markov property appear in circumstances where it was not originally apparent. In fact, by making the state space sufficiently large, any evolution can be forced to be Markov. On the other hand, the more complicated the state space, the less useful is the Markov property. Thus, in practice, what one seeks is the ‘simplest’ state space on which one’s evolution possesses the Markov property.

**Stochastic Markov processes**

Roughly speaking, Markov processes fall into one of two categories. Those in the first category are ‘deterministic’ in the sense that their state space is sufficiently detailed that the individual states give complete and unambiguous information. Both the examples given above are deterministic. The mathematical analysis of deterministic Markov processes has a proud history going back to Newton which includes major contributions by such luminaries as P. Chebyshev, A. Markov, A. Lyapounov, H. Poincaré, and J. Moser. The second category of Markov processes, and the one on which the rest of this article will concentrate, are ‘probabilistic’ or ‘stochastic’ Markov processes. To understand where and why these processes arise, consider the problem of describing the state of all the gas molecules in a room. Each litre of gas contains approximately Avogadro’s number, \( 6.02214199 \times 10^{23} \), of molecules. Thus, even a small room will contain something on the order of \( 10^{26} \) molecules. Moreover, because, by Newton’s laws of motion, the state of each individual molecule will lie in its individual phase space, the state of the entire system of molecules will have to specify the positions and velocities of all \( 10^{26} \) molecules. Stated mathematically, the state space of the system will be \( \mathbb{R}^{6 \times 10^{26}} \), on which any sort serious analysis is too daunting to contemplate.

When one is confronted with a problem which is intractable as presented, the time-honoured procedure of choice is to reformulate the problem in a way which makes it more tractable. In the case just described, the reformulation was made by G. W. Gibbs (1902) and L. Boltzmann (1896; 1898), the fathers of statistical mechanics. They abandoned any hope of saying exactly where all the molecules will be and reconciled themselves to settling for a description of the statistics of the molecules. That is, instead of asking exactly where all the molecules would be, they asked what would be the probability of finding a molecule in various regions of phase space. From this point of view, the state of the system will not be an element of \( \mathbb{R}^{6 \times 10^{26}} \) but of \( \mathbb{M}_1(\mathbb{R}^6) \), the space probability distributions on the individual phase space \( \mathbb{R}^6 \). Of course, Gibbs and Boltzmann’s reformulation only changes the problem, it does not solve it. Indeed, although Newton’s equation determines how the system of molecules evolves and therefore how their distribution will evolve, the use of Newton’s equation would remove the advantage which Boltzmann and Gibbs hoped to gain from their reformulation. Thus, they had to come up with an alternative way of describing the transition rule which governs the evolution of the distribution of the system as a Markov process on \( \mathbb{M}_1(\mathbb{R}^6) \). The description proposed by Boltzmann is given by the famous Boltzmann equation. Unfortunately, Boltzmann’s equation is itself so complicated that it is only recently that substantial progress has been made toward understanding it in any generality. On the other hand, Gibbs and Boltzmann’s idea of studying Markov processes on the space of probability distributions is seminal and has proved to be both ubiquitous and powerful.

The abstract setting for a stochastic Markov process starts with a non-empty set \( \mathbb{S} \), the deterministic state space, and the associated space \( \mathbb{M}_1(\mathbb{S}) \) of probability distributions on \( \mathbb{S} \). The easiest and most commonly studied stochastic Markov processes are those for which the transition rule \( T: \mathbb{M}_1(\mathbb{S}) \to \mathbb{M}_1(\mathbb{S}) \) is a linear (more correctly, an affine) function. To be definite, suppose \( \mathbb{S} \) is a finite set. Then \( \mathbb{M}_1(\mathbb{S}) \) is the set of all functions \( \mu \) on \( \mathbb{S} \) which assign each \( x \in \mathbb{S} \) a number \( \mu(\{x\}) \in [0, 1] \) (the
Markov processes: The New Palgrave Dictionary of Economics

The probability of \( \{ x \} \) under \( \mu \) in such a way that \( \sum_{x \in \mathbb{S}} \mu(\{x\}) = 1 \). (The use of \( \mu(\{x\}) \) instead of \( \mu(x) \) here is a little pedantic. However, one must remember that probabilities are assigned to events – that is, subsets of the sample space – and that \( \{ x \} \) is the event that ‘\( x \) occurred’. Clearly, if \( \mu \) and \( \nu \) are in \( \mathcal{M}_1(\mathbb{S}) \) and \( \theta \in [0, 1] \), then the convex combination \( \theta \mu + (1 - \theta) \nu \) is again an element of \( \mathcal{M}_1(\mathbb{S}) \). Sets with this property are said to be ‘affine’ (as distinguished from ‘linear’, which refers to sets which are closed under all linear, not just convex, combinations), and a function on an affine set is said to be affine if it commutes with convex combinations. Thus, for \( \mathcal{M}_1(\mathbb{S}) \), the transition rule \( T \) is affine if

\[
T(\theta \mu + (1 - \theta) \nu) = \theta T(\mu) + (1 - \theta) T(\nu).
\]

Because \( \mathbb{S} \) is finite, one can dissect such transition rules in the following way. First, for each \( \mathbf{x} \in \mathbb{S} \), let \( \delta_x \) denote the element of \( \mathcal{M}_1(\mathbb{S}) \) which assigns 1 to \( \{ x \} \) (and therefore 0 to \( \mathbb{S} \setminus \{ x \} \)). Next, set

\[
P(\mathbf{x}, \cdot) = T(\delta_x).
\]

That is, \( P(\mathbf{x}, \cdot) \) is the element of \( \mathcal{M}_1(\mathbb{S}) \) to which \( T(\delta_x) \) takes \( T(\delta_x)(\cdot) \). Because, for any \( \mathbf{u} \in \mathcal{M}_1(\mathbb{S}) \) which is not equal to \( \delta_x \), \( \mu(\{x\}) = \mu(\{x\} \delta_x + (1 - \mu(\{x\})) \mu^x \), where \( \mu^x \in \mathcal{M}_1(\mathbb{S}) \) is determined so that \( \mu^x(\{y\}) \) equals \( (1 - \mu(\{x\}))^{-1} \mu(\{y\}) \) or 0 depending on whether \( y \neq x \) or \( y = x \), the affine property of \( T \) means that

\[
T(\mu) = \mu(\{x\}) P(\mathbf{x}, \cdot) + (1 - \mu(\{x\})) T(\mu^x).
\]

Hence, after peeling off one \( x \) at a time, one concludes that

\[
T(\mu) = \sum_{\mathbf{x} \in \mathbb{S}} \mu(\{x\}) P(\mathbf{x}, \cdot)
\]

(1)

when \( T \) is affine.

**Probabilistic interpretation**

The representation of \( T \) given by (1) admits an intuitively pleasing probabilistic interpretation: namely, \( P(\mathbf{x}, \{y\}) \) can be thought of as the probability that the system will next be in the state \( y \) given that is now in state \( x \). With this interpretation in mind, probabilists call \( \mathbf{x} \in \mathbb{S} \rightarrow P(\mathbf{x}, \cdot) \in \mathcal{M}_1(\mathbb{S}) \) a transition probability on the state space \( \mathbb{S} \). The terminology here is confusing. From the point of view adopted earlier, one might, and should, have thought that \( \mathcal{M}_1(\mathbb{S}) \) is the state space. However, the probabilistic interpretation is most easily appreciated if one thinks of \( \mathbb{S} \) as the state space and \( \mathbf{x} \in \mathbb{S} \rightarrow (\mathbf{x}, \cdot) \in \mathcal{M}_1(\mathbb{S}) \) as a random transition rule. To complete this picture, probabilists introduce random variables to represent the random points in \( \mathbb{S} \) visited. More precisely, again assume that \( \mathbb{S} \) is finite, and suppose that \( \mu \in \mathcal{M}_1(\mathbb{S}) \) describes the initial distribution of the process under consideration. Then probabilists construct a sequence \( \{ X_n : n \geq 0 \} \) of random variables, called a Markov chain, in such a way that, for any \( n \geq 0 \),

\[
P(X_0 = x_0, \ldots, X_n = x_n) = \mu(\{x_0\}) P(x_0, \{x_1\}) \cdots P(x_{n-1}, \{x_n\}).
\]

In words, this says that the right-hand side above is the probability that the chain with initial distribution \( \mu \) starts at \( x_0 \) and then goes on to visit, successively, the points \( x_1 \) through \( x_n \). To see that the probabilistic interpretation is completely consistent in the deterministic case, observe that a deterministic Markov process can be formulated as a stochastic Markov process. That is, if \( T \) is the transition rule for the deterministic process, take \( P(\mathbf{x}, \cdot) = \delta_T(\mathbf{x}) \), and check that, with probability 1, the Markov chain with transition probability \( P(\mathbf{x}, \cdot) \) follows the same path as the deterministic one with transition rule \( T \). Equivalently, with probability 1, \( X_n = T^n(x_0) \) for all \( n \geq 1 \).

**Ergodic theory of Markov chains**

Continue in the setting of the preceding section. One of the phenomena predicted by Gibbs in connection with his and
Boltzmann's study of gases was that, no matter what the initial distribution of the gas, after a long time the gas should equilibrate in the sense that it will achieve a stationary distribution (that is, a distribution that does not change with time) which does not depend on how it was distributed initially. One's experience with the behaviour of gases makes this prediction entirely plausible: place an opened bottle of perfume in the corner of a room; wait an hour, and confirm that the perfume will have become more or less equi-distributed throughout the room. Be that as it may, the prediction, which goes by the name of Gibbs's 'ergodic hypothesis', has been mathematically verified in only one physically realistic model. Nonetheless, as will be explained next, ergodicity is relatively easy to verify for most stochastic Markov processes on a finite state space.

To develop some intuition for what ergodicity means and why it might hold for a stochastic Markov process on a finite state space, it is best to first know how to recognize when a \( \mu \in M_1(\mathcal{S}) \) is stationary. But, if \( \mu \) is stationary, then it is left unchanged as the system evolves, and, in terms of the transition probability, this means that

\[
\mu(\{y\}) = \sum_{x \in \mathcal{S}} \mu(\{x\})P(x, \{y\}) \text{ for all } y \in \mathcal{S}.
\]  

(2)

Now suppose that \( \mathcal{S} = \{1, 2\} \), and consider the problem of finding a solution to (2). That is, we want to find \( \mu \in M_1(\{1, 2\}) \) so that

\[
\mu(\{1\}) = \mu(\{1\})P(1, \{1\}) + \mu(\{2\})P(2, \{1\}) \mu(\{2\}) = \mu(\{1\})P(1, \{2\}) + \mu(\{2\})P(2, \{2\}).
\]  

(3)

At first sight, there appear to be too many conditions on \( \mu \): not only must it satisfy the two equations in (3), it also has to satisfy \( \mu(\{1\}) + \mu(\{2\}) = 1 \) as well as being non-negative. Even if one ignores the non-negativity, one suspects that three linear equations are just too many for a pair of numbers to satisfy. On the other hand, after a little manipulation, one sees (remember that \( P(1, \cdot) \) and \( P(2, \cdot) \) are probability distributions) that both the equations in (3) are equivalent to \( \mu(\{1\})P(1, \{2\}) = \mu(\{2\})P(2, \{1\}) \). Hence the two equations in (3) are equivalent, and so there are really only two equations to be satisfied: \( \mu(\{1\})P(1, \{2\}) = \mu(\{2\})P(2, \{1\}) \) and \( \mu(\{1\}) + \mu(\{2\}) = 1 \). There are two cases to be considered. The first case is when the chain never moves, or, equivalently, \( P(1, \{2\}) = 0 = P(2, \{1\}) \). In this case there are two solutions, namely, \( \delta_1 \) and \( \delta_2 \), which is exactly what one should expect for a chain which never moves. In the second case, the one corresponding to a chain which can move, either \( P(1, \{2\}) > 0 \) or \( P(2, \{1\}) > 0 \). In both these cases, one can easily check that the one and only solution to (3) is given by

\[
\mu(\{1\}) = \frac{P(2, \{1\})}{P(1, \{2\}) + P(2, \{1\})} \text{ and } \mu(\{2\}) = \frac{P(1, \{2\})}{P(1, \{2\}) + P(2, \{1\})}.
\]

Continuing in the setting of the preceding, we want to examine when Gibbs's ergodic hypothesis holds. Obviously, at the very least, ergodicity requires that there be only one stationary \( \mu \), otherwise we could start the chain with one of them as initial distribution, in which case it would never get to the other. Thus, we need to assume that \( P(1, \{2\}) + P(2, \{1\}) > 0 \), and, to simplify matters, we will assume more, namely, that \( m \equiv m_1 + m_2 > 0 \), where \( m_1 = \min \{P(1, \{1\}), P(2, \{1\})\} \) and \( m_2 = \min \{P(1, \{2\}), P(2, \{2\})\} \), and, under this assumption we (following Doeblin) will show that, for any \( \nu \in M_1(\{1, 2\}) \)
\[
\|\nu P - \mu\| \leq (1 - m)\|\nu - \mu\|
\]

(4)

where \(\nu P(\{y\}) = \sum_{x=1}^{2} \nu(\{x\})P(x, \{y\})\)

and, for any pair \(\nu_1, \nu_2 \in M_1(\{1, 2\}), \|\nu_2 - \nu_1\| = \sum_{x=1}^{2}\|\nu_2(\{x\}) - \nu_1(\{x\})\|\). To prove (4), first observe that, because \(\mu\) is stationary, \(\nu = \nu P\), and therefore, since \[\sum_{x=1}^{2}(\nu(\{x\}) - \mu(\{x\})) = 1 - 1 = 0,\]

\[
\nu P(\{y\}) - \mu(\{y\}) = \sum_{x=1}^{2}(\nu(\{x\}) - \mu(\{x\}))P(x, \{y\}) = \sum_{x=1}^{2}(\nu(\{x\}) - \mu(\{x\}))(P(x, \{y\}) - m_y).
\]

Next, take the absolute value of both sides, remember that the absolute value of a sum of numbers is dominated by the sum of their absolute values, and arrive at

\[
\|\nu P - \mu\| \leq \sum_{y=1}^{2}\left(\sum_{x=1}^{2}|\nu(\{x\}) - \mu(\{x\})|(P(x, \{y\}) - m_y)\right) = \sum_{x=1}^{2}\left(\sum_{y=1}^{2}|\nu(\{x\}) - \mu(\{x\})|(P(x, \{y\}) - m_y)\right) = (1 - m)\|\nu - \mu\|
\]

Given (4), it becomes an easy matter to check ergodicity. Indeed, \(\nu P\) is the distribution of the chain at time 1 when it is started with initial distribution \(\nu\). Similarly, its distribution at time 2 will be \(\nu P^2 = (\nu P)P\), and so

\[
\|\nu P^2 - \mu\| \leq (1 - m)\|\nu P - \mu\| \leq (1 - m)^2\|\nu - \mu\|.
\]

Proceeding by induction, one sees that distribution \(\nu P^n = (\nu P^{n-1})P\) at time \(n\) will satisfy \[\|\nu P^n - \mu\| \leq (1 - m)^n\|\nu - \mu\|\] Hence, because \(m > 0\), this implies that \(\|\nu P^n - \nu\|\) tends to 0 exponentially fast, which means that the chain possesses an extremely strong form of ergodicity.

Other directions

In this article we have discussed only the most elementary examples of Markov processes. In particular, in order to avoid technical difficulties, all our considerations have been about processes for which the time parameter is discrete. As soon as one moves into the realm of processes with a continuous time parameter, the theory becomes much more technically involved. However, the price which one has to pay in technicalities is amply rewarded by the richness of the continuous time theory. To wit, Brownian motion (also known as the Wiener process) is a continuous parameter Markov process which makes an appearance in a surprising, and ever growing, number of places: harmonic analysis in pure mathematics, filtering and separation of signal from noise in electrical engineering, the kinetic theory of gases in physics, price fluctuations on the stock market in economics, and so on. Thus, for the sake of the curious, the bibliography below gives a very brief and enormously inadequate list of places where one can learn more about Markov processes.

Markowitz, Harry Max (born 1927)

Donald D. Hester
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Harry M. Markowitz shared the 1990 Nobel Memorial Prize in Economics with Merton Miller and William Sharpe for their contributions to financial economics. He is principally known for his Cowles Foundation monograph, *Portfolio Selection: Efficient Diversification of Investments*, in which he developed and made accessible to general readers the concept of an efficient portfolio, that is, a collection of assets that has a maximum rate of return for an arbitrary rate of return variance. The monograph provided a rigorous justification for portfolio diversification. He has also developed important applied mathematical tools for working with sparse matrices and performing simulations.

Keywords

American Finance Association; capital asset pricing model (CAPM); Cholesky factorizations; customary wealth; expected utility hypothesis; linear programming; Markowitz, H.; portfolio selection; quadratic utility function; risk

Article

Harry M. Markowitz is a Nobel laureate who shared a 1990 prize with Merton Miller and William Sharpe for their contributions to financial economics. A native of Chicago, he received undergraduate and graduate degrees from the University of Chicago, culminating in a Ph.D. in 1954. His article on portfolio selection (1952a), drawn from his dissertation, was a path-breaking contribution that would be fully developed in his 1959 Cowles Foundation monograph, *Portfolio Selection: Efficient Diversification of Investments*. The monograph provided a strong case for receiving the Nobel Memorial Prize.

Markowitz is a gifted applied mathematical economist who responds creatively to observed behaviour and has a strong interest in providing tools that facilitate applications of economics. As a graduate student he published a second influential article (1952b), which extended and qualified an important
contribution by Friedman and Savage (1948) that proposed an explanation for why individuals both
insure and gamble. Specifically, he transformed their argument to describe bets that involved deviations
from an individual’s ‘customary wealth’, which is wealth exclusive of recent windfall gains or losses,
and imposed a third inflection point, which was needed to satisfy the expected utility hypothesis
requirement that a utility function be bounded from below. By describing how the Friedman and Savage
model could not account for some commonly observed behaviour, this article afforded a clear insight
into the way Markowitz analysed decisions about risk. It takes only one simple division to transform
deviations from an individual’s customary wealth to rates of return on customary wealth.
Markowitz’s article on portfolio selection lucidly explained why focusing on the expected rate of return
(hereafter, ‘return’ means ‘rate of return’) was inadequate to account for widely observed portfolio
diversification. By simultaneously considering expected return and the variance of return (E and V), he
developed a set of efficient EV portfolios that would have a maximum return for an arbitrary variance of
return. Further, almost all of these efficient portfolios would have more than one asset and thus be
diversified. Using elegant geometric arguments, the article explained how in a problem involving N
securities the set of efficient portfolios could be represented by a set of connected line segments. This
insight underlies the algorithm for computing efficient portfolios that is presented in his monograph.
In that article and in his monograph, Markowitz was careful to emphasize that he was developing a
method for using an investor’s beliefs (or perhaps those of security analysts) about expected return and
variance so that he or she could use them in an optimal way. In neither did he explain how expectations
should be formed. Similarly, he was agnostic about whether the probabilities investors used in forming
expectations were objective or subjective. Finally, he did not assume that returns were normally
distributed or that an investor had a quadratic utility function, although one of these conditions is
formally necessary to describe portfolio choice in terms of expected return and variance of return. The
complications raised in the preceding three sentences are briefly considered in the final section of the
monograph and would absorb many journal pages in the coming years. Levy and Markowitz (1979)
addressed the limitations of restricting attention to expected return and variance and argued that by
focusing on these two measures investors were not likely often to be misled.
The monograph was an expositional tour de force and consequently had an enormous impact on the
theory and practice of finance. Its first chapters were quite intuitive and made no technical demands on
the reader. The third and fourth chapters contain elementary discussions of the concepts of expected
return and variance, the fifth and sixth generalize the discussion to cover large numbers of securities and
aggregation over time, and the seventh provides a clear geometric interpretation of efficient portfolios.
The eighth chapter presents the critical line method for isolating efficient portfolios and solving the
underlying quadratic programming problem. The ninth chapter restates the argument using a semi-
variance. The remaining four chapters describe rational portfolio behaviour and discuss how the
expected utility hypothesis can be applied to the portfolio selection problem. They include the topics of
portfolio choice over time and when objective and subjective probabilities differ.
Technical derivation of the critical line method is reported in Appendix A in the monograph, which
generalizes its original exposition in Markowitz (1956). The method works because the set of efficient
portfolios is convex, in part because there are assumed to be upper and lower bounds on the holdings of
any asset. In the monograph no short sales are allowed, although this restriction can be relaxed. If we
ignore some minor technical issues involving singularities that cannot be dealt with here, the method can
be described intuitively. It is initiated by finding the security with the highest expected return. A
portfolio fully invested in this security is an element in the set of efficient portfolios. Then, find the security or linear combination of securities that can be substituted for that highest-yielding security in a manner which respects the balance sheet identity that the sum of asset shares equals unity and provides the minimum reduction in return per unit decrease in variance. This substitution is continued until one or more of the securities reach zero (or a lower bound) or until a security not in this combination can be beneficially introduced, at which point another linear combination is chosen. The algorithm stops when no substitution is possible that further lowers the variance of a portfolio.

The monograph and a contemporaneous paper by Tobin (1958) underlay the development of the capital asset pricing model (CAPM) by Sharpe (1964), which argued that an asset's return was determined by its correlation with the return of the market portfolio. This model greatly increased interest in EV models among practitioners and the academic community. In his presidential address to the American Finance Association, however, Markowitz (1983) expressed some reservations about the CAPM because it failed to take into account limits on borrowing.

Apart from his work on modelling portfolio decisions, Markowitz made significant contributions to management science. In Markowitz (1957), he developed sparse matrix techniques for simplifying the solution of linear programming problems, which continue to be used in present-day algorithms that employ Cholesky factorizations. In Markowitz and Manne (1957) an important set of applications, discrete programming problems, were analysed. In Manne and Markowitz (1963), applications of ‘process analysis’ are reported in which Markowitz was a co-author on several papers that studied metal-working industries. Process analysis examines production capabilities in an industry. Also, he made many contributions that led to improvements in simulations, including the construction of a programming language, SIMSCRIPT (see Markowitz, Hausner and Karr, 1963, and Dimsdale and Markowitz, 1999).

Markowitz spent much of his career outside academia. From 1952 through 1963 he was on the staff of the RAND Corporation and from 1974 through 1983 he was at IBM's T. J. Watson Research Center. His monograph was largely written when he was a visitor at Yale University in 1955–6, on leave from RAND. He joined the faculty of Baruch College of the City University of New York as a distinguished professor of finance and economics in 1982, and in 2004 was a research professor at the University of California at San Diego. In 1989 he was awarded the prestigious Von Neumann Prize in Operations Research by the Operations Research Society of America and The Institute of Management Science for his work on ‘portfolio selection, mathematical programming, and simulation’.

The New Palgrave Dictionary of Economics

Marriage and Divorce

Yoram Weiss
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We document the increase in marital turnover and survey economic models of the marriage market. Couples match based on attributes but sorting is constrained by costs of search. Divorce is caused by new information on match quality, and remarriage requires further search. Although most men and women marry, they are single more often than before and more children live in one-parent household. The impact on children depends on child-support transfers. Such transfers may rise with the aggregate divorce (remarriage) rates.

Keywords

Altruism; assortative matching; child care; collective models; commitment; comparative advantage; complementarity; division of labour; household production; increasing returns; leisure; marriage and divorce; marriage market; matching model; multiple equilibria; Poisson process; reservation utility; search models; sharing rules; stable sharing rule; time use; transferable utility; unitary models of the household

Article

This article summarizes the economic analysis of marriage markets. The first section provides a description of stylized facts that motivate the interest of economists in this problem. It is shown that marital status is closely tied with ‘economic’ variables such as work and wages. We illustrate these facts using mainly US data but the patterns are similar in all developed countries. The second section demonstrates how the tools of economists bear on ‘non-economic’ subjects such as marriage, fertility and divorce, often analysed by researchers from other fields. The final section highlights some connections between the theory and empirical evidence.

Basic facts

Marriage and divorce

The 20th century was characterized by substantial changes in family structure (Figure 1). More men and women are now divorced and unmarried or have alternative arrangements, such as cohabitation. Interestingly, the rise in divorce rates is associated with an increase in remarriage rates (relative to first marriage rates), reflecting higher turnover. Most people had a first marriage, and most divorces end in remarriage. Moreover, the remarriage rate is greater than the first marriage rate and far exceeds the divorce rate, suggesting that, despite the larger turnover, marriage is still a ‘natural’ state (Table 1). Women enter the first marriage faster than men. However, following divorce, men remarry at higher rates than women, especially at old ages. This pattern reflects the earlier marriage of women and their longer lives, which causes the ratio of men to women to decline with age.

</table>

One consequence of higher marital turnover is the large number of children who live in single-parent and step-parent households. In 2002, 23 per cent of US children younger than 18 years lived only with their mother, and five per cent lived only with their father. Children of broken families are more likely to live in poverty and to underperform in school. Lower attainments of such children are observed also prior to the occurrence of divorce, suggesting that bad marriage rather than divorce may be the cause (Piketty, 2003).

### Marriage and work

Time use data (Table 2) show that men work more than women in the market; women do more housework than men. Per day, single women work at home three hours while single men work less than two hours. These figures roughly double for married couples with young children, showing clearly that children require a substantial investment of time and that most of this load is carried by the mother. The total time worked and the corresponding amount of leisure is about the same for married men and women.

Figure 2 displays the work patterns within couples. The most common situation is that the husband works full-time and the wife works part-time or does not work at all. However, the proportion of such couples has declined and the proportion of couples where both partners work full-time has risen sharply, reflecting the increased entry of married women into the labour force.

Figure 3
Figure 4
Economic theory of marriage and divorce

From an economic point of view, marriage is a voluntary partnership for the purpose of joint production and joint consumption. As such, it is comparable to other economic organizations that aim to maximize some private gains but are subject to market discipline.

Gains from marriage

Consumption and production in the family are broadly defined to include non-marketable goods and services, such as companionship and children. Indeed, the production and rearing of children is the most commonly recognized role of the family. We mention here five broad sources of economic gain from marriage, that is, why ‘two are better than one’:

1. Sharing of collective (non-rival) goods; both partners can equally enjoy their children, share the same information and use the same home.
2. Division of labour to exploit comparative advantage or increasing returns; one partner works at home and the other works in the market.
3. Extending credit and coordination of investment activities; one partner works when the other is in school.
4. Risk-pooling; one partner works when the other is sick or unemployed.
5. Coordination of child care, which is a collective good for the parents. Although children can be produced and raised outside the family, the family has a substantial advantage in carrying out these activities. Two interrelated factors cause this advantage: by nature, parents care about their own children and, because of this mutual interest, it is more efficient that the parents themselves determine the expenditure on their children. If the parents live separately, whether single or remarried, the non-custodial parent loses control of child expenditures. Lack of contact further reduces the incentive or ability to contribute time and money to the children. Together, these factors reduce the welfare of both parents and children when they live apart (Weiss and Willis, 1985).

Family decision making

The existence of potential gains from marriage is not sufficient to motivate marriage and to sustain it. Prospective mates are concerned whether the potential gains will be realized and how they are divided. Family members have potentially conflicting interests and a basic question is how families reach decisions. The old notion that families maximize a common objective appears to be too narrow. Instead of this unitary model, it is now more common to consider collective models in which partners with different preferences reach some binding agreement that specifies an efficient allocation of resources and a stable sharing rule. (Browning, Chiappori and Weiss, 2005, ch. 3).

In a special case, referred to as transferable utility, it is possible to separate the issues of efficiency and distribution. This situation arises if there is a commodity (say, money) that, upon changing hands, shifts utilities between the partners at a fixed rate of exchange. In this case, the family decision process can be broken into two steps: actions are first chosen to maximize a weighted sum of the individual utilities, and then money is transferred to divide the resulting marital output. In general, the problems of efficiency and distribution are intertwined. We may still describe the family as maximizing a weighted sum of the individual utilities, but the weights depend on the individual bargaining powers, and any shift in the weights will affect the family choice. The bargaining power may depend on individual attributes such as earning capacity, subjective factors such as impatience and risk aversion, and on market conditions, such as the sex ratio and availability of alternative mates (Lundberg and Pollak, 1993).

The question remains: what enforces the coordination between family members? One possibility is that the partners sign a formal ‘marriage contract’ that is enforced by law. However, such contracts are quite rare in modern societies, which can be probably ascribed to a larger reliance than in the past on emotional commitments and the presumption that too much contracting can ‘kill love’. In the absence of legal enforcement, efficient contracts may be supported by repeated interactions and the possibility to trade favours and punishments. This possibility arises because marriage is a durable relationship, forged by the long-term investment in children and the accumulation of marital specific capital, which is lost or diminished in value if separation occurs. However, repeated game arguments cannot explain unconditional giving, such as taking care of a spouse stricken by Alzheimers who would never be able to return the favour. Emotional commitments and altruism play a central role in enforcing family contracts (Becker, 1991, ch. 8).

The marriage market

Individuals in society have many potential partners. An undesired marriage can be avoided or replaced by a better one. This situation creates competition over the potential gains from marriage. In modern societies, explicit price mechanisms are not observed. Nevertheless, the assignment of partners and the sharing of the gains from marriage can be analysed within a market framework.

Matching models provide a starting point for such analysis. These models investigate the mapping from preferences over prospective matches into a stable assignment (Roth and Sotomayor, 1990). An assignment is said to be stable if no married person would rather be single and no two (married or unmarried) persons prefer to form a new union. To illustrate, assume that each male is endowed with a single trait, \( m \), and each female is endowed with a single trait, \( f \). Let

\[
 z = h(m, f).
\]

be the household production function that summarizes the impact of traits of the matched partners on marital output, \( z \), and assume that \( h(m, f) \) is increasing in \( m \) and \( f \).

Suppose, first, that \( z \) is a public good that the partners must consume jointly. Then, the only stable assignment is such that males with high \( m \) marry females with high \( f \); and, if there are more (fewer) eligible men than women, the men (women) with the fewest endowments remain unmarried. All men want to marry the best woman, and she will accept only the best man. After this pair is taken ‘out of the game’, we can apply the same argument to the next-best couple and proceed sequentially. Such a matching pattern is called positive...
assortative matching.

If one assumes, instead, that \( z \) can be divided between the two partners and that utility is transferable, then a man with low \( m \) may obtain women with high \( f \) by giving up part of his private share in the gains from marriage. The type of interaction in the gains from marriage determines the willingness to pay for the different attributes. Complementarity (substitution) means that the two traits interact in such a way that the benefits from a woman with high \( f \) are higher (lower) for a male with high \( m \) than for a male with low \( m \). Thus, a positive (negative) assortative matching occurs if the two traits are complements (substitutes). An important lesson is that in a marriage market with sufficient scope for compensation within marriage, the best man is not necessarily the one married to the best women, because, with negative interaction, either one of them can be bid away by the second-best of the opposite sex (Becker, 1991, ch. 4).

What determines the division of marital gains? If each couple is considered in isolation then, in principle, any efficient outcome is possible, and one has to use bargaining arguments to determine the allocation. However, in an ‘ideal’ frictionless case, where partners are free to break marriages and swap partners at will, the outcome depends on the joint distribution of male and female characteristics in the market at large. Traits of the partners in a particular marriage have no direct impact on the shares of the two partners, because these traits are endogenously determined by the requirement of stable matching.

These features show up more clearly if one assumes a continuum of agents and continuous marital attributes. Let \( F(m) \) and \( G(f) \) be the cumulative distributions of the male and female traits, respectively, and let the measure of women in the total population be \( r \), where the measure of men is normalized to 1. Assume that the female and male traits are complements and transferable utility. Then, if man \( m' \) is married to woman \( f' \), the set of men with \( m \) exceeding \( m' \) must have the same measure as the set of women with \( f \) above \( f' \). Thus, for all \( m \) and \( f \) in the set of married couples,

\[
1 - F(m) = r(1 - G(f)). \tag{2}
\]

This simple relationship determines a positively sloped matching function, \( m = \varphi(f) \).

A sharing rule specifies the shares of the wife and husband in every marriage that forms. Let \( v(m) \) be the reservation utility that man \( m \) requires in any marriage and let \( u(f) \) be the reservation utility of woman \( f \). Then the sharing rule that supports a stable assignment must satisfy

\[
v(m) = \max_f (h(m, f) - u(f)), \quad \text{and} \quad u(f) = \max_y (h(z, y) - v(y)). \tag{3}
\]

That is, each married partner gets the spouse that maximizes his or her ‘profit’ from the partnership over all possible alternatives. As we move across matched couples, the welfare of each partner changes according to the marginal contribution of his/her own trait to the marital output, irrespective of the potential impact on the partner whom one marries. With a continuum of agents, there are no rents in the marriage market because everyone receives roughly what can be obtained in the next-best alternative. Another condition for a stable assignment is that, if there are unmarried men, the least attractive married man cannot get any surplus from marriage. Otherwise, slightly less attractive men could bid away his match. A similar condition applies for unmarried women.

From these considerations, one can obtain a unique sharing rule, provided that \( r \neq 1 \). Basically, one first finds the sharing in the least attractive match, using the no-rent condition. Then the division in better marriages is determined sequentially, by using the condition that along the stable matching profile each partner receives his or her marginal contribution to the marital output. The sharing rule is fully determined by the sex ratio and the respective trait distributions of the two sexes. It can be shown that a marginal increase in the ratio of women to men in the marriage market improves (or leaves unchanged) the welfare of all men, and reduces (or leaves unchanged) the welfare of all women. From (2), it is seen that an upward (downward) first-order shift in the distributions of traits is equivalent (in terms of the effects on the sharing rule) to a marginal increase (decrease) in the female–male ratio. In this regard, there is close correspondence between the impact of changes in quality (that is, the average trait) and size of the two groups that are matched in the marriage market.
Search

The process of matching in real life is characterized by scarcity of information about potential matches. Models of search add realism to the assignment model because they provide an explicit description of the sorting process that happens in real time.

Following Mortensen (1988), consider infinitely lived agents and assume that meetings are governed by a Poisson random process (these two assumptions are made to ensure a stationary environment). The total marital output is observed upon meeting and, on the assumption of transferable utility, marriage will occur whenever this marital output exceeds the sum of the values of continued search of the matched partners. This rule holds because it implies the existence of a division within marriage that makes both partners better off.

Because meetings are random and sparse in time, those who actually meet and choose to marry enjoy a positive rent. The division of these rents between the partners is an important issue. Two considerations determine the division of the gains from marriage: outside options, reflected in the value of continued search, and the self-enforcing allocation that would emerge if the marriage continued without agreement (Wolinsky, 1987). If these two considerations are combined, the sharing rule is influenced by both the value of search as single and the value of continued search during the bargaining process, including the option of leaving when an outside offer arrives. In this way, a link is created between the division of marital output gains and market conditions.

Search models explain why, despite the gains from marriage, part of the population is not married and individuals move between married and single states. The steady state proportions of the population in each state are such that the flows into and out of each state are equalized. These two flows are determined by the search strategies that individuals adopt.

Search models may have significant externalities. For instance, it may be easier to find a mate if there are many singles searching for mates. There are several possible reasons for such increasing returns in the matching process. One reason is that the two sexes meet in a variety of situations (work, sport, social life and so on) but many of these meetings are ‘wasted’ in the sense that one of the individuals is already attached and not willing to divorce. A second reason is that the establishment of more focused channels, where singles meet only singles, is costly. These will be created only if the ‘size of the market’ is large enough. Third, the intensity of search by unattached decreases with the proportion of attached people in the population who are less likely to respond to an offer (Mortensen, 1988). In such a case, the marriage (divorce) rates will be above (below) their efficient levels, as each person fails to consider the effect of marriage or separation on the prospects of other participants in the marriage market.

Search and assortative matching

The presence of frictions modifies somewhat the results on assortative matching. Following Burdett and Coles (1999), consider a case of non-transferable utility with frictions. Assume that if man $m$ marries women $f$, he gets $f$ and she gets $m$. There is a continuum of types with continuous distributions and meetings are generated by a Poisson process with parameter $\lambda$. Upon meeting, each partner decides whether to accept the match or to continue the search. Marriage occurs only if both partners accept each other and, by assumption, a match cannot be broken.

Each man (woman) chooses a reservation policy that determines which women (men) to accept. The reservation values for men and women, $R_m$ and $R_f$, respectively, depend on the individual’s own trait. Agents at the top of the distribution of each gender can be choosier because they know that they will be accepted by most people on the other side of the market. Hence, continued search is more valuable for them. Formally, let

$$R_m = b_m + \frac{\lambda \mu_m}{\tau} \int_{R_m}^\infty (f - R_m) dG_m(f),$$

and

$$R_f = b_f + \frac{\lambda \mu_f}{\tau} \int_{R_f}^\infty (m - R_f) dG_f(m).$$
where the flow of benefits as single, \( b \), the proportion of meetings that end in marriage, \( \mu \), and the distribution of ‘offers’ if marriage occurs, all depend on traits, as indicated by the \( m \) and \( f \) subscripts. The common discount factor, \( r \), represents the cost of waiting.

In equilibrium, the reservation values of all agents must be a best response against each other, yielding a (stationary) Nash equilibrium. In particular, the ‘best’ woman and the ‘best’ man will adopt the policies

\[
R_m = b_m + \frac{\lambda}{r} \int_{R_m}^T (f - R_m) dG(f),
\]

\[
R_f = b_f + \frac{\lambda}{r} \int_{R_f}^\infty (m - R_f) dF(m).
\]

Thus, the best man accepts some women who are inferior to the best woman and the best woman accepts some men who are inferior to the best man, because a bird in the hand is worth two in the bush.

The assumption that the ranking of men and women is based on a single trait introduces a strong commonality in preferences whereby all men agree on the ranking of all women and vice versa. Because all individuals of the opposite sex accept the best woman and all women accept the best man, \( \mu \) is set to 1 in eq. (5) and the distribution of offers equals the distribution of types in the population. Moreover, if the best man accepts all women with \( f \) in the range \( [R_m, \bar{f}] \), then all men who are inferior in quality will also accept such women.

But this means that all women in the range \( [R_m, \bar{f}] \) are sure that all men accept them and therefore will have the same reservation value, \( R_f \), which in turn implies that all men in the range \( [\bar{R}_f, \bar{m}] \) will have the same reservation value, \( R_m \).

These considerations lead to a class structure with a finite number of distinct classes in which individuals marry each other. Having identified the upper class, we can then examine the considerations of the top man and woman in the rest of the population. Lower-class individuals face \( \mu < 1 \) and a truncated distribution of offers because not all meetings end in marriage but, in principle, these can be calculated and then one can find the reservation values for the highest two types and all other individuals in the group forming the second class. Proceeding in this manner to the bottom, it is possible to determine all classes. This pattern is similar to the case without frictions and non-transferable utility except that, because of the need to compromise, low- and high-quality types mix within each class.

With frictions and transferable utility, there is still a tendency towards positive (negative) assortative matching based on the interaction in traits. If the traits are complements, individuals of either sex with a higher endowment will adopt a more selective reservation policy and will be matched, on the average, with a highly endowed person of the opposite sex. However, with sufficient friction it is possible to have negative assortative matching even under complementarity. This, again, is driven by the need to compromise. With low frequency of meetings and costs of waiting, males with low \( m \) expect some women with high \( f \) to accept them. If the gain from such a match is large enough, they will reject all women with low \( f \) and wait until a high \( f \) woman arrives.

Divorce and remarriage

Divorce is motivated by uncertainty and changing circumstances. Thus, individuals may enter a relationship and then break it if a better match is met. Or changing economic and emotional circumstances may dissipate the gains from marriage. As time passes, new information on match quality and outside options is accumulated, and each partner decides whether to dissolve the partnership. In making this choice, partners consider the expected value of each alternative, where the value of remaining married includes the option of later
divorce and the value of divorcing includes the option of later remarriage. Under divorce at will, divorce occurs endogenously whenever one partner has an alternative option that the
current spouse cannot, or is unwilling to, match by a redistribution of the gains from marriage.
Following divorce, the options for sharing and coordination of activities diminish. The divorced partners may have different economic prospects, especially if children are present.
Asymmetries arise because the mother usually loses earning capacity as a result of having a child. To mitigate these risks, the partners have a mutual interest in signing binding
contracts that stipulate post-divorce transfers. Such contracts are negotiated ‘in the shadow of the law’ and are legally binding. Child support payments are mandatory but the non-
custodial father may augment the transfer to influence child expenditures by the custodial mother. Payments made to the custodial mother are usually fungible and, therefore, the
amount that actually reaches the children depends on the mother’s marital status. If she remarries, child expenditures depend on the new husband’s net income, including his child-
support commitments to his ex-wife. Hence, the willingness of each parent to provide child support depends on commitments of others. These interdependencies can yield multiple
equilibria, with and without children and correspondingly low and high divorce rates (Browning, Chiappori and Weiss, 2005, ch. 11).

Theory and evidence

There is a growing body of empirical research that addresses the testable implications of the models outlined above.

1. The unitary model of the household implies that the consumption levels of husband and wife depend only on total family income. This, however, is rejected by the data
   (Lundberg, Pollak and Wales, 1997). Nevertheless, consumption and work patterns of married couples indicate that they act efficiently (Browning and Chiappori, 1994),
   implying that a collective model fits the data.
2. Matching models with transferable utility imply positive assortative matching based on the spouses’ schooling but negative matching based on their wages (Becker, 1991,
   ch. 10). In fact, the correlation between the education levels of married partners (about .6) is substantially higher than the correlation between their wages (about .3).
3. Because partners are matched based on their traits as observed at the time of marriage, both positive or negative surprises trigger divorce (Becker, 1991, ch. 10). Weiss and
   Willis (1997) find an impact of unexpected changes in husband's and wife's incomes on the probability of divorce.
4. Unanticipated shocks are less destabilizing if partners are well matched. Anticipating that, couples would sort into marriage according to characteristics that enhance the
   stability of marriage. In fact, individuals with similar schooling are less likely to divorce and are more likely to marry. This pattern holds for religion and ethnicity, too (•Weiss
   and Willis, 1997).
5. Individual types congregate into locations that facilitate matching; gays in San Francisco (Black et al., 2000) or Jews in New York (Bisin, Topa and Verdier, 2004). Such
   patterns suggest increasing returns in search. Higher wage variability among men induces women to search longer for their first or second husband, consistently with an
   optimal search strategy (Gould and Paserman, 2003).
6. Marital choices and family decisions respond to aggregate marriage market conditions. Black women in the United States delay their marriage and have children out of
   wedlock because of a shortage of eligible black men (Willis, 1999); a higher male–female ratio reduces the hours worked by wives and raises the hours worked by husbands
   (Chiappori, Fortin and Lacroix, 2002).
7. The sharp increase in divorce in the United States and other countries during 1965–75 seems to constitute a switch across two different equilibria. A marriage market is
   capable of such abrupt change because of inherent positive feedbacks in matching and contracting. Explanations for the timing of the change include the appearance of the
   contraceptive pill, the break-up of norms and legal reforms (Michael, 1988; Goldin and Katz, 2002).

How to cite this article

The term ‘marriage market’ refers to the application of economic theory to the analysis of the process that determines how men and women are matched to each other through marriage and how this process influences other choices including human capital investment and the allocation of marital surplus. The specific sub-topics in this article include a characterization of stable assignment in marriage, consideration of the effects of marriage allocations on distribution within marriage, discussion of the extent to which partners who marry have similar characteristics, and a review of results on marriage timing.

Keywords
assortative mating; dowries; fertility; human capital investment; inequality; marriage markets; non-market production; stable assignment; transferable utility

Article
The marriage market is a term used by economists to characterize the process that determines how men and women are matched to each other through marriage. Formally the marriage market may be thought of as an allocative process that, given the preferences and endowments of two sets of individuals (men and women), yields a set of couples and unmatched individuals and a distribution of resources within each match. Marriage markets are generally distinguished from other sorting processes such as worker–firm matching by the assumption that each member of each set of individuals is matched to at most one member of the other set. However, the basic concept of the marriage market may also be applied to other cases such as polygamy or same-sex partnerships. It is also generally assumed that one's well-being within marriage is determined by the characteristics of one's partner and the distribution of resources within the marriage, but not the matches of other individuals in the marriage market conditional on these factors. The economics literature on the marriage market has built importantly on a two-part...
foundational article on the economics of marriage published in 1973 and 1974 (Becker, 1973; 1974). However, the phrase ‘marriage market’ is considerably older, with a first citation in the *Oxford English Dictionary* of 1842.

**Stable assignment**

Central to the notion of a marriage market is the notion of stable assignment. A stable assignment may be characterized as a set of partner allocations and distributions of resources within marriage so that no individual of one sex would be willing to make an offer (in terms of partnership and a distribution of resources within that partnership) to an individual of the other sex which that individual strictly prefers to his or her equilibrium allocation.

An early and important divide in terms of economic models of marriage arises with respect to the question of transferable utility. Transferable utility arises when well-being within the household may be freely transferred between members of the household through a reallocation of household resources. Under these conditions the question of who marries whom can be importantly separated from the question of how resources are distributed within marriage and any stable marriage assignment can be characterized as the outcome of the maximization of a linear programme (Bergstrom, 1997).

At the other extreme from a transferable utility model is one in which there is no possibility of transferring resources within or across marriage. A key feature of such models is that there is generally a wide variety of possible stable equilibria. Gale and Shapley (1962) illustrate two such stable equilibria, by the construction of two matching algorithms based on who makes offers and who makes the decision to accept, tentatively accept, or reject those offers. Each man is at least as well off in the equilibrium in which men make offers relative to the equilibrium in which women makes offers and vice versa.

**Distributive effects**

Becker’s (1973) pioneering analysis of the marriage market considered, among other things, the effects of the marriage market on household distribution. Consider, for example, a simplified version of this model in which there is heterogeneity in tastes for being single, transferable utility within marriage, and no heterogeneity across couples in total utility within marriage. The outcome of the model is a distribution parameter that characterizes the share of total marital utility going to each partner within marriage and a number of marriages, with those individuals of both sexes with the highest taste for being single remaining unmarried. Among other things the model illustrates how a rise in the female wage raises the utility of married females within marriage even when married women are not active in the labour market. The increased opportunities for women outside marriage implies that women must, at the margin, receive a higher share of marital utility in order to be willing to marry.

There is substantial debate about the importance of marriage market structure in influencing transfers between partners and their respective households of origin at the time of marriage. Of particular relevance is the evidence of a historical transition from bride-price to dowry in parts of South Asia and the very large levels of dowry relative to annual income that are sometimes observed in that region. A number of factors have been argued to play an important role in this regard, including changes in the relative sizes of female and male populations of marriageable age associated with population growth and...
the gap in typical ages at marriage, changes in inequality and economic opportunity, and changes in the relative merits of different forms of parental transfers in their children.

Assortative mating

A second issue that has received significant theoretical and empirical scrutiny is the question of the extent to which the marriage market matches men and women with similar characteristics. This issue is thought to be important because of its implications for interhousehold inequality and for intergenerational transmission of inequality. If high-earning men match with high-earning women, and these high-earning couples transfer these resources to their children in the form of financial assistance and/or human capital, then inequality is likely to be more persistent across generations than would be the case otherwise. Assortative mating by religion and/or immigrant status is also thought to be both an indicator of and contributor to the process of assimilation. Finally, assortative mating on unobservable (to analysts) attributes can affect inferences about household behaviour that condition on household composition. For example, if men with a high unobservable taste for child human capital match with more educated women, then highly educated women will appear to have more educated children even if there is no direct effect.

A simple transferable utility model in which marital output is increasing in the product of male and female quality yields the prediction that there should be positive assortative mating on such attributes as intelligence, wealth and beauty. A possible exception arises with respect to market earnings capacity to the extent that, as postulated by Becker (1973), one member of the couple specializes in the production of non-market goods. Interestingly, the theoretical prediction of positive assortative mating across classes of individuals can arise within the marriage market with imperfect information (Burdett and Coles, 1997).

The evidence supports the prediction of positive assertive mating on partner attributes, although there have been changes over time in the degree to which this is observed. In particular, the degree of educational assortative mating fell between 1940 and 1960 in the United States but has increased subsequently, largely due to a decline in the share of low-education individuals marrying (Schwartz and Mare, 2005). There has also been a shift in the sign of the correlation in partner earnings from negative to positive since the 1960s (Schwartz, 2005), a pattern that has contributed to the overall increase in interhousehold inequality in income.

Marriage timing

A third set of marriage-market issues relates to the timing of marriage, particularly for women. It is argued that early marriage can result in higher fertility, lower rates of human capital investment, and an adverse bargaining position from the perspective of women. Boulier and Rosenzweig (1984), in an early contribution on this subject, showed how unobserved attractiveness could lead to incorrect inference about the role of education in delaying marriage and increasing spousal quality. Bergstrom and Bagnoli (1993) show how the process of uncertainty resolution with regard to the marital prospects may differentially affect the timing of marriage for men and women of different qualities. It also is the case that timing of marriage can play an important role in the equilibration of marriage markets given
substantial differences in the relative numbers of eligible men and women arising from sex differences in mortality or a gap in the age at marriage for men and women for a growing population. In particular, because of how changes in the timing of marriage for sequential cohorts of eligible men and women affect the number of marriages taking place at a particular point in time, a persistent ten per cent excess in the number of eligible females relative to males can be accommodated with an increase in the female relative to male age at marriage by just one year over a decade (Foster, Khan and Protik, 2004).

**How to cite this article**

The diversity of Jacob Marschak's education and early experience made it likely that he would approach the study of economic behaviour with more than the average breadth of interest and vision. He was born in Kiev on 23 July 1898, and studied mechanical engineering at the Kiev Institute of Technology. At the beginning of the Russian Revolution he served briefly as Minister of Labour in the Menshevik government of Georgia but was forced to escape to Germany. There he went first to the University of Berlin, where he studied economics and statistics with L.V. Bortkiewicz, and then to the University of Heidelberg, where he received his Ph.D. in economics in 1922. His professors at Heidelberg included E. Lederer in economics, A. Weber in sociology, K. Jaspers in philosophy and G. Anschuetz in public law. Following his doctoral studies at Heidelberg, he earned his living for the next eight years as an economic journalist and applied economist. He was economic editor for the Frankfurter Zeitung (1924–5), a research associate at the Research Centre for Economic Policy in Berlin (1926–8), and supervisor and editor of research for a Parliamentary Commission of Exporting Industries, at the Institute of World Economics of the University of Kiel (1928–30). Also, in 1926 he spent time in London on a travelling fellowship from the University of Heidelberg.

In 1930 he was appointed as a Privatdozent in economics at the University of Heidelberg, but three years later, once again the victim of political events, he left Germany and went to Oxford as a university lecturer. In 1935 he became Reader in Statistics and Director of the Oxford Institute of Statistics, where he remained until 1939. During this period he wrote extensively on theoretical and statistical aspects of demand analysis, a field in which he was a pioneer (Marschak, 1931).

In 1939 Marschak moved to the United States, where he lived the rest of his life, teaching at the New School for Social Research (1940–42), the University of Chicago (1943–55), Yale University (1955–60), and the University of California at Los Angeles (1960–77).
During the first dozen years Marschak was an active participant in the econometric revolution that is commonly associated with the Cowles Commission for Research in Economics. This revolution was nurtured at an early and crucial stage by the seminar on econometric methods and results that Marschak organized at the National Bureau of Economic Research, while he was on the faculty of the New School for Social Research. The intensive contacts fostered in this seminar led, in particular, to three fundamental papers on the statistical estimation of systems of simultaneous equations, by Haavelmo (1943), Mann and Wald (1943), and Marschak and Andrews (1944). Two further publication landmarks in this movement were the Cowles Commission Monographs No. 10 and No. 14, to which Marschak contributed the opening chapters (Marschak, 1950a; 1953).

Two other topics on which Marschak worked presaged his later work on decision and organization. First, he was, for a number of years, interested in the demand for money, and through his work and that of others the idea evolved that this demand could be better understood in the context of a more general theory of the joint demand for various assets (Marschak, 1938; 1949; 1950b). Furthermore, since the ultimate values of assets are rarely known with certainty at the time they are acquired, such a general theory needed to be based on a more systematic theory of decision in the face of uncertainty than was then available.

A second topic was the subject of his first scientific publication, a contribution to the debate on the efficiency, or even viability, of socialism. A central issue in that debate was whether the centralization of economic authority in a socialist state was compatible with the decentralization of information necessary in a complex economy. From 1950 on, Marschak's research and writing was concerned with the general area of decision, information and organization. More specifically, one can identify at least three topics to which he made substantial contributions: (1) stochastic decision, (2) the economic value of information, and (3) the theory of teams.

Stochastic decision

In a series of articles (Marschak, 1959a; 1964a; Marschak and Block, 1960; Marschak and Davidson, 1959b; Marschak, Becker and DeGroot, 1963a; 1963b; 1963c; 1964b), Marschak proposed and elaborated the theory of stochastic decision and reported on a number of experiments. This work had its roots in the theory of rational economic choice or utility theory and in certain theories of psychological measurement.

Marschak developed a framework for describing the behaviour of economic decision makers who are approximately rational or consistent, or whose consistency of behaviour cannot be exactly verified through observation because of the observer's inability to control or identify all of the relevant factors in the decision-making situation. It had long been recognized that economic decision makers did not exhibit exact consistency in their detailed choices. Economists were and remain loath to abandon the general framework of rational decision making that has appeared to be so fruitful in the analysis of the economic system as a whole, Marschak's theory provided a theoretical model that could be used for econometric studies of individual choice behaviour and that was connected in a coherent way with the general hypothesis of economic rationality. The work of Marschak and his co-authors was at first more appreciated by psychologists than by economists. His papers on this subject are still standard references in the theory of psychological...
scaling (Luce, Bush and Galanter, 1963, vol. 3, ch. 19). More recently, this theory has provided the basis of statistical studies of individual choice behaviour (McFadden, 1982), as well as of a new approach to the theory of economic equilibrium that takes account of the uncertainty of individual behaviour (Hildenbrand, 1971; Bhattacharya and Majumdar, 1973).

**Economic value of information**

Marschak was probably the first to develop a systematic theory of the economic value of information. In this development he recognized that the measurement of quantity of information used by communication engineers, and associated with the work of Wiener and Shannon, was not adequate to measure the value of information. Indeed, it was not possible to identify a single measure of information such that more is always better.

Instead, Marschak turned to the newly developed theory of statistical decision for the source of his framework. For him, the value of a particular information system – or more generally, a system of information gathering, communication and decision – was related to the particular class of economic decision problems under consideration. His theoretical analysis of the value and cost of information pointed to the importance of more empirical knowledge concerning the technology of observation, information processing, communication and decision making, although he, himself, did not do any empirical work in this field. These ideas are elaborated in a long series of papers beginning with his contribution to *Decision Processes* (Marschak, 1954) and summarized in his paper ‘Economics of Information Systems’ (1971).

**Economic theory of teams and organization**

In an economic or other organization, the members of the organization typically differ in (1) the actions or strategies available to them, (2) the information on which their actions can be based, and (3) their preferences among alternative outcomes and their beliefs concerning the likelihoods of alternative outcomes given any particular organization action. Marschak recognized that the difficulty of determining a solution concept in the theory of games was related to differences of type 3. However, a model of an organization in which only differences of types 1 and 2 existed, which he called a team, presented no such difficulty of solution concept, and promised to provide a useful tool for the analysis of problems of efficient use of information in organizations. Such a model provided a framework for analysing the problems of decentralization of information so central to both the theory of competition and the operation of a socialist economy. The idea of a team was introduced in Marschak (1954; 1955), and a systematic development of the theory of teams is provided in Marschak and Radner (1972).

Towards the end of his career, Marschak returned to the theoretical issues concerning conflict of interest among the members of a decentralized organization. He approached this primarily in terms of the normative problem of devising incentives for the members of a ‘team’ to behave in accord with the goals of the organization. Of course, to the extent that such incentives are needed, the organization is no longer a team, in the technical sense of the term and the problem is back in the domain of the more general theory of games. It was left to others to make substantial progress on this set of problems. An important early effort in this direction was by T. Groves, who in his doctoral dissertation (1969) and his...
Marschak, Jacob (1898–1977) : The New Palgrave Dictionary of Economics

subsequent article, ‘Incentives in Teams’ (1973) presented – in a particular case – a solution to the problem of providing incentives to decentralized decision makers to both send truthful messages and make optimal decisions. These ideas were further developed in the contexts of the theory of public goods, the allocation of resources in a divisionalized firm and the principal–agent relationship. (For references to the literature on these developments see Groves and Ledyard, 1987; Hurwicz, 1979; Radner, 1986.)

Besides the significance of Marschak's individual contributions to economic analysis, I would like to emphasize the cumulative significance of his life's work. Through his work ran the important message that economists must come to grips with problems of uncertainty. He led the way, not only through his own research, but through his indefatigable and successful efforts at explaining these problems to his colleagues in economics and related disciplines. His work drew from psychology, statistics and engineering, and in turn influenced research in those disciplines. Indeed, more than any other economist I know, Marschak typified the best in behavioural science.

Selected works

A bibliography of Marschak's publications (excluding most book reviews and all newspaper articles) can be found in McGuire and Radner (1986). A large number of his papers have been reprinted in Marschak (1974).

Marshall Plan

Francisco Alvarez-Cuadrado
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Marshall Plan transferred over US$12.5 billion to Western European countries between 1948 and 1951. This article contrasts the main views on its impact on the post-war European performance. It concludes that, although the direct impact of the plan through private and public investment was rather limited, Marshall Aid provided the recipient economies with a temporary solution for the severe dollar constraint that posed a threat to the continuation of the European miracle. Furthermore the Plan played an important role in promoting collaboration among former adversaries.

Keywords

aid; Marshall Plan; OEEC; post-war economics

Article

In Europe during the Second World War the productive effort of more than an entire generation was lost, with per capita income returning to the levels of the turn of the century. This fall in output reflected not only the destruction of capacity but also the disruption of channels for obtaining inputs and distributing production. The reconstruction process began right after the war, with industrial production reaching pre-war levels as soon as 1947. The weather conditions in 1947 substantially depressed agricultural yields, leading to important food and energy shortages. The substantial trade deficits of the recovering economies combined with the negative experience of international investors after the First World War lead to a ‘dollar gap’ which posed a threat
to the continuation of the European miracle.

These were the circumstances that surrounded the development of the Marshall Plan, officially the European Recovery Program (ERP). The views on the motivations behind the ERP range from plain American imperialism (Kolko and Kolko, 1972) to pure altruism; in the words of Galbraith (1998), ‘the primary purpose of the Plan was compassionate good will, the notion that our former allies needed to have the help of the US’. Nonetheless most of the literature acknowledges that, beyond the concern for former allies, the political and social stability of non-communist Europe and the continuity of export markets for US products were two of the main concerns of the Truman administration.

The initial Plan proposal was presented in June 1947 by secretary of state George Marshall, asking European governments to design a coordinated aid programme to be funded by the United States. The offer included the Soviet Union and its allies, but the conditional terms on economic collaboration and disclosure of information guaranteed that the Soviet Union would never accept it. In response to the American offer the final aid recipients, Austria, Belgium, Denmark, France, West Germany, Great Britain, Greece, Iceland, Ireland, Italy, Luxembourg, the Netherlands, Norway, Sweden, Switzerland and Turkey, formed the Organization for European Economic Cooperation (OEEC) to coordinate a proposal based on national needs and consistent with American objectives on trade and economic cooperation between recipient countries. US President Truman signed the Plan into a law on 3 April 1948, establishing the American-led Economic Cooperation Administration (ECA) to administer the programme.

Over the four years that followed its approval by Congress, the Plan transferred $12.5 billion of US aid to Western Europe. The allocation of funds did not follow a simple rule, although it was mainly determined by the dollar balance of payment deficits of the recipient economies, taking also into account geopolitical considerations especially in the cases of France and the United Kingdom. Marshall Aid represented 2.1 per cent of US GNP in 1948, rose to 2.4 per cent in 1949 and then fell to 1.5 per cent in the remaining two years. In terms of national income of the recipient economies, the funds ranged from 0.3 per cent per year for Sweden to 14 per cent for Austria. For the large Western European economies it represented an average yearly transfer of 2.5 per cent of GDP for France, 2.2 per cent for Italy, 1.3 per cent for the United Kingdom and 1.2 per cent for Germany.

The OEEC took the leading role in allocating funds, conditional on the
approval of the ECA. The American supplier was paid in US dollars, which were debited against the ERP account corresponding to the European buyer. This buyer paid for the American imports in local currency, which was deposited by its own government in a counterpart fund. These additional resources were used for local investment projects and eventually were absorbed into the recipient's national budget.

The impact of the plan on the European recovery is not free of controversy. On the one hand, early triumphalist accounts (Jones, 1955; Mayne, 1970; Arkes, 1972) describe the Plan as vital for the reconstruction of productive capacity, the development of the necessary institutions for cooperation among former adversaries, and the restoration of European confidence in market capitalism. In the words of Mayne (1970), Marshall Aid ‘was a precondition of all later affluence and economic miracles, as well as moves toward European unity’. On the other hand, Milward (1984) discounts the importance of ERP transfers, arguing that the recovery was well under way before 1948 and the reconstruction of the damaged private and public capital stocks was almost completed. Somewhere in between, De Long and Eichengreen (1993) argue that Marshall Aid helped the recipient economies more in terms of political economy than macroeconomics. The ERP bought European governments the political space needed to avoid the attrition wars that characterized the interwar period, allowing an institutional environment conducive to growth.

Until the influential work of Milward (1984), the literature agreed on the vital importance of the ERP funds for Western European growth. According to this view Marshall Aid allowed for the reconstruction of the capital stock, the elimination of bottlenecks that obstructed production, the public provision of infrastructures and the surge in intra-European trade. In the words of Arkes (1972), ‘the plan was critical at the margins having a multiplier effect of three or four times its value’. A superficial analysis of the data suggests that this view is exaggerated. If we compute the growth rates of per capita GDP for the recipient economies, we find that in the three years that preceded the ERP, yearly growth averaged 6.5 per cent, while during the Plan it averaged 4.4 per cent, falling to four per cent between 1953 and 1956.

Eichengreen et al. (1992) argue that if the effects of the Plan worked mainly through private and public capital accumulation, there should be a significant correlation between output growth and ERP allotments as a share of GDP across recipient economies. Contrary to this view, their statistical analysis does not turn up a significant coefficient on Aid allotments. Alvarez-Cuadrado
and Pintea (2008) present a two-sector neoclassical growth model with public capital to explore the direct impact of the ERP. Their numerical analysis suggests that the transfers increased the rate of private investment by less than one percentage point, leading to no more than half a percentage point increase in the growth rate of output. Since average yearly transfers represented no more than half a year's worth of post-war growth, it is not surprising that the effects of the Plan through capital accumulation are rather limited. Along similar lines, Milward (1984) argues that the outstanding performance of Western European economies would have not been very different in the absence of the Plan. He discounts the direct impact of the Plan and convincingly documents that the leverage afforded by the ERP was insufficient for the United States of America to force through its vision of the United States of Europe. In Milward's view the primary role of the ERP was limited to sustaining the flow of capital imports necessary to prolong the recovery.

In a different spirit, De Long and Eichengreen (1993) argue that political economy considerations lie behind the true impact of the Plan. Marshall Aid provided the currency needed to relax the foreign exchange constraint, giving European policy makers extra room to manoeuvre. This political space, together with aid conditionality, induced European governments to balance their budgets, restore internal financial stability, and maintain their commitment to free markets. Their counterfactual vision of Western Europe suggests a permanent influence of Communist parties, an expansion of government controls and regulations, and a resurgence of economic nationalism and isolationism.

This argument, although it has its merits, does not seem to account for the variety of institutional arrangements present in the recipient economies. For instance, two of the fastest-growing economies, France and Germany, adopted rather different growth strategies. The French economy was characterized by major involvement of the state in key economic sectors, while the German approach illustrates the growth potential of relatively free markets. In my view, although the functioning of the market mechanism was constrained in many countries as a result of war priorities, there was a tacit consensus that this was only a temporary interruption of the long European experience with free markets, and therefore the influence of the Plan was rather limited in this respect.

To sum up, the direct impact of the Plan led to no more than half of a percentage point of growth per year. Along the lines of Milward (1984), I
believe the plan provided European governments the means to prolong the recovery process which began after the war. In some cases the transfers complemented export revenues, preventing a balance-of-payment crisis, while in others they only postponed its occurrence. The political economy argument is more difficult to evaluate, but given the prior European experience with free markets and the existence of a well-developed system of property rights, it is difficult fully to accept the counterfactual scenario drawn by De Long and Eichengreen (1993). Finally, the Marshall Plan played an important role by inducing British and French support for a strong Germany. Although the forces that led to the process of European integration responded more to internal political and economic developments in the European countries than to American pressure, the Marshall Plan helped promote collaboration among former adversaries.

Marshall, Alfred (1842–1924)

John K. Whitaker
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

English economist Alfred Marshall, founder of the Cambridge School of economics, was a leading and internationally prominent figure in the development of economic thought between 1870 and 1920. He played a significant role in professionalizing British economics, always stressing the social importance of wider economic understanding. His influential ideas on economic theory were conveyed primarily in his *Principles of Economics* (1890). Accounts of his life, career and general views on economics are followed by a more technical treatment of his contributions to various aspects of economic analysis. Guides to his writings and to the secondary literature on him are appended.

Article

Alfred Marshall, Professor of Political Economy at the University of Cambridge from 1885 to 1908 and founder of the Cambridge School of Economics, was born in Bermondsey, a London suburb, on 26 July 1842. He died at Balliol Croft, his Cambridge home of many years, on 13 July 1924 at the age of 81. His magnum opus, *Principles of Economics* (1890a) evolved through eight editions in his lifetime, the final edition (1920) being most commonly cited today. It was one of the most influential treatises of its era and was for many years the Bible of British economics, introducing many still familiar concepts. The Cambridge School rose to great eminence in the 1920s and 1930s. A.C. Pigou and J.M. Keynes, the most important figures in this development, were among Marshall's pupils. Marshall's biography and career are outlined initially, after which descriptions are given of his views on the social setting, aims and methods of economics, and his intellectual debts to others. An analysis of his fundamental ideas on theories of value and distribution, which were mainly set out in *Principles*, follows, after which his contributions to monetary and international-trade theory are considered briefly. A final section provides additional documentation and general suggestions for further reading. Also, some of the more technical sections have attached to them brief ‘bibliographic notes’ offering suggestions for further exploration. All bibliographic references lacking an author's name are to works by Marshall, and the bibliographic details of all his cited publications can be found in the list of ‘Selected works’ below. The bibliographic details for all cited works written or edited by others are listed in the concluding ‘Bibliography’.

Biography and career

Marshall grew up in the London suburb of Clapham, being educated at the Merchant Taylors’ School where he showed academic promise and a particular aptitude for mathematics. Eschewing the more obvious path of a closed scholarship to Oxford and a classical education, he entered St John's College, Cambridge, in 1862 on an open exhibition. There he read for the Mathematical Tripos, Cambridge University's most prestigious degree competition, emerging in 1865 in the exalted position of Second Wrangler, bettered only by the future Lord Rayleigh. This success ensured Marshall's election to a Fellowship at St John's. Supplementing his stipend by some mathematical coaching, and abandoning doubtless because of a loss of religious conviction – half-formed earlier intentions of a clerical career, he became engrossed in the study of the philosophical foundations and moral bases for human behaviour and social organization. In 1868 he became a College Lecturer in Moral Sciences at St John's, coming to specialize in teaching political economy. By about 1870 he seems to have committed his career to developing this subject, seemingly ripe for reform, and helping to transform it into a new science of economics.

For several years he laboured persistently to develop and refine his economic ideas, and to deepen his understanding and grasp of both the existing economic literature and the economic reality that was its subject matter. In 1875 he visited the United States to probe economic conditions, and throughout his life he was tireless in his efforts to master the practicalities of the economic world. Prior to 1879 his publications were meagre. He had embarked on a book on international trade and problems of protectionism in the mid-1870s, and before that he had worked out many of his distinctive theoretical ideas in the form of short essays, many now reproduced in Whitaker (1975). But the only part of this material to be made public was four chapters from the theoretical appendices for the proposed international-trade volume. In 1879 Henry Sidgwick had these printed for private circulation under the title The Pure Theory of Foreign Trade: The Pure Theory of Domestic Values (1879a). (An amplified version together with surviving portions of the text of the abandoned trade volume is also reproduced in Whitaker, 1975.) The year 1879 also saw the publication of Marshall's first book, The Economics of Industry (1879b), written jointly with his wife Mary Paley Marshall.

Mary Paley had been one of the first group of students at Newnham Hall (later Newnham College) where Marshall, an early supporter of the informal scheme of Cambridge lectures for women, taught her political economy. Their marriage in 1877 required Marshall to give up his Cambridge position under the celibacy rules then in force. He found a new livelihood as principal of the recently established University College, Bristol, where he also became Professor of Political Economy. There The Economics of Industry was brought to completion and published by the house of Macmillan, which continued as Marshall's publisher thereafter. Ostensibly an elementary primer, this book contained the first general statement of Marshall's emerging theories, and a considerable sophistication lay beneath its deceptively simple surface. Together with the powerful Pure Theory chapters published by Sidgwick, a few copies of which circulated outside Cambridge, The Economics of Industry marked Marshall as a rising star in the economics firmament. With the death of W. S. Jevons in 1881, he moved into the public eye as the leader in Britain of the new scientific school of economics.

The duties of the Bristol principalship proved irksome to Marshall, especially as the college was struggling financially. He was anxious to proceed with his writing, having by 1877 conceived the plan for the book that was to become the Principles. His frustrations were increased by the onset in 1879 of a debilitating illness, diagnosed as kidney stones, which restricted his activities. He was persuaded to continue as principal until 1881, when he resigned both posts at the college. The next year was spent travelling, with an extended sojourn in Palermo, and it was in this year that composition of the new book began in earnest.

At Bristol, Marshall had got to know well Benjamin Jowett, the famed Master of Balliol, who was one of the governors of the struggling college. It was probably by Jowett's generosity that Marshall was able to return to Bristol in 1882 as Professor of Political Economy. And it was doubtless at Jowett's instigation that the Marshalls moved to Oxford in 1883, when a Balliol lectureship became vacant on the unexpected death of Arnold Toynbee. Marshall had considerable success as a teacher in Oxford and appeared settled in for an indefinite stay. But an ‘Oxford School of Economics’ was not to be. The sudden death of Henry Fawcett, who had been Professor of Political Economy at Cambridge since 1863, opened up the irresistible prospect of a return to Cambridge and a position with great potential for academic leadership. Marshall, the dominant candidate, was duly elected in December 1884, holding the chair until 1908, when he resigned to devote himself entirely to writing.

In many ways Cambridge's inviting prospects were to prove illusory. Economics was taught as part of
the Historical and Moral Sciences Triposes, but neither avenue provided a supply of able interested students, nor was there much scope for advanced work. Marshall struggled for many years, with limited success, to increase the scope for economic teaching. But it was not until 1903, with the establishment of a new Tripos in Economics and Politics, that his goal was achieved. Even then, few resources were made available by the university and colleges for the teaching of economics, and the staffing of the new Tripos relied heavily on Marshall's willingness to support two young lecturers from his own pocket. The flowering of the new school came about mainly after his retirement, but the seeds were certainly planted by his efforts.

Absorbed in the struggle for his own subject, Marshall took relatively little part in general university affairs. Indeed, his rather obsessive personality and proneness to magnify details would have made him ineffectual as a university statesman even if he had aspired in that direction. But he did play a prominent part in the successful campaign of 1896–7 against the granting of Cambridge degrees to students of the women's colleges – this despite his wife being at the time a lecturer at Newnham. He was not opposed to women's education, indeed had been a warm supporter in his early days, but was vehemently opposed to the assimilation of women into an educational system designed for men.

But the dominant fact in Marshall's life after his return to Cambridge, and certainly the aspect of greatest interest to posterity, is his long struggle to give adequate written expression to the stores of economic knowledge and understanding he had accumulated. The demands of teaching and administration left him little time or energy for sustained composition during term time and it was in the jealously guarded long vacations, usually spent away from Cambridge on the south coast of England or in the Tyrol of Austria, that the only real progress could be made. By 1887 the book commenced in 1881 had grown into a projected two-volume treatise. He hoped to complete the first volume in time for it to appear in the autumn of that year with the second volume appearing by 1889. In fact, the first volume (1890a) appeared as the Principles of Economics, Volume One, only in July 1890, when it was received with great and immediate acclaim and established Marshall firmly as one of the world's leading economists. The second volume never appeared. It was to have covered foreign trade, money, trade fluctuations, taxation, collectivism and aims for the future – a tall order!

Marshall struggled for the next 13 years with his intractable second volume, meanwhile spending much time on substantial, but not very substantive, recastings of the first volume in new editions of 1891, 1895 and 1898, and in preparing a digest of it to replace the earlier Economics of Industry which he had come to dislike intensely. (The digest, 1892, appeared under the title Elements of the Economics of Industry, Volume One. Like the earlier work it included material on trades unions that was never incorporated into Principles.) By 1903 much material had been accumulated for the second volume, but the scope was becoming unmanageable as Marshall became increasingly preoccupied with problems of trusts, trades unions, international trade, and comparative economic development, and decreasingly concerned with matters of pure theory. In that year, partly from the impetus of writing a private memorandum on trade policy for the use of the then Chancellor of the Exchequer, and partly because the tariff controversy was at full heat, Marshall was tempted into writing a short topical book on foreign trade questions, intending to publish it speedily. But this project too grew unmanageably in his hands. In 1907, the preface to the fifth edition of Principles (the last major rewriting) announced the abandonment of the proposed continuation and promised instead a volume, already partly in print, on ‘National Industry and Trade’, to be followed soon by a companion volume on ‘Money, Credit and Employment’ (Guillebaud, 1961, vol. 2, p. 46). To reflect this change, the title of the sixth and subsequent editions of Principles was changed
to *Principles of Economics: An Introductory Volume*. Retirement in 1908, at the age of 66, freed
Marshall to concentrate on these projects, but progress continued to be slow. He appears to have
suffered from recurrent dyspepsia and high blood pressure, necessitating a strict regimen and limiting his
ability to work. But the more fundamental problem was that the world kept changing and the
increasingly realistic and factual tone of his enquiry called for incessant recasting and revision. Nothing
had been completed by the time war broke out in 1914, and then much rewriting was required to take
into account the radical changes that were transforming the world economy and its post-war prospects.
At last, when Marshall was 77 years old, *Industry and Trade* (1919), his second masterpiece, finally
appeared. It was a magisterial, largely factual, consideration of trends in the British and international
economy and of future economic prospects. But, lacking an obvious theoretical skeleton, it has not
received from economists the kind of attention lavished on *Principles*, although interest in it is now
beginning to stir among historians of economics.

In its final form, *Industry and Trade* was narrower in scope than had been intended earlier, while the
proposed book on ‘Money, Credit and Employment’ still remained to be written. Over the next four
years, by a remarkable effort, and despite rapidly waning powers, some of the mass of accumulated raw
material remaining was pulled together in *Money, Credit and Commerce* (1923). This contains
Marshall’s fullest treatment of the theories of money and international trade, but it is an imperfect
pastiche of earlier material, some dating back almost 50 years.

In the last months of his life, Marshall toyed with the occasional writings and the memoranda and
evidence for governmental enquiries that he had prepared at various stages during his career, with the
hope of editing them for publication in book form. This was not to be, but his plan was largely fulfilled
after his death in two books sponsored by the Royal Economic Society (Pigou, 1925; Keynes, 1926).

Judged by what might have been, Marshall's authorial performance after 1890 was a sorry one, marked
by repeated procrastination and inconstancy and by chronically over-optimistic expectations. The mantle
of leadership that he had assumed on Jevons's death had proved a heavy one. Both temperamentally and
by virtue of his acknowledged position as the doyen of British economists, Marshall was compelled to
attempt the magisterial and to denigrate the kind of forceful direct essay of which he was eminently
capable.

As Cambridge professor and unquestioned leader of British orthodox economists, Marshall could hardly
avoid becoming a public figure whose pronouncements carried more than a personal weight. His
consciousness of this, and of the precarious public standing of economics, as well as his own
temperament, made him peculiarly reluctant to enter into public controversy, although he would on
occasion fire off a letter to *The Times* on some issue of the day. He served as an expert witness for
several government enquiries and was an influential member of the Royal Commission on Labour of
1890–94. As President of Section F of the British Association in 1890 he took the formal lead in the
movement to found the British (later Royal) Economic Association, but he was not a prime mover.
Indeed, he was not a clubbable or organizational man and relied on others to further whatever goals he
desired for economics and the economics profession at large. But neither was he a recluse. Balliol Croft
received a continuing stream of visitors, ranging from working class leaders to distinguished foreign
economists, while students or young colleagues were always welcomed and offered generous advice
mixed with exhortation.

Although able students interested in economics were in short supply, Marshall did over the years teach
and influence several students who were to make contributions to the subject. From the early Cambridge
period H.S. Foxwell, H.H. Cunynghame, J.N. Keynes and J.S. Nicholson might be mentioned. The Oxford period brought L.L.F.R. Price and E.C.K. Gonner, while the period as Professor in Cambridge produced, among others, A. Berry, A.W. Flux, C.P. Sanger, A.L. Bowley, S.J. Chapman, A.C. Pigou, J.H. Clapham, D.H. Macgregor, C.R. Fay, and, last but not least, J.M. Keynes. The undoubted fact of Marshall's professional leadership of British economics calls for some explanation. He was far from suited to such a role by temperament, and his fussiness and inflexibility could be irritating. For example, Sidgwick, J.N. Keynes, and Foxwell, the most important of his early allies in Cambridge, were all eventually alienated. Marshall's success can be attributed partly to sheer persistence. As in the case of the new Tripos, he had a clear idea of what he wanted to accomplish and worried away at it until he exhausted the opposition and was allowed to have his way. But it must also have been due to the lack of any alternative. The relevant question is not 'Why Marshall?' but 'Who else?' Economics was rapidly evolving as a profession around the turn of the 20th century, creating a leadership vacuum. Leadership was unlikely to emanate from outside Oxford, Cambridge or London, but F.Y. Edgeworth at Oxford was perhaps the last man capable of meeting the need, while E. Cannan at the new London School of Economics, although more suited than Marshall to the hurly-burly of professional politics, was too much the perennial critic and iconoclast to fill the bill. Moreover, whatever Marshall's foibles, the sheer power of his intellectual vision, his international standing as Britain's leading economic thinker, and his ability to inspire an impressive flow of budding scholars, all conspired to make him the only feasible contender.

Marshall's views on the social setting, aims and methods of economics

Marshall saw economics as concerned with those aspects of human behaviour open to pecuniary influences and sufficiently regular and ubiquitous to permit statements of broad scope and some persistence. While maintaining, especially in earlier work, that some heeded moral imperatives might be impervious to pecuniary considerations, he conceded that most behaviour lay within the ambit of the measuring rod of money. On the other hand, he emphasized that motivation was not merely a matter of pursuing pecuniary self-interest, even if broadly conceived to include interests of family and friends. He was anxious to lay the ghost of *homo economicus* and emphasized the human desires to obtain social approbation or distinction and to enjoy the pleasures of skilful activity. He saw actors as diverse as captains of industry and sculptors driven more by the joys of creative activity and the striving for the regard of peers than by the desire for material acquisition. As well as not being pecuniary maximizers in any narrow sense, individuals were for the most part seen as imperfect optimizers. The working classes, especially, often lacked the knowledge and foresight to judge their long-term interests. Marshall's actors were not imbued with complete knowledge of their environment but had to acquire knowledge slowly, and often painfully, through experience. Nor were they endowed with fixed desires and an intrinsic, unchanging character. Indeed, character and preferences evolved as individuals were exposed to new possibilities and chose to enter into new activities. The workplace, in particular, was an important moulder of character. Self-improvement and character development induced by environmental changes, planned or unplanned, both figured largely in Marshall's world view. He believed that social institutions, such as land tenancy practices, were pliable and ultimately moulded themselves into conformity with the individual interests involved, rather than presenting a permanent constraint on mutually desired accommodations. (For this he was taken to task
by his most vehement critic, W. Cunningham, who denied the applicability of modern economic theory to medieval practices – see Cunningham, 1892.) But institutional change must be slow, slower even than changes in individual character and wants, because informal customs and tacit agreements are hard to change. Thus, while the institutions and informal understandings and prohibitions that constrain and mould economic behaviour might ultimately be endogenous they will often be ill adapted to current circumstances and thereby act as an independent constraint on the pursuit of mutually desired accommodations. Institutions, in the broad sense, are important and not always socially rational constraints on individual action.

Marshall was impelled to economics because ‘the study of the causes of poverty is the study of the causes of the degradation of a large part of mankind’ (1920, p. 3). For the bulk of the population, mired in poor living and working conditions, little progress in habits, aspirations and self-esteem could be expected without prior improvement in economic conditions. Such improvement was socially important not so much for its own sake, at least once the pangs of immediate want were assuaged, but because of its instrumental role in permitting and stimulating improvement in the quality and character of the population. What Marshall really valued was not improvement in the standard of living but the enhancement of the standard of life that this improvement made possible. And he entertained little doubt about what constituted a qualitative improvement here, even though – or perhaps because – his values may seem quite parochial and culture-bound.

Economic improvement required appropriate institutions, incentives and attitudes, and would be threatened by wide-scale government intrusions into economic affairs, although some forced income redistribution could be tolerated. But even if economic conditions were improved, the full yield of social betterment would be garnered only if enlarged consumption were turned to ennobling and horizon-expanding channels (rather than, say, to strong drink), involved a due consumption of beneficial leisure, and was accompanied by healthier and less stultifying conditions of working and town life. The government had a guiding role to play here. But even more important would be the assistance and example of employers and the upper and middle classes, who must first rid themselves of a frequent propensity to showy and ostentatious consumption and excessive materialism. The working-class leaders and skilled artisans who had already raised their own standard of life had an important leadership role too. Voluntary individual efforts to assist the rise of the underprivileged must rest on an adequate understanding of economic consequences. For this, as well as to secure an informed electorate, the diffusion of sound economic knowledge was an essential and integral element in the process of socio-economic transformation. Economics thus was itself a noble activity of high importance for the future of mankind.

The broad view of the economy suggested by the foregoing is of a complex evolutionary process of combined economic, social and individual change in which each individual’s abilities, character, preferences and knowledge develop jointly, along with social institutions, markets and the technologies of production and communication. The pursuit of self-interest, broadly conceived, is ubiquitous in directing this evolutionary process, but is subject to inertia, ignorance and limited foresight, not to mention individual mutability.

Unfortunately, Marshall was able to bring little formal analysis to bear on this general ‘biological’ vision of the economy and could only evoke it descriptively. It might be true that ‘the Mecca of the economist lies in economic biology rather than in economic dynamics’ (1920, p. xiv). Nevertheless, the only available analytical tools were those of classical mechanics, tools that Marshall’s early mathematical
training had equipped him to employ skillfully. In fact, chief reliance had to be put on that branch of classical mechanics dealing with statics. Dynamics, beyond a few qualitative applications, required more precise information than was likely to be available. Perforce then, much of Marshall's formal analysis, like that of W.S. Jevons or Léon Walras, was based on simple assumptions of individual optimization and market equilibrium, taking preferences, technology and market institutions for granted. Such provisional or tentative ‘statical’ treatments could often be valuable. Indeed Marshall viewed them as indispensable for the correct analysis of many questions. But he was always anxious to stress that the analysis was preliminary, and perhaps of only transitory validity. This awareness made him impatient of over-elaboration, so that, for example, he showed no interest at all in pushing the statical approach to its logical conclusion in the general equilibrium analysis of the stationary state. For him, equilibrium analysis was an indispensable but rough and ready instrument that needed to be employed with due caution and a continuing awareness of its limitations in the face of a complex ever-evolving reality. It was only a tool and did not itself constitute concrete knowledge.

Marshall had no great profundity as a philosopher of science and had little patience with metaphysics: ‘in a sense … he held no views on method’ (Coase, 1975, p. 27). Marshall's discussions of methodology largely reflect the philosophical presuppositions of his day. His method was in the general deductive tradition of John Stuart Mill, but he sought to emphasize the relativity of particular theories, as contrasted with the universality of the general theoretical ‘organon’ or economists’ toolbox. Anxious to present a public image of the unity of economics in the face of the Methodenstreit among economists in the late 19th century, he attempted to maintain an uneasy balance on method, decrying extended chains of deductive reasoning but denying the possibility of purely inductive inference unguided by a coherent conceptual framework. Economics had room for specialists in both deductive and inductive methods, but both must ultimately be co-workers. Assumptions must be selected with close regard to the facts of the case and potential disturbing causes must be kept prominently in mind and due allowance made for them. J.N. Keynes described Marshall's analytical method as ‘deductive political economy guided by observation’ (1891, p. 217n) and Keynes's chapter ‘On the Deductive Method in Political Economy’ (1891, pp. 204–35) is perhaps as good a rationalization of Marshall's method as one can find.

**Intellectual debts**

The intellectual background to Marshall's work in economics was established in the 1860s, partly in his stringent mathematical training, but perhaps more importantly in the heady mixture of utilitarianism, evolutionism and German idealism which he eagerly imbibed in the years immediately following his graduation. He seems to have started on economics from J.S. Mill's *Principles of Political Economy* (1848), moving on to the classic works of Smith and Ricardo. At a fairly early stage, probably around 1868, he discovered Cournot's *Récherches* (1838), which provided examples of the application of mathematics to economic questions. Acquaintance with J.H. von Thünen's work, which influenced Marshall's distribution theory, must have come somewhat later, in the early to mid-1870s. During the 1870s and early 1880s Marshall also read widely on economic development and socialism, including much literature in German, the only foreign language he mastered thoroughly. After that, his reading seems to have been concentrated mainly on factual and practical matters. Once his own theoretical views had crystallized, he appears to have been reluctant to do more than attempt to explain and clarify them to
others, and to have taken remarkably little interest in new theoretical issues or in the theoretical ideas of others.

In many ways, the list of Marshall's denials of theoretical indebtedness is more remarkable than that of his acknowledgments. He claimed to have developed his ideas on consumer surplus before learning of anticipations by J. Dupuit and H. Fleeming Jenkin. The grudging attitude to W.S. Jevons's marginal utility theory shown in his review (1872) of Jevons (1871), although subsequently relaxed, was never replaced by any acknowledgement of indebtedness. He showed little or no interest in the work of Walras, gave meagre credit to Carl Menger, whose work must have become known to him by the early 1880s, patronized Pantaleoni and Böhm-Bawerk, largely ignored Pareto, and so on. Even in the case of Edgeworth, one of his few intimates, Marshall felt that undoubted theoretical powers were guided by an unreliable judgement and refused to follow Edgeworth's subtle elaborations far. In fact, the only major theorist of the day to command Marshall's entire admiration and respect was J.B. Clark, and even here there was no acknowledgement of serious indebtedness. This tendency to denigrate the work of his contemporaries was matched by an equally strong tendency to overvalue the achievements of the British Classical School led by A. Smith, D. Ricardo and J.S. Mill. For one reason or another – perhaps a personality quirk, perhaps an effort to boost the public esteem of economics – Marshall was prone to exaggerate the intellectual continuity and maturity of his subject – see O'Brien (1990) on this.

A growing interest in wider intellectual influences on Marshall in his formative years 1865–70 has been sparked by the publication and analysis of his early philosophical manuscripts (Raffaelli, 1994, 2003), especially a paper entitled ‘Ye Machine’ that outlines a mechanism capable of learning new routines from experience, thus freeing its limited learning ability to gradually establish new and higher level routines, and so on. It appears that Marshall's ambitions in these early years lay in the area of ‘psychology’ or perhaps better in the ‘philosophy of mind’. Whether the world lost more than economics gained from his switch to economics remains an open and perhaps insoluble question. But it does appear that the pattern of a sequential routinizing of new methods, continually leading to new levels of individual or organizational complexity, continued to play a significant part in Marshall's economic thought. More generally it is clear that he read philosophical literature widely in his formative years: Kant, Hegel, H. Spencer, and others. But whether and how these sources influenced his economic thought remains uncertain, partly because evidence is slight or absent.

**Demand theory**

So far the discussion has remained on a very general level, dealing with broad aspects of Marshall's life and work. At this point there begins a much more detailed and technical consideration of various aspects of his theoretical contributions, commencing with his demand theory. Marshall's treatment of the theory of demand is sketchy and incomplete, concentrating on the demand for a single commodity, or commodity group, against a loosely defined background. A utility-maximizing individual's utility is defined by \( u(x) + w(y) \) where \( x \) is the individual's consumption of the particular good \( X \), while \( y \) is the individual's expenditure on all other goods. This expenditure is measured in money of constant purchasing power: that is, deflated by a general price index. How this index is defined and whether, as seems appropriate, the price of \( X \) is excluded from it, is left unclear. Such money can be treated as a composite good, \( Y \), and \( y \) can be regarded as the amount of this composite good consumed. If \( m \) is the
individual’s initial endowment of Y, then \( y = m \) whenever \( x = 0 \), while if X can be freely purchased at a fixed price of \( p \) units of Y per unit of X then \( x \) and \( y \) must satisfy the constraint \( px + y = m \). Marshall assumes that the utility functions \( u(x) \) and \( w(y) \) have positive but diminishing marginal utility so that \( u'(x) > 0 > u''(x) \) and \( w'(y) > 0 > w''(y) \), where single and double primes are used to denote first and second derivatives. The maximum expenditure, \( e \), that the individual is willing to make to secure \( x \) units of X is implicitly defined as a function \( e(x, m) \) by \( u(x) + w(m - e) - w(m) = 0 \). Providing that \( x \) and \( y \) are both positive, the rate at which \( e \) increases with \( x \) is \( u'(x) / w'(m - e) \) by the implicit function theorem. This ratio would be the demand price for the \( x \)th unit of X if all previous units had been acquired at their corresponding demand prices: that is, if the individual had faced perfect price discrimination in exchanging Y for X. Alternatively, if the individual had been able to obtain any amount of X at fixed per unit price, \( p \), the resulting demand function \( x(p, m) \) for X would be implicitly defined (given \( x \) and \( y \) are both positive) by the first-order condition \( u'(x) - pw'(m - px) = 0 \). Partial differentiation of \( x(p, m) \) shows that \( x \) falls as \( p \) increases, while an increase in \( m \) increases both \( x \) and \( y \): thus, the Giffen possibility of an increase in \( p \) increasing the quantity of X demanded is excluded. But an increase in \( p \) may lower or raise the value of \( px \), so that demand for X may be price elastic or price inelastic at a given \( p \).

The possibility of buying at a fixed price rather than facing perfect price discrimination creates a consumer surplus of \( e(x(p, m), m) - px(p, m) \). This is the additional amount that could have been extracted by perfect price discrimination for all units up to the price-taking optimal one. That this surplus is positive follows from the fact that every infra-marginal unit of X acquired creates a surplus utility when the individual faces a fixed price (since \( u'(x) > pw'(m - px) \) for each such \( x \)) but no surplus when the individual is faced with perfect price discrimination.

Marshall’s mathematical notes (1920, pp. 838–42) on his general case are obscure and puzzling. Doubtless he felt this case was too dependent on unobservables to be of much practical value. He therefore emphasized the special case in which the marginal utility of money is treated as a constant. The rationale offered is that an individual’s ‘expenditure on any one thing … is only a small part of his whole expenditure’ (1920, p. 842). This simplifies \( e = e(x, m) \) above to \( e = u(x) / w'(m) \) while \( x(p, m) \) is now defined implicitly by \( u'(x) / w'(m) = p \). At the \( x \) value defined by the latter equation, consumer surplus arising from the ability to buy any amount of X at the per-unit price \( p \) can be expressed in utility terms as \( u(x) - xu'(x) \) or in money terms as \( u(x) / w'(m) - xu'(x) / w'(m) \). These formulae are exactly analogous to the standard formula for Ricardian land rent, with the first term the output obtained on a piece of land from the application of \( x \) doses of variable input, each dose remunerated at the common marginal product. Partly because of this analogy, Marshall used the term ‘consumer rent’ rather than ‘consumer surplus’ prior to 1898.

Although priority must go to Dupuit, Marshall’s simple concept of consumer surplus based on the assumption of a constant marginal utility of money has been influential. But he was well aware of the complications arising from variation in the marginal utility of money: ‘Strictly speaking we ought to take account of the fact that if he spent less on tea the marginal utility of money to him would be less than it is, and he would get an element of consumers’ surplus from buying other things at prices which now yield him no such rent’ (1920, p.842). Although such influences may be ‘of the second order of
smallness’ they raise the more disquieting issue of assessing the overall welfare effects of changes that affect many markets simultaneously. On this Marshall had little to say: ‘the task of adding together the total utilities of all commodities, so as to obtain the aggregate of the total utility of all wealth, is beyond the range of any but the most elaborate mathematical formulae’ (1920, p. 131n.). It was a task he chose not to pursue. Apart from generalizing for the possibility that a certain quantity of good X might be indispensable, Marshall elected not to develop his demand theory further, or even to generalize it to incorporate utility functions that were not additively separable (1920, p. 845). It is clear that each commodity in turn might take the spotlighted role of good X and that in certain circumstances simultaneous consumer surpluses for several goods might be added (1920, p. 842). An unpublished early manuscript note from the 1870s on the theory of taxation (Whitaker, 1975, vol. 2, pp. 285–305) had advanced matters considerably further by working formally with the maximization of utility under a budget constraint, but this lead was not followed up in print and some of its lessons for welfare economics were apparently forgotten. Principles gave a clear intuitive account of the consumer’s overall optimization problem (1920, pp. 117–23), but failed to connect it to the resulting interrelated set of demand functions for the various goods consumed. Indeed, it is clear that for positive purposes Marshall was willing to treat market demand functions in a quite pragmatic way, admitting, for example, close substitutes or complements and the Giffen exception, all inconsistent with the simple formal theory set out above. In judging this, it must be borne in mind that consistency and generality of ‘statical’ analysis were not Marshall’s real goal. Rather, ‘fragmentary statical hypotheses are used as temporary auxiliaries to dynamical – or rather biological – conceptions’ (1920, p. xv).

The market demand for a good that is offered to all actual or potential buyers at the same given price is of course obtained as a function of that price by summing the amounts demanded at that price by all the consumers. A sufficient but not necessary condition for market demand to fall as price increases is that each individual’s demand decreases. The now familiar concept of market demand elasticity – proportional quantity change divided by proportional price change – was first introduced by Marshall, although several authors had come close to the idea previously. It appeared without flourish in (1885c), and appeared more prominently in Principles. But Marshall himself made relatively little use of it. Bibliographic note: Marshall’s treatment of demand is essentially contained in (1920, pp. 92–137, 838–43). An influential, although controversial, interpretation of Marshall’s demand theory is given by Friedman (1949). Biswas (1977) gives another alternative to the orthodox reading provided by Stigler (1950) that is largely adopted here. An excellent overview is Aldrich (1996). On consumer surplus see Chipman (1990).

Production and long-period competitive supply

In deriving the long-period supply curve of a commodity in Principles, Marshall envisages production as organized by firms, typically family businesses. Each firm strives to minimize its production costs, substituting one productive factor or production method for another according to the ‘Principle of Substitution’. In its simpler forms this involves marginalist adjustment to bring relative marginal value products into line with relative marginal costs. But more generally, the Principle of Substitution is akin to a natural selection process, being ‘a special and limited application of the law of survival of the fittest’ (1920, p. 597). Marshall’s firms do not have costless access to a common production function, but
must grope and experiment their way to cost-reducing modifications. The long-period supply curve is defined for a given state of general scientific and technical knowledge. But each firm must explore this to some extent anew.

Although the distinction is not entirely clear – distinctions seldom are for Marshall – two polar cases may be distinguished within his theory of long-period competitive supply. These will be referred to as the ‘agricultural’ and the ‘industrial’ cases. The former is much the more straightforward and involves an industry in which production is relatively simple, internal economies of scale are minimal, and the product is homogeneous and easily marketed. The optimal firm size is small, and management is sufficiently routine to need no exceptional ability to keep a firm operating efficiently. As the overall market expands, new firms may be added, but changing composition of the population of firms is not an essential feature of this case.

The long-period supply price per unit of output at which such an industry can supply any quantity of output must just cover the cost of maintaining that level of output indefinitely. That is, it must just suffice to pay all the inputs (including management) needed to produce that level of output in a cost-minimizing way at rates that just ensure that the requisite input quantities will continue to be forthcoming indefinitely. In the case of skilled workers, in particular, the rate must just suffice to induce parents to apprentice new workers to the industry at a rate exactly offsetting the attrition through retirement and other causes. Similarly, the return to fixed capital must just suffice to induce replacement of the existing stock of fixed assets, while the return to management must keep up the necessary replacement flow of managers. On the other hand, the return to land services must just suffice to prevent these services from migrating elsewhere, replacement not being necessary. As the level of industry output being considered is increased, the supply price will probably rise, mainly because of the need to pay a higher return to land so as to attract a greater supply from other uses, but perhaps also because of the need to pay more for rare natural talents that, like land, must be attracted in greater quantity from other uses, not being capable of replication through education and training. Such a tendency for long-period supply price to rise with output may be mitigated though seldom eliminated by substitution against inputs whose supply price is rising, and by possible external economies that increase each firm's efficiency by influences that depend, not on its own output, but on the entire industry's output. A tendency for supply price to rise with output will imply that infra-marginal units of those inputs whose supply prices are rising receive rents, since all units will be remunerated at the rate necessary to induce continuing supply of the marginal unit. In the absence of external economies (or diseconomies) the total rent or producer surplus generated will be the ‘triangular’ area above the supply curve. That is, it will be

$$ R = xg(x) - \int_0^x g(v) dv $$

where $g(x)$ is the supply price of output quantity $x$, an increasing function of $x$. This result does not apply in the presence of external economies. In later editions of the Principles, Marshall introduced the device of the ‘particular expenses curve’ (1920, pp. 810–12) to display rent in such a case, but this ex post construction does not give an independent basis for determining rent.
It is clear that the long-period supply curve of an industry depends on the general economic background against which the industry is assumed to operate. As is the case with demand, Marshall does not consider this background in detail. He assumes prices to be expressed in money of constant purchasing power and recognizes on occasion that there may be close interrelations between two industries (for example, they may compete for the same specialized land). He also recognizes that ‘a theoretically perfect long period must give time enough to enable not only the factors of production of the commodity to be adjusted to the demand, but also for the factors of production of those factors of production to be adjusted and so on’ (1920, p. 379n.), and that this leads ultimately to the assumption of a stationary state. But he is not willing to follow this route far and is content in general to take the supply conditions of the factors of production for granted when analyzing long-period price determination.

In the ‘manufacturing’ case, to which we now turn, the product is differentiated, marketing is difficult, and each firm must build up and retain goodwill and a customer connection for its own specialized product. There are substantial internal economies of scale in production and successful management calls for business ability of a high and rare character. In this environment, a family business may be built up by an exceptional founder, but this build-up must be slow because of the difficulty of establishing a market and perhaps also because of constraints on financing. And when the founder passes on, his successors are unlikely to have equal talents or even the lesser talents required to prevent the firm's business from languishing. By the third generation of succession, the firm is likely to expire. Even a joint stock company (a case added rather as an afterthought) is likely to ossify into bureaucratic stagnation, and presumably the same is true of family businesses that rely on paid managers. Thus, the typical firm in the manufacturing case passes through a finite life cycle, and the industry is comprised of a population of such firms at various phases of the life cycle, some in the early expanding phase, others in decline.

The long-period supply price at which such an industry can supply a specified level of output must now be regarded as an index of the prices of all the different firms’ products. It must meet all the conditions required in the agricultural case. Thus, the price must allow for a continuing replacement flow of the various types of workers (including managers) and fixed assets, as well as the retention of the necessary ‘land’ services. But now there must also be a surplus sufficient to induce a replacement flow of new firms – a supply of ‘business organization’ that will just suffice to replace the expiring firms and keep the age distribution of firms constant.

Industry equilibrium does not require each firm to be in an unchanging equilibrium any more than the trees in the proverbial forest. A new firm will be established if the prospective earnings over the expected life cycle appear to justify the cost and trouble involved. The firm's initial earnings are likely to be negative as it slowly builds up its technical expertise and market connections, but these early losses can be regarded as investments to be recouped in the later stages of the firm's prospective life cycle.

It is here that Marshall's ‘representative firm’ enters the picture. It is best regarded as a parable that avoids the need to consider the entire distribution of firms. By definition, the long-period supply price of any level of industry output is the average cost of the representative firm at that level of output. Industry-level magnitudes may then be regarded as if they were generated by a fixed number of unchanging representative firms rather than by the actual heterogeneous body of ever-changing firms. In other words, the manufacturing case may be treated as if it were an agricultural case populated by representative firms only. Such arguments add nothing conceptually and are prone to confuse, although it might be noted that Marshall believed an acute well-informed observer could select an actual firm that...
was close to being representative in this sense.
The average cost and size of the representative firm will change as industry output changes. There are two main reasons for this. A larger industry output is likely to generate more external economies, lowering the costs of every firm. But more importantly, the larger industry demand is, the easier it will be for a new firm to build up a market, and so the larger the size to which firms will grow before they begin to decline. This will bring about greater access on average to unexhausted internal economies of scale, again leading to lower costs on average. For both these reasons, long-period supply price is likely to decline as a larger industry output is considered, even though the opportunity cost of obtaining greater supplies of land services and rare natural talents may rise. Again, the particular expenses curve may be used to display the producer surpluses or rents accruing to such scarce factors at any given level of industry output, but the relationship of this family of curves to the long-period supply curve is tenuous and complex. Rent obviously cannot be represented by a ‘welfare triangle’ above the supply curve when the latter is falling.
The conception of competition in Marshall's manufacturing case is much closer to later ideas of imperfect or monopolistic competition than to modern notions of perfect competition. Products are differentiated and firms are not price takers, but face at any time downward-sloping demand curves in their special markets. Even if the difficulties of rapidly building up a firm's internal organization can be overcome, the resulting enlarged output cannot be sold at a price covering cost – even granted substantial scale economies in production – without going through the slow process of building up a clientele and shifting the firm's particular demand curve. The time this takes is assumed to be considerable relative to the duration of the firm's initial vitality. But in some cases the difficulties of rapid expansion may be overcome. They may not have been very severe, as when different firms’ products are highly substitutable, or the firm's founder may have unusual genius. In such cases the industry will pass into a monopoly or be dominated by a few, strategically interacting firms, or ‘conditional monopolies’ as Marshall termed them.
Marshall's reconciliation of persisting competition with increasing returns and falling supply price is complex and problematic, but it does not depend in any essential way on scale economies being external to the firm. The concept of external economies is one of his significant contributions, although his treatment of it can hardly be called pellucid. But it was added more for verisimilitude than because it was theoretically essential to the structure of his theory.
The issues surrounding Marshall's representative firm, and the problem of reconciling the persistence of competition with the presence of unexhausted internal economies of scale, continue to receive attention among historians of economic thought but no definitive reading has yet been attained, or perhaps ever will be. The account given above is well supported by Marshall's text, but as is often the case with Marshall, elements of ambiguity and vagueness remain.

Price determination and period analysis
The long-period supply curve for any good indicates for each market quantity the least price at which that quantity will continue to be supplied indefinitely. The long-period equilibrium price and quantity are determined by the intersection of this supply curve with the market demand curve, assumed to be negatively sloped, that indicates the highest uniform price at which any total quantity can be sold. In the agricultural case, equilibrium will be unique as the supply curve slopes positively. But in the manufacturing case, the supply curve, as well as the demand curve, may have negative slope, so that multiple equilibria can occur. Equilibrium is adjudged locally stable if demand price is above (below) supply price at a quantity just below (above) the equilibrium quantity. The intuitive justification for this is that the actual price of any available quantity is determined by the demand price, while quantity produced tends to increase (through both expansion of existing firms and entry of new firms) whenever an excess of market price over supply price promises high profits, while it tends to decrease in the opposite case.

This stability argument is sketchy and, in any case, there still remains the question of exactly how a new long-period equilibrium is attained following some change, such as a permanent shift in the demand curve. One possibility would be to consider explicitly the adjustment process through time, but Marshall preferred to approach the problem by another route – his period analysis, one of his most memorable and lasting contributions. (His passing claim (1920, p. 808) that the long-period supply curve may not be reversible, supply price depending upon past-peak output as well as current output, is something of an exception to this generalization. It appears to rest on some restriction of the degree of downward supply adjustment, and so not to involve a true long-period analysis, or else to invoke a kind of learning by doing that once attained is not readily lost.)

Period analysis is Marshall's most explicit and self-conscious application of the comparative-static, partial-equilibrium method with which his name will always be associated. As he observed,

> the most important among the many uses of this method is to classify forces with reference to the time which they require for their work; and to impound in *Caeteris Paribus* those forces which are of minor importance relatively to the particular time we have in view. (Guillebaud, 1961, vol. 2, p. 67)

Which forces or variables are to be hypothetically frozen or impounded, and which are to be determined by the requirements of equilibrium (an equilibrium contingent upon the contents of the *ceteris paribus* pound, of course), should be determined pragmatically in each case with the aim of focusing on the features deemed dominant in that case. As a general rule, those forces should be impounded which move very slowly, or else bounce around very rapidly, relative to the length of ‘the particular time we have in view’. This is well illustrated by Marshall's example of a fish market, where the focus may be on the determinants of price over a few days, a few months, or several years, or even decades (1920, pp. 369–71). As an expositional matter, however, and also to embody distinctions of wide (but not universal) applicability, Marshall emphasized three broad cases. Temporary or market equilibrium analysis proceeded on the assumption of a fixed stock of output already available or in the pipeline. Short-period normal equilibrium analysis permitted output to be varied, but not the stock of productive ‘appliances’ available to produce that output. ‘Appliances’ must be taken here to cover skilled labour and business organization as well as fixed capital assets, so that the existing set of firms is to be taken as given. Finally, long-period normal equilibrium, which has already been considered, allows the stock of
appliances, as well as the level of output, to be freely varied. In this case equilibrium incorporates the conditions necessary for inducing an exact replacement flow of each kind of appliance, including a replacement flow of new firms in the manufacturing case. Temporary equilibrium for a perishable commodity is simply a matter of selling off the existing stock. Marshall recognizes the possibility of ‘false trading’ – sales at a non-equilibrium price – but argues that (a) this will not affect the eventual price if the marginal utility of money is constant, and (b) price will quickly settle close to the uniform price that would just clear the market if used in all transactions. With a storable good there is the further speculative possibility of holding back supply for future sale, and this gives expected future cost of production an indirect role in influencing current market price. Cost of production already incurred is an irrelevant bygone, however.

In short-period normal equilibrium, output is adapted to demand within the constraints set by the fixed supply of available ‘appliances’. High demand will raise equilibrium output, but only within the limits possible by working existing appliances more intensively or pulling in versatile unspecialized labour and land from elsewhere. Low demand will lead to low utilization of appliances, perhaps idleness of some, and migration of unspecialized inputs to elsewhere. In the agricultural case a firm will change output until marginal prime or variable cost equals market price. In the manufacturing case, a fear of spoiling the future market or invoking retaliation from competitors tends to make a firm’s output more responsive to variation in market price, and hence to make market price less responsive to demand shifts. Otherwise, the two cases are similar, both involving a fixed population of firms and a rising supply curve.

The return received by an appliance will often exceed the minimum necessary to induce its operation at the chosen intensity (its prime cost) and this excess is a ‘quasi rent’. To the extent that land and rare natural talents are immobile in the short period, or less mobile in the short period than the long, their returns too will often have a quasi-rent element. Otherwise, they will receive only differential rents, though often at rates differing from their long-period values. It should be stressed that the concepts of quasi-rent and differential rent are relative to a specific use. The prime cost necessary to retain an input in this use may itself include rent or quasi-rent when viewed in the context of a more inclusive set of alternative uses. Thus, from the viewpoint of all possible uses in the economy, the return to any factor in fixed supply is entirely a rent or quasi-rent (the latter if fixity is only short-period).

Marshall paid little attention to the possibility that forces similar to those constraining the adjustment of supply when time is limited might also operate on the side of demand. Thus the same considerations underlie the market demand curve whether it is coupled with a temporary, short-period or long-period supply curve. In each case, market equilibrium price and quantity are determined by the intersection of the appropriate demand and supply curve. The stability of temporary equilibrium is directly asserted. The stability of short-period equilibrium depends on the same quantity-adjustment argument invoked for long-period equilibrium, but since the short-period supply curve is always positively sloped, uniqueness and stability are assured.

The theory of short-period normal equilibrium was designed as a tool for analysing unemployment and economic fluctuations in the never-completed second volume of Principles. But it also has use in explaining adjustment to a permanent disturbance. Suppose, for instance, that an industry is in long-period equilibrium when a permanent shift in demand occurs. The immediate or short-period effects can be analysed by freezing output and stocks of appliances at their initial levels. Insight into the actual adjustment through time can then be obtained by appropriately changing the output level assumed in the
temporary equilibrium, so that movement of temporary equilibrium towards short-period equilibrium can be traced out as output, but not stocks of appliances, adjusts. Similarly, the levels assumed for the stocks of appliances in this short-period equilibrium can be allowed to change and the movement of short-period equilibrium towards long-period equilibrium traced out. Such arguments are now a staple of elementary pedagogy. They clearly require additional assumptions about the adjustment of output and the way in which investment or disinvestment in appliances proceeds, and are only a poor and ambiguous substitute for an explicit dynamic analysis. But such ‘statical’ procedures, although imperfect, may, in Marshall's words, be ‘the first step towards a provisional and partial solution in problems so complex that a complete dynamical solution is beyond our attainment’ (Pigou, 1925, p. 312).

Marshall's period analysis, and more generally his partial-equilibrium approach to price determination, was designed in large part as a usable tool for the analysis of concrete issues. Its longevity amply testifies to its usefulness in this respect. But it was also meant to serve the more doctrinal purpose of clarifying the respective roles utility and cost of production play in determining value. The aim was to show that the greater the scope for supply adjustment permitted in the definition of equilibrium, the more dominant the supply side influence on price becomes. This doctrinal goal helps to account for the rather heavy weight given to long-period analysis in *Principles*. For, as Marshall recognized, its value as a tool of applied analysis is seriously qualified by the fact that ‘violence is required for keeping broad forces in the pound of Caeteris Paribus during, say, a whole generation, on the ground that they have only an indirect bearing on the question in hand’ (1920, p. 379n). That is, there is no good ground for assuming that background forces such as technology and tastes will remain constant for the length of time required for long-period equilibrium to be practically relevant. For concrete analysis of problems of such long duration it will often be necessary to transcend the period analysis, with its reliance on statical equilibrium, and undertake directly an analysis of secular change, of which Book 6, Ch. 12 of *Principles* on the ‘General Influence of Economic Progress’ (1920, pp. 668–88) offers the main example, but not a very impressive one.

In emphasizing the role that cost of production plays in the determination of long-period value, Marshall was not content to rest on money costs of production but sought to go behind these costs to the real costs – the efforts and abstinences – for which in a non-coercive economy the money costs are recompense. In doing so he purported to follow Ricardian tradition, but is more plausibly viewed as attempting to place the newer subjective value theories in broader (but still subjective) focus. Just as the price paid by a consumer serves as a measure of marginal utility, with a consumer surplus gained on infra-marginal units, so the unit price received by a worker or saver measures the real cost or disutility at the margin, with a producer surplus on the inframarginal units of effort or abstinence. But, as Marshall recognized, the parallel holds imperfectly in the long period when workers must be regarded as produced means of production as well as final consumers and cost bearers. In particular, parental sacrifice for raising and training offspring obtains little or no direct pecuniary reward.

Normal value and normal profit

Implicit in the preceding discussion are Marshall's conceptions of normal value and normal profit. Normal value is defined as the value that would result ‘if the economic conditions under view had time to work out undisturbed their full effect’ (1920, p. vii). It is contrasted with market value, which is ‘the actual value at any time’ (1920, p. 349). Normal value is hypothetical, resting on a *ceteris paribus* condition, its role being to indicate underlying tendencies. The normal value of a commodity may approximate its average value over periods sufficiently long for the ‘fitful and irregular causes’ (1920, pp. 349–50) that dominate market value to cancel out, but this should not be presupposed automatically outside a hypothetical stationary state.

The distinction between normal and market value is closely related to the distinction between natural and market value found in the work of Smith and the classical economists. In 1879 Marshall had identified normal value with ‘the results which competition would bring about in the long run’ (1879b, p. vii), but in *Principles* he switched to the view that ‘Normal does not mean Competitive’ (1920, p. 347) and admitted any kind of regular influence so long as it was sufficiently persistent. The economic forces hypothetically permitted to achieve full mutual accommodation could now be chosen appropriately for each case. In particular, the distinction between short-period and long-period normal (or ‘sub-normal’ and ‘true-normal’ in earlier editions) was emphasized.

Profit was viewed by Marshall as the residual income accruing to a firm's owner, a return on the investment of the owner's own capital and recompense for the pains of exercising 'business power' in planning, supervision and control. Normal profit is essentially an opportunity cost, the minimum return necessary to secure the owner's inputs to their current use, or rather to accomplish this for an owner of normal ability. Marshall presumes that there is a large and elastic supply of versatile actual or potential owner managers of normal ability. In long-period equilibrium each of these must just receive the same normal rates of return on investment and exercise of business power whatever the line of business. However, those who are exceptional may do better, essentially by exerting greater business power. These common rates of normal return are simultaneously determined, along with the normal returns to other kinds of effort and abstinence, by Marshall's macroeconomic theory of the long-period determination of factor incomes (see below). Although it is the case that profits are a residual, rather than a contractually agreed amount like other incomes, this difference is immaterial in long-period equilibrium. In particular, a long-period equilibrium analogy between ordinary wages and the normal earnings of business power is stressed. Normal profit is a necessary element in the costs that underlie the long-period normal supply curve, but actual profit is a quasi-rent or producer surplus for shorter periods.

Normal profits are a return to ‘business power in command of capital’ and compensate for three distinct elements: ‘the supply of capital, the supply of the business power to manage it, and the supply of the organization by which the two are brought together and made effective for production’ (1920, p. 596). The combined compensation of the latter two components comprises ‘gross earnings of management’, the return to the second component being ‘net earnings of management’. In long-period equilibrium, the normal return to the first element is imputed at the market interest rate on default-free loans, and that to the second component at the rate paid to hired managers performing comparable tasks. The residual third element, the return to ‘organization’, is most straightforwardly interpreted as an extra return on owned capital equivalent to the premium for default risk, or 'personal risk', that would have to be paid on borrowed capital. In the manufacturing case, the annual level of normal profit for each firm in an
industry must be interpreted as the annualized equivalent of the expected stream of returns that is just sufficient to induce an individual of normal ability to found a firm in the industry rather than divert energies and capital elsewhere. Normal ability here is defined relative to other potential founders of firms, a group already exceptional relative to the population as a whole. By construction, such normal profits must be earned by the representative firm.

**Welfare economics**

To serve as a tool of welfare economics, monetary measures of consumer surplus, producer surplus and rent must be aggregated over individuals. But how are the resulting sums to be interpreted? Marshall's very limited and proximate attempts at formal welfare arguments are carried out within a utilitarian framework, for which the goal is maximizing aggregate utility. He implies that interpersonal utility comparisons are possible in principle and that utility functions will be similar for all members of any group that is homogeneous in terms of mental, physical and social attributes. Within such a group, the marginal utility of money will be the same for two individuals having the same income, and lower for the richer of two individuals with differing incomes, on the assumption in each case that both individuals face the same trading opportunities. A postulated government action may impose gains and losses on various individuals that can be measured and aggregated in money-equivalent terms. But how can these measures be translated into statements about aggregate gains and losses of utility? Marshall emphasizes two special cases. First, if the gains and losses are both proportionately distributed over income classes in exactly the same way, then net aggregate gain (positive or negative) in money will serve as an ordinal index for the net aggregate gain in utility. A corollary of this is that if two alternative actions affecting the same group have the same relative distributions of gains and losses over income classes then the alternative yielding the greater net aggregate gain in money must have the greater net aggregate gain in utility. Second, if some change makes for a zero net aggregate change in money terms, but the gains accrue to individuals of lower income than those bearing the costs, then the aggregate net utility gain must be positive – a warrant for certain redistributive policies. In other cases he sees that careful assessments of the marginal utility of money to the various injured and benefited groups would be needed, assessments that could be used to transform monetary gains and losses into utility measures. He toys (1920, pp. 135, 842–3) with using the Bernoulli hypothesis on the relation between wealth and utility as a basis for such calculations, but gives little indication as to how assessments might be made in practice.

Marshall's best known and most successful foray into formal welfare analysis was his proof that total welfare might be increased by using the proceeds of a tax on an ‘agricultural’ industry to subsidize a ‘manufacturing’ industry. All comparisons involved long-period equilibria and relied on the validity of aggregated money-equivalent measures of gains and losses. He demonstrated that the gain in consumer surplus in the expanded decreasing-cost manufacturing industry might exceed the combined loss in consumer and producer surplus in the contracted increasing-cost agricultural industry. No formal account was taken of a possible gain in producer surplus in the manufacturing industry as this merely
makes the argument hold *a fortiori*. The crucial point in this argument, as Marshall recognized, is that producers are not harmed by ‘a fall in price which results from improvements in industrial organization’ (1920, p. 472). It is immaterial whether the improved organization of the enlarged manufacturing industry is due to external economies or to internal economies resulting from an increase in the size of the representative firm. Contrary to much subsequent opinion, Marshall's tax-subsidy argument is not necessarily dependent upon external economies.

Another significant, but overlooked, welfare analysis provided by Marshall was that of a monopolistic public enterprise in a situation where taxation involves an excess burden (1920, pp. 487–93, 857–8). In the absence of this excess burden Marshall proposes that the enterprise seek to maximize ‘total benefit’, the sum of net profit and consumer surplus. This implies marginal cost pricing, since the area below the demand curve and above the marginal cost curve is maximized when the two curves intersect. But, given that taxation involves an excess burden, it may be desirable to augment tax receipts from monopoly revenue if the sacrifice of consumer surplus is small. Marshall proposes the alternative goal of maximizing ‘compromise benefit’, the sum of consumer surplus and monopoly revenue when the latter is in effect multiplied by the marginal cost of raising a unit of government revenue from other sources. Maximization of compromise benefit leads to the setting of what has come to be termed a ‘Ramsey price’.

The two examples of welfare analysis just described proceed within a partial equilibrium framework, treating each industry as negligible compared to the entire economy and regarding the marginal utility of money as approximately constant to each individual. Marshall's rather fragmentary remarks on optimal tax systems, income redistribution and the ‘doctrine of maximum satisfaction’ cannot be restricted in this way, and so raise serious unresolved analytical difficulties. On the other hand, his tax-subsidy argument was a valid counterexample to arguments that competition must lead to a social optimum, or that optimal indirect tax systems must involve uniform tax rates. It must also be borne in mind that utilitarian welfare economics was for Marshall only a first step towards a more evolutionary analysis of possible modes of improving the physical quality and the values and activities of mankind.

### Interrelated markets and distribution theory

Marshall was anxious to emphasize the interdependence of markets and introduced his treatment of joint and composite demand and supply largely for this purpose. A group of goods is jointly supplied if all are outputs of a single productive activity and jointly demanded if all are inputs. On the other hand, a particular good is compositely supplied or demanded if it is provided or acquired by several distinct productive activities. Marshall's formal treatment of joint demand and supply proceeded on the general assumption that the products involved were consumed or produced in fixed proportions, as did his related analysis of the ‘derived demand’ for any one of several jointly demanded inputs – ‘derived’ since
the demand for such inputs is derived from the demand for their joint product. The derived demand curve for a specific input can be constructed conceptually by supposing that its supply is perfectly elastic at an arbitrary price and that the markets for the output and all the inputs (including the specific input) adjust to equate quantity demanded to quantity supplied in each market. This gives a price quantity combination on the derived demand curve for the specific input. Other such combinations can be obtained by varying the arbitrarily chosen price and repeating the exercise, and so on. Marshall laid down four rules for inelasticity of derived demand. These were that the input should have no good substitutes, that the product it helps make should be inelastically demanded, that the input should account for only a small part of production costs, and that cooperating inputs should be inelastically supplied. Fixity of input ratios guaranteed the first condition, but the more general case was asserted rather than proven. The advantage of working with the derived demand curve for an input is that it permits a more transparent analysis of the effects of changes in the supply conditions of the singled-out input.

The prime example of joint demand is the demand for productive inputs, and Marshall's analysis of market interdependence was carried through more fully in this specific connection, the role of substitution among inputs receiving full acknowledgement. The principle of substitution ensured that input usage tended to be adjusted by firms so as to minimize the total production cost of any level of output. Thus, the value of the marginal product of an input (or the ‘net product’ as Marshall termed it) tended under competition to equal the unit price of the input. There has been some confusion about the relation between ‘net product’ and marginal product because the former allows usage of other inputs to adjust consequentially when the chosen input is increased while the latter does not. But, provided that the initial situation is cost-minimizing, the adjustment of other inputs (if small) has no effect on the change in output – an application of the envelope theorem. Marshall recognizes this explicitly (1920, p. 409n) and there is no good reason for refusing to classify him as a marginal productivity theorist.

Interdependence among input markets was further highlighted in the analysis of the competition of several industries for an input that is in temporarily or permanently fixed overall supply. A peculiarity of this last analysis was the insistence on excluding from the marginal cost of any industry the cost of bidding such fixed resources away from other uses. This is a perfectly legitimate application of the general envelope theorem: provided resource use is optimally adjusted, the marginal cost of increasing output will be the same whatever input or sub-group of inputs is increased. But Marshall's insistence on asymmetry where there is really symmetry can be accounted for only by his desire to legitimize, and extend to quasi-rent, the classical doctrine that rent is price determined rather than a price-determining element of cost.

Marshall's vision of market interdependence culminates in his treatment of income distribution, where he seeks to bring out the extents to which the interests of different factors of production are harmonious or conflicting. Distribution is determined by the interaction of the demands and supplies for the various inputs, the demands being essentially joint demands. Marginal productivity is a theory of input demand, not a complete theory of distribution, because the supplies of the various inputs cannot be viewed as fixed, at least in the long period. Indeed, in the long period the dominant influences on the prices of factors other than land are exerted by their supply conditions. The costs that then have to be met must ensure that various kinds of labour and capital continue to be replaced in their existing uses and quantities.

From an overall view ‘The net aggregate of all the commodities produced is itself the true source from
which flow the demand prices for all these commodities, and therefore for the agents of production used in making them’ (1920, p. 536). This aggregate, ‘the national dividend’, is distributed among the factors of production. It is at once the aggregate net product of, and the sole source of payment for, all the agents of production within the country: it is divided up into earnings of labour; interest of capital; and lastly the producer's surplus, or rent, of land and of other differential advantages for production. It constitutes the whole of them, and the whole of it is distributed among them; and the larger it is, the larger, other things being equal, will be the share of each of them. (1920, p. 536)

The share going to any class of inputs will depend upon the need people have for its services: ‘not the total need, but the marginal need’ (p. 536, italics original). But a complicating influence for distribution theory, although one ‘more full of hope for the future of the human race than any that is known to us’ lies in the fact that ‘highly paid labour is generally efficient and therefore not dear labour’ (p. 510). Influenced by F.A. Walker, Marshall was a strong proponent of the ‘economy of high wages’ argument that high wages increase labour efficiency, not perhaps immediately, but cumulatively over time and perhaps over generations: effects that transcend simple theorizing in terms of static equilibrium. All the different productive factors cooperating in production have a common interest in increasing the size of the pie to be shared, the national dividend or income, but each factor has a selfish interest in restrictive practices that increase its own share, even if they reduce the size of the pie slightly. A prime question of social policy for Marshall is how these divergent incentives can be reconciled: how combined action by various groups, such as unions, can be prevented from assuming forms that, while perhaps individually beneficial to any one group in isolation, are certainly mutually harmful if undertaken by all.

Marshall here enters into macroeconomic forms of argument, and it is indeed true that he did toy with the formal specification of macroeconomic models of growth and distribution (see Whitaker, 1975, vol. 2, pp. 305–16). But, with this exception, it should be emphasized that his treatment of market interdependence fell far short of a full theory of general equilibrium on Walrasian lines. Even when formalizing market interdependence in the mathematical appendix to Principles (1920, pp. 846–56), he simply treated the demand or supply of each commodity as a function of nothing but the price of the commodity itself. The links between the generation of income in factor markets and the expenditure of that income in product markets were left quite vague. Again, it must be recalled that the development of comprehensive fully articulated equilibrium theories was not Marshall's aim.

Monopoly and combination
Marshall's analysis of price and output determination by a profit-maximizing monopolist, and of the effects of taxing such a monopolist, followed the lead of Cournot. The concept of marginal revenue was implicit in the mathematical statement, but Marshall's chosen vehicle was geometrical. Curves of average revenue and cost, and of their difference, average net revenue, y, (all functions of the quantity sold, x) were superimposed on a grid of iso-profit hyperbolae of form \( xy = \text{constant} \). Profit was maximized when the average net revenue curve touched the highest such iso-profit curve. Weighting consumer surplus into the maximand, as well as net revenue, gave rise to the welfare analysis of 'compromise benefit' already mentioned.

Monopoly analysis was applied to trades unions, with the use of the concept of the derived demand for an input. A union controlling a labour input for which derived demand is inelastic can certainly raise wages – not only the wage rate but the total wages received – although at the price of unemployment of some members. Whether such a monopolistic restriction can be sustained for long is more doubtful, as there will be pressures both to enter the union and to evade its grasp by the relocation or reorganization of production.

A more problematic question was whether 'labour's disadvantage in bargaining' meant that combined action by workers could raise wages, even without any restriction of labour supply. Marshall believed that it did, but emphasized that the result might be less capital accumulation by non-workers, an outcome that could harm workers eventually.

The extremes of monopoly and competition were both covered by the theory of normal value, even though the competition might be more akin to later concepts of imperfect or monopolistic competition than to any ideal form of perfect competition. But 'normal action falls into the background, when Trusts are striving for the mastery of a large market' (1920, p. xiv). The incidents, tactics and alliances of oligopolistic conflict defied reduction to a simple general theory. They were to have been considered in the uncompleted second volume of *Principles* and were to some extent covered by *Industry and Trade*. The latter's treatment of entry-limiting behaviour by a 'conditional monopolist', who dominates the market but does not control entry, is of considerable interest in the light of much recent work on this class of problems.

Liebhafsky (1955) summarizes the relevant arguments of *Industry and Trade*.

**Monetary theory**

Marshall was in full command of previous British discussions of monetary issues, but not himself a major contributor to the development of monetary theory. His evidence before royal commissions in 1887 and 1899 showed an impressive mastery of monetary analysis, both domestic and international, and was minutely examined by successive generations of Cambridge students, serving for many years virtually as a textbook. But it was not until 1923, with the appearance of *Money Credit and Commerce*, that Marshall put forward his monetary views in a systematic way. By then these had not the novelty, nor he the vigour, to advance contemporary discussion.

Marshall's most important contribution to monetary theory was to place the overall demand for money in
the context of individual choices as to the fraction of one's wealth to keep on hand as ready cash. This approach, set out clearly in a manuscript of the early 1870s (Whitaker, 1975, Vol. I, pp. 164–77), was developed by Marshall's Cambridge successors, especially A.C. Pigou and F. Lavington, into what is termed the ‘Cambridge k’ approach. It laid the background for the treatment of the demand for money in J.M. Keynes (1936). On international monetary theory, Marshall espoused a form of purchasing power parity.

Marshall's name is particularly associated with his proposals for ‘symmetalism’, the use of a fixed-weight combination of gold and silver as the monetary base, and for indexed contracts based on a ‘tabular standard of value’, or price index, to be maintained by the government. The former was offered as an improvement on fixed-ratio bimetallism, of which he was never more than a lukewarm adherent. Marshall had interesting, if fragmentary, insights into business fluctuations and general unemployment, which he viewed as temporary disequilibrium consequences of credit market dislocations. These spilled over into general coordination failures, with unemployment in one market spreading to others by reducing demand in cumulative fashion – the germ at least of the multiplier concept. On the other hand, Say's Law was maintained as an equilibrium truth of great importance. He saw the remedies for cyclical unemployment in the ‘continuous adjustment of means to ends, in such a way that credit can be based on the solid foundation of fairly accurate forecasts’, and in curbs on reckless inflations of credit that are ‘the chief cause of all economic malaise’ (1920, p. 710).

International trade

Marshall's major contribution to international trade theory was his well-known geometrical analysis of the equilibrium and stability of two-country trade by means of intersecting offer curves. Each country's offer curve indicated the number of ‘bales’ of home goods it was prepared to exchange for a specified number of bales of foreign goods, demand being elastic or inelastic as an increase in the latter caused the former to increase or decrease. Possibilities of multiple and unstable offer-curve intersections were noted. The offer curves themselves were taken as data, although complex readjustments of production and consumption underlay them. The need for a separate theory of international trade was justified, in classical vein, by the supposed international immobility of factors of production that remain mobile domestically.

The main purpose of this theoretical apparatus was to examine the effects of tariffs. A country might gain by selfishly exploiting its monopoly power through restricting trade, and would certainly gain if trading equilibrium occurred on an inelastic portion of the foreign offer curve. But Marshall came to doubt increasingly the transferability of this result to a multi-country case, although admitting that it might apply to an export tax on an exceptional commodity (like British steam coal) lacking close substitutes and incapable of being produced elsewhere.

A related attempt to construct a theoretical measure of the ‘net benefit’ a country gains from foreign
trade, analogous to the measures of consumer and producer surplus, was not entirely satisfactory as the partial equilibrium context had clearly been transcended.

On matters of concrete trade policy for Britain, Marshall was a firm but cautious adherent of free trade, even unilateral free trade, but became increasingly concerned with the prospects for Britain's position in the world economy. The discussion in *Industry and Trade* of the links between foreign competition and domestic industrial organization and structure reflected this concern.

**A brief survey of Marshall's writings with suggestions for further reading**

The first editions of Marshall's five books were (1879b), (1890a), (1892), (1919), (1923). *Economics of Industry* (1879b) had a new edition in 1881 and was reprinted with minor changes several times up to 1892. It is an important source for Marshall's views on distribution theory, trades unions and business fluctuations. His magnum opus, *Principles* (1890a), had new editions in 1891, 1895, 1898, 1907, 1910, 1916 and 1920. The title was changed to its final form (as in (1920)) in the fifth edition. *Principles* is the basic source for Marshall's views on the theories of value and distribution as well as his broader views on economics and social welfare. Since the rewritings between editions were substantial, the ninth variorum edition, edited by C.W. Guillebaud, Marshall's nephew (Guillebaud, 1961), is essential for serious study. The first of its two volumes is a facsimile of the eighth edition of 1920. The second volume contains deleted passages from earlier editions, editorial notes, and various supporting documents. Users of the differently paginated Macmillan paperback edition of the eighth edition should note that all page references to the eighth edition given above must be located by using the table of correspondences appended to the paperback version.

*Elements of the Economics of Industry* (1892) had new editions in 1896 and 1899 and frequent reprints. The last preface is dated 1907. It is essentially an abridgement of *Principles*, designed to replace *Economics of Industry*, a book that Marshall had come to despise, quite unjustifiably. *Elements* contains Marshall's fullest treatment of trades unions. *Industry and Trade* (1919) had new editions in 1919, 1920 and 1923 but only the first of these involved significant changes. Its three books deal with ‘Some origins of present problems of industry and trade’, ‘Dominant tendencies of business organization’, and ‘Monopolistic tendencies: their relations to public well-being’. It adopts a largely historical and comparative approach and focuses on contemporary issues. Nevertheless, it contains many passages and insights of permanent interest and warrants closer attention by economists than it has received until recently. *Money Credit and Commerce* (1923) had only one edition and conveys Marshall's views on money, international trade and business fluctuations. Although blemished, it should not be dismissed.

An almost comprehensive annotated list of Marshall's occasional writings is found in Pigou (1925, pp. 500–8), which also reprints many of the texts of these writings. Guillebaud (1961) reproduces further
occasional pieces. The ‘Pure Theory’ chapters (1879a), privately printed by Sidgwick, were first published in reprint form in 1930. A corrected and amplified version is included in Whitaker (1975). The two volumes of the latter also reproduce Marshall's unpublished early manuscripts, mainly from the 1870s, including several manuscript chapters from the abandoned volume on foreign trade. Marshall's important contributions to official enquiries are collected in J.M. Keynes (1926), a book that is supplemented by Groenewegen (1996).

The literature on Marshall's life and thought is too extensive to allow for more than a highlighting of some significant contributions. The splendid memorial essay by J.M. Keynes (1924) is not to be missed, although outdated on some points, nor is the charming memoir by Marshall's wife (M.P. Marshall 1944). Pigou (1925) includes fascinating vignettes by several of Marshall's colleagues and friends and Guillebaud (1971) gives a nephew's reminiscences. A major scholarly biography (Groenewegen 1995) covers Marshall's life and thought exhaustively, while a comprehensive three-volume edition of Marshall's correspondence (Whitaker 1996) provides much new information. Additional primary material on Marshall is provided in Raffaelli, Biagini and McWilliams-Tullberg (1995), where notes on Marshall's 1873 lectures to women students are reproduced, and Raffaelli (1994), where Marshall's essays on philosophical and psychological manuscripts from the late 1860s are reproduced and analyzed. See also Harrison (1963). Newspaper reports on public lectures Marshall gave during his years in Bristol are reproduced in Coase and Stigler (1969), Whitaker (1972) and Butler (1995).

Valuable overall assessments of Marshall are provided by Cannan (1924), Schumpeter (1941), Viner (1941), Shove (1942) and O'Brien (1981). Maloney (1985) studies Marshall's involvement in the professionalization of British economics. An extensive body of detailed analysis and criticism of Marshall's thought, mainly conducted in academic journals, continues to expand, with growing tributaries from Italy and Japan in particular. Wood (1982; 1996) assembles in eight volumes a somewhat miscellaneous collection of 239 pieces on Marshall, but standard bibliographic aids such as EconLit are recommended for a comprehensive search. The 1990 centenary of the publication of Principles produced two books of essays on Marshall (Whitaker 1990, McWilliams-Tullberg 1990) and several symposia on Marshall in economics journals. Samples of recent research can be found in Arena and Quéré (2003). On Marshall's social and behavioural views see Parsons (1931; 1932), Whitaker (1977) and Chasse (1984). For Marshall's views on socialism and trades unions see, respectively, McWilliams-Tullberg (1975) and Petridis (1973).

Article

British economist, born in Ufford (Nottinghamshire) on 24 October 1850; died in Cambridge 7 March 1944. Great-granddaughter of the great theologian William Paley, she was brought up in a strictly evangelical faith in Ufford, her father's vicarage. Thomas Paley, had taken a good degree in mathematics (33rd wrangler) in 1833 at Cambridge, and had been, for a period, a fellow of St John's College. Mary had one elder sister and two younger brothers.

In 1871, with a scholarship, she went up to Cambridge to complete her education with studies at university level. Under the whimsical chaperon Anne J. Clough (sister of the poet), and the teaching of a handful of young voluntary dons committed to the cause of higher education of women (among them Henry Sidgwick and Alfred Marshall), she took the Moral Sciences Tripos. She graduated, albeit informally, in 1874 (the first woman to achieve such a distinction in Cambridge) but the board of examiners (W.S. Jevons was among them) was so bitterly divided that in the certificate they recorded, very unusually, that she had received two votes for a first class and two for a second.

Shortly after her degree Mary Paley began to teach and to tutor female students in the newly opened Newnham Hall. In 1876, on request, she began to write a small economic textbook for Extension Lectures, that eventually became *The Economics of Industry* (1879). In the same year she became engaged to Alfred Marshall. They married in Ufford in July 1877. From that date onwards, till the death of Alfred Marshall in 1924, her life was essentially devoted, first in Bristol, where they settled after marriage, then in Oxford (1883–4) and finally in Cambridge, to helping him in his scientific work and to saving him from all the normal nuisances of life.

For several decades Mary Paley Marshall taught and tutored female students of economics in Newnham college. A member of many associations (Charity Organization Society, Ethical Society, and so on) she participated in the founding group of the British Economic Association. After 1924 she became the first librarian of the newly founded Marshall Library, which she visited regularly until her 90th year. In 1928
the University of Bristol awarded her an honorary degree. She was a gifted amateur water colour painter and her posthumous Memoir, *What I Remember* (1947), shows glimpses of literary talent. Mary was not buried beside Alfred, but her ashes were scattered in the garden of her house.

Mary Paley Marshall's claims to be considered as an economist by herself are, strictly speaking, unassessable. Personally she signed only a few short notes in the early issues of the *Economic Journal*, which show a clear mind, a good style and a balanced judgement, but no more. Her only title to fame resides in the green-covered *Economics of Industry*, co-authored with Alfred Marshall. This small textbook, reprinted many times and translated into several foreign languages, was rated very highly by contemporaries. J.M. Keynes went so far as to say: 'It was, in fact, an extremely good book; nothing more serviceable for its purpose was produced for many years, if ever.' From the viewpoint of the development of economic analysis the book is relevant as a sort of half-way house between the *Principles* of J.S. Mill and the *Principles* of A. Marshall. Despite some hints to the contrary by J.M. Keynes, the respective positions (teacher and pupil) and ages (Alfred was older by eight years) suggest that Mary Paley's contribution was only secondary and subordinate.

Worthy of mention is the help she afforded Alfred Marshall in preparing and amending all his works. In a letter to John Neville Keynes, there is a hint of a substantial collaboration: 'My wife and I', writes Alfred Marshall, alluding to an article by J.L. Laughlin (*Quarterly Journal of Economics*, 1887), 'find it very hard to see Laughlin's points & perhaps we underrate the strength of his attack.' Had it not been for the suffocating influence of Alfred, Mary Paley, with her clear mind, earnestness and strong will, would have become herself, we can confidently guess, an economist of repute and not, as is the case, a minor figure in the shadow of Alfred Marshall.

In the comparative-statical calculations of the simplest two-commodity barter theory of international trade, the outcomes invariably depend on the magnitude of the sum of the two import-demand elasticities, one relating to the country under study (the 'home' country) and the other to the rest of the world (collectively, the 'foreign' country); in particular, the response of a variable to a disturbance will be in one direction if the sum of elasticities is less than minus 1 and in the opposite direction if the sum is greater than minus 1. On the other hand, for some dynamic or 'disequilibrium' models of international trade it is a necessary and sufficient condition of local stability that the same sum of elasticities be less than minus 1. Let us define $\Delta$ as one plus the sum of the two elasticities of import demand. Then the so-called Marshall–Lerner condition requires that $\Delta$ be negative. Evidently the condition provides a link between the comparative-statics of international trade and some forms of trade dynamics. That such a link exists is, of course, the essence of Samuelson's correspondence principle.

Proceeding to a more detailed account of the Marshall–Lerner condition, let us suppose that the home country imports the first commodity, the foreign country the second; and let us denote by $p$ the world price of the second commodity in terms of the first and by $\alpha$ and $\alpha^*$ parameters of the home and foreign economies, respectively. Then, in the absence of trade impediments and autonomous international transfers, we may write the general-equilibrium or mutatis mutandis home import-demand function as $\varphi(1/p, \alpha)$, the foreign import-demand function as $\varphi^*(p, \alpha^*)$ and the condition of world equilibrium as

$$\varphi(1/p, \alpha) - p\varphi^*(p, \alpha^*) = 0.$$
Suppose now that an initial equilibrium is disturbed by small changes in \( \alpha \) and \( \alpha^* \). Differentiating (1) totally we obtain

\[
\left( p^{-2} \varphi_1 / \rho + \varphi^* + p \varphi^*_p \right) \delta p = \varphi \delta \alpha - p \varphi^* \delta \alpha^*
\]

or, equivalently,

\[
\Delta \delta p \equiv \left( 1 + \xi + \xi^* \right) \delta p = \left( \varphi \delta \alpha - p \varphi^* \delta \alpha^* \right) / \varphi^*
\]

where the subscripts indicate partial derivatives and where \( \xi \equiv \varphi_1 / \rho \) and \( \xi^* \equiv p \varphi^*_p / \varphi^* \) are the price elasticities of home and foreign import demand, respectively.

On the other hand, we may consider the dynamic tâtonnement defined by the differential equation

\[
p \equiv \frac{\delta p}{\delta t} = f \left[ \varphi^* \left( p, \alpha^* \right) - \varphi \left( 1 / p, \alpha \right) / p \right]
\]

where \( f \) is a differentiable sign-preserving function of the world excess demand for the second commodity and \( t \) denotes time. Evidently (3) is a dynamic extension of (1). For the local stability of \( p \) at an equilibrium value it is necessary and sufficient that \( \delta f / \delta p \) be negative in a sufficiently small neighbourhood of the equilibrium value. Now a little calculation shows that

\[
\Delta \frac{\delta f}{\delta p} = \frac{\delta f}{\delta p} \Delta \frac{\varphi^*}{p}
\]

where the prime indicates differentiation; moreover, since \( f \) is differentiable and sign-preserving, \( \frac{\delta f}{\delta p} \) is necessarily positive sufficiently near the equilibrium value of \( p \). For local stability, therefore, it is necessary and sufficient that \( \Delta \) be negative.

By way of illustration we may consider the traditional 'transfer problem'. Identifying \( \alpha = \alpha^* \) with the amount transferred from the foreign to the home country, in terms of the numeraire, eq. (1) reduces to
\[ \varphi(1/p, \alpha) - p\varphi^*(p, \alpha) - \alpha = 0 \]

and, if \( \alpha \) is initially zero, eq. (2) reduces to

\[ \Delta d\rho = \left( \varphi_\alpha - 1 + p\varphi^*_\alpha \right) d\alpha / \varphi^*. \]

Evidently \( \varphi_\alpha \) and \( 1 - p\varphi^*_\alpha \) are home and foreign marginal propensities to consume the first commodity. Thus, in stable systems, the terms of trade move in favour of the recipient of a small payment if and only if that country’s marginal propensity to consume the imported commodity is less than the foreign country’s marginal propensity to consume the same commodity.

The home and foreign economies have been specified in terms of the functions \( \varphi \) and \( \varphi^* \) only. Whether in any particular context the Marshall–Lerner condition is satisfied depends on the structure imposed on \( \varphi \) and \( \varphi^* \) by the context. Evidently the appropriate structure will be quite different for economies with and without chronic unemployment and, more generally, for economies with and without internal market-clearing. It will also be quite different for rural and industrial economies, for growing and declining economies and for rich and poor economies.

While the inequality \( \Delta < 0 \) is now widely known as the Marshall–Lerner condition, the label is inappropriate in a context of dynamic analysis. For Alfred Marshall developed a quite different stability condition (see Marshall, 1879, II; 1923, Appendix J; Samuelson, 1947, pp. 266–7); Amano, 1968; Kemp, 1964, pp. 89–90); and Abba Lerner was not at all concerned with disequilibrium dynamics (see Lerner, 1944).

Harriet Martineau, the best-selling popularizer of classical political economy, was born in Norwich, England, on 12 June 1802, the sixth of eight children of Thomas Martineau, a Unitarian textile manufacturer, and Elizabeth Rankin Martineau. She was educated at home, except that from 1813 to 1815 she studied French, Latin, and English composition at a school run by the Reverend Isaac Perry. Her early writings were religious, beginning with an article on ‘Female Writers on Practical Divinity’ for the *Monthly Repository*. After her father's death in 1826, she became engaged, but her fiancé died before they could be married. She remained single for the rest of her life. Investment losses in 1829 forced her to support herself by writing: William Johnson Fox's *Monthly Review* hired her as a book reviewer for 15 pounds a year, and when the Central Unitarian Association offered prizes for essays to convert Catholics, Jews, and Muslims, Martineau won all three prizes, for 15 guineas each. These prizes enabled her to visit her brother in Dublin in 1831. While there, she planned the series *Illustrations of Political Economy*, stories that would expound (especially to the working classes) the principles of classical political economy, to which she had been introduced by Jane Marcet's *Conversations on Political Economy* (1816) and James Mill's *Elements of Political Economy* (1821). The first of the 34 tales of political economy, of the Poor Laws, and of taxation was published in February 1832 by Charles Fox (brother of William Fox), and distributed by the Society for the Diffusion of Useful Knowledge. By 10 February, the first printing of 1,500 copies had all been sold, and a second printing of 5,000 copies ordered.

The success of *Illustrations of Political Economy* (1832–4; 2004a) made Martineau a celebrity: Henry Brougham, the Lord Chancellor, provided her with private papers on the impending reform of the Poor Law, while Robert Owen attempted, without success, to convert her to socialism. Although poor health interrupted her work several times, Harriet Martineau refused offers of government pensions from Lord Grey in 1835, Lord Melbourne in 1841, and W.E. Gladstone in 1873, lest her independence be
compromised. Instead, her friends raised funds for an annuity for her in 1843, and, when her health permitted she worked with great diligence, writing more than 1,600 articles for the *Daily News* from 1852 to 1866. Although her income was modest, she was a philanthropist, founding a building society among other charitable projects.

Harriet Martineau disclaimed originality for *Illustrations of Political Economy*, insisting that its purpose was didactic, making established principles better known. Her presentation of the principles was original, and her work stood out for its recognition of women as rational economic agents (1985). In her *Illustrations*, Martineau upheld laissez-faire and property rights. In later life, Martineau endorsed married women's property rights, condemned slavery as an illegitimate form of property, gave qualified support to workers’ cooperatives, and accepted the need for state intervention in certain very limited circumstances. Her lectures at working men's institutions stressed education rather than state intervention as the remedy for most social ills. Her subsequent writings on America and slavery (1837; 2002) demonstrated that she was an adept economic analyst, not just a popularizer. For example, Martineau recognized the limited demand for the services of prostitutes in the South as evidence of the sexual exploitation of slaves, and identified the inability of slaveholders to make credible long-term commitments to their slaves as a source of inefficiency in slave agriculture (Levy, 2003). Martineau's *Society in America* (1837) emphasized the incompatibility of slavery and of the legal, political, and economic position of American women (lacking votes and, if married, property rights) with America's founding rhetoric of liberty. Her study of the United States was accompanied by her *How to Observe Morals and Manners* (1838), a methodological manual on comparative sociology and ethnography. In 1853, Martineau published a translation and abridgement of the pioneer sociologist Auguste Comte's *Philosophie positive*, an adaptation that pleased Comte so much that he had it translated back into French.

In 1855, anticipating death from heart disease, Martineau wrote her autobiography for posthumous publication (1877), but she lived until 27 June 1876.

doi:10.1057/9780230226203.1049
A martingale is a mathematical model of a fair game, or of some other process that is incrementally random noise. The term, which also denotes part of a horse's harness or a ship's rigging, refers in addition to a gambling system in which every losing bet is doubled; it was introduced into probability theory by J.L. Doob. Among stochastic processes, martingales have particular constancy properties with respect to conditioning. The time parameter may be either discrete or continuous, but since the latter is more important in economic applications, we concentrate on it.

Suppose that on a basic probability space there is defined a history \( \mathcal{H} = (\mathcal{H}_t)_{t \geq 0} \) representing observable events as a function of time. For each \( t \), \( \mathcal{H}_t \) is the \( \sigma \)-algebra comprising events determined by observations over the interval \( [0,t] \), so that \( \mathcal{H}_s \subseteq \mathcal{H}_t \) when \( s \leq t \). Then a stochastic process \( M = (M_t)_{t \geq 0} \) is a martingale with respect to this history if

1. (a) For each \( t \), \( M_t \) is \( \mathcal{H}_t \) measurable (i.e., the state of the process at \( t \) is observable over \( [0,t] \));
2. (b) \( E[|M_t|] < \infty \) for each \( t \);
3. (c) The 'martingale property' holds: whenever \( s < t \),

\[
E[M_t | \mathcal{H}_s] = M_s.
\]

(1)

When no history is specified, it is usually understood that \( \mathcal{H}_t = \sigma(M_s, s \leq t) \). One specific consequence is that \( E[M_t] = E[M_0] \) for each \( t \), so that a martingale is constant in the mean. Written as

\[
E[M_t - M_s | \mathcal{H}_s] = 0, \ s \leq t,
\]
the martingale property implies that the optimal (in the sense of minimum mean squared error, or MMSE) predictor of a future increment of a martingale is zero. Thus, a martingale is indeed a mathematical idealization of a fair game. In some ways this property is clearest in differential form: assuming that the differential $dM_t$, which always extends forward in time from $t$, can be defined, then $M$ is a martingale provided that

$$E[dM_t | \mathcal{F}_t] = 0$$

(2)

for each $t$. Thus, a martingale can be interpreted as a ‘noise’ process, in which the MMSE prediction of the differential $dM_t$ is simply zero; in many applications this interpretation becomes quite literal.

Martingales are also analogous to the residuals in a regression problem, where what remains unexplained by the model should reduce, ideally, to chance variation.

One can also define *supermartingales*, for which (1) becomes

$$E[M_t | \mathcal{F}_s] \leq M_s,$$

(3)

and *submartingales*, in which the sense of the inequality in (3) is reversed. A supermartingale represents a less-than-fair game.

All martingales are in some sense convex combinations of (generalizations of) two key examples, namely the Wiener and Poisson processes. If $(W_t)$ is a Wiener process (Brownian motion), then the processes $W_t$ and $W^2_t - t$ are both martingales; in fact, these properties characterize the Wiener process.

In discrete time, martingales generalize sums of independent, mean zero random variables; the Wiener process, which has independent and stationary increments, is a continuous time counterpart of these partial sum processes.

If $(N_t)$ is a point process (or counting process), with $N_t$ the number of events occurring in $[0, t]$, then under quite general assumptions there exists a nonnegative, predictable (a technical term, which in practice means left-continuous) random process $(\lambda_t)$, the stochastic intensity of $N$, such that the process

$$M_t = N_t - \int_0^t \lambda_s ds$$

is a martingale. Since $\lambda_t dt = E[dN_t | \mathcal{F}_t]$, $M$ represents the new information realized as a function of time and, because of this and applications in statistics and state estimation, is known as the innovation martingale. For a Poisson process, which like the Wiener process has independent and stationary increments, the stochastic intensity is deterministic and equal to the rate of the process.
Square integrable martingales are especially important. A martingale $M$ is *square integrable* if 
$$\sup_t E[M_t^2] < \infty,$$
and in this case there exists a predictable process $\langle M \rangle$, the *predictable variation* of $M$,
such that $M_t^2 - \langle M \rangle_t$ is a martingale. That the predictable variation is incrementally a conditional
variance is confirmed by the differential relationship

$$d\langle M \rangle_t = E[(dM_t - E[dM_t|\mathcal{F}_t])^2|\mathcal{F}_t] = E[(dM_t)^2|\mathcal{F}_t].$$

Here the second equality holds because $M$ is a martingale.

For the Wiener process $\{W_t\}$ in particular, the predictable variation is deterministic, a property
characteristic of processes with independent increments. For a point process $N$ with stochastic intensity
$\lambda$, the predictable variation of the innovation martingale $dM_t = dN_t - \lambda_t dt$ is given by
$$d\langle M \rangle_t = \lambda_t dt,$$
which implies that a point process is locally and conditionally Poisson, in the sense that the incremental
conditional mean and variance coincide.

Existence of the predictable variation is proved via the Doob-Meyer decomposition theorem, a
cornerstone of the theory. The principal theoretical results pertaining to martingales fall into three
classes: inequalities, convergence theorems and optimal sampling theorems.

So-called maximal inequalities, which provide upper bounds for probabilities of the form
$$P\{\sup_{s \leq t} |M_s| > \varepsilon\},$$
are not only of inherent interest, but also the key tools for proving convergence
theorems. Moreover, these inequalities form the basis of a profound connection between martingales and
classical mathematical analysis.

Under various assumptions, given a martingale $M$ there exists a random variable $M_\infty$ such that $M_t \to M_\infty$
almost surely as $t \to \infty$. Convergence obtains both almost surely and in $L^1$ if $M$ is uniformly integrable,
and in this case $M_t = E[M_\infty|\mathcal{F}_t]$ for each $t$. Not all martingales converge, however; those that fail to
converge include, for example, the Wiener process and most innovation martingales.

Optional sampling theorems require the further concept of a stopping time. A random time $T$ (a random
variable with values in $[0, \infty]$), interpreted as the time at which some event occurs – with $T=\infty$
corresponding to its not occurring) is a *stopping time* of the history $\mathcal{F}_t$ if $\{T \leq t\} \in \mathcal{F}_t$ for each $t$.
Intuitively, whether a stopping time has occurred by $t$ can be determined from observations over $[0, t]$,
and does not require prescient knowledge of the future. The rule by which a gambler quits a game must
be a stopping time. Associated with a stopping time $T$ is a $\sigma$-algebra $\mathcal{F}_T$ representing events determined
by observations over the random time interval $[0, T]$ in the same way that for deterministic $t$, $\mathcal{F}_t$
corresponds to the interval $[0, t]$.

Martingale property extends from deterministic times to stopping times, and imply in particular that an
unfair game cannot be made fair by means of a stopping time. More precisely, if $M$ is a martingale and $S$
and $T$ are stopping times with $S \leq T$, then under broad – albeit not universal – conditions,

$$E[M_T|\mathcal{F}_S] \leq M_S.$$
With $S=0$ in (4), taking expectations yields $E[M_\tau] = E[M_0]$. The corresponding result for supermartingales,

$$E[M_\tau|\mathcal{F}_s] \leq M_s,$$

(5)

demonstrates that an unfair game cannot be made fair via a stopping time, and dooms gambling systems without infinite resources to eventual failure.

Significant applications of martingales include mathematical statistics (likelihood ratio processes are martingales), queueing theory, filtering and prediction (for example, in signal processing) and economics.

A common feature of these applications is that they involve a random system ‘driven’ by a martingale in precisely the same manner that a dynamical system is driven by a forcing function. Given a (square integrable) martingale $M$ and a predictable process $C$ fulfilling integrability restrictions, the stochastic integral process

$$(C \ast M)_t = \int_0^t C_s dM_s$$

is itself a martingale, for which $M$ acts as driving term. (Since $M$ may change state discontinuously, whether endpoints are included in the interval of integration must be specified; in this case, the integral is over the closed interval $[0, t]$.) Construction of stochastic integrals is a difficult, subtle problem: none of the conventional definitions can be applied pathwise (typically the sample paths of $M$ are not of bounded variation), and instead one must employ sophisticated probability theory. The predictable variations satisfy

$$d\{C \ast M\}_t = C_t^2 d\{M\}_t.$$

Economic applications include, e.g., models of securities prices.

In applications, the inclusion of a ‘$dt$’-integral is often desirable or necessary, leading to
semimartingales, which are random processes $Z$ of the form

$$Z_t = \int_0^t A_s \, ds + \int_0^t C_s \, dM_s,$$

(6)

where $M$ is a martingale, $C$ is a predictable process and $A$ fulfills a technical property known as progressive measurability. (Integrability conditions must be satisfied as well.) The differential version of (6) is

$$dZ_t = A_t \, dt + C_t \, dM_t.$$

(7)

If the processes $A$ and $C$, rather than specified exogenously, are functionals of $Z$, then (7) becomes a stochastic differential equation

$$dZ_t = \mu(Z_t) \, dt + \sigma(Z_t) \, dM_t,$$

(8)

or, more generally,

$$dZ_t = \mu(Z_s; s \leq t) \, dt + \sigma(Z_s; s \leq t) \, dM_t.$$  

(9)

These equations can be solved – however, not using pathwise methods – under a variety of assumptions, but essentially only when the driving term is a martingale. For example, if the martingale is the Wiener process, solutions to (8) and (9) are known as diffusions and Itô processes, respectively, and the resultant theory as the Itô calculus, after its principal inventor, K. Itô. Alternatively, if $M$ is the innovation martingale associated with a point process $N$ then, inter alia, solutions to (8) can be used to construct recursive methods for filtering to extract signals from noise.

Marx, Karl Heinrich (1818–1883)

Ernest Mandel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article summarizes the methodology and economics of Karl Marx. After a brief account of his life, it deals with his historical materialism, and then his labour theory of value, his theories of rent, money, surplus value, and crises, his account of the laws of motion of the capitalism mode of production, and his and Engels's conception of the economy of post-capitalist societies.

Keywords

accumulation of capital; Asiatic mode of production; Böhm-Bawerk, E. von; Bukharin, N.; capitalist mode of production; class; commodity theory of money; communism; concentration (centralization) of capital; constant and variable capital; credit cycles; economic crisis; economic laws; economic science; Engels, F.; exploitation; feudalism; Hilferding, R.; historical materialism; ideology; invisible hand; iron law of wages; labour power; labour theory of value; land rent; Lassalle, F.; laws of motion of capitalism; Lenin, V.; market value; Marx, K.; mobility of capital; modes of production; monopoly; organic composition of capital; overproduction; paper money; post-capitalist society; prices of production; proletariat; rate of profit; rent; reserve army of labour; Ricardo, D.; social polarization; socialism; Sraffa, P.; surplus value; technological change; trade unions; transformation problem; underconsumptionism

Article

Karl Marx was born on 5 May 1818, the son of the lawyer Heinrich Marx and Henriette Pressburg. His father was descended from an old family of Jewish rabbis, but was himself a liberal admirer of the Enlightenment and not religious. He converted to Protestantism a few years before Karl was born to escape restrictions still imposed upon Jews in Prussia. His mother was of Dutch-Jewish origin.

Life and work
Karl Marx studied at the Friedrich-Wilhelm Gymnasium in Trier, and at the universities of Bonn and Berlin. His doctoral thesis, *Differenz der demokritischen und epikurischen Naturphilosophie*, was accepted at the University of Jena on 15 April 1841. In 1843 he married Jenny von Westphalen, daughter of Baron von Westphalen, a high Prussian government official.

Marx's university studies covered many fields, but centred around philosophy and religion. He frequented the circle of the more radical followers of the great philosopher Hegel, befriended one of their main representatives, Bruno Bauer, and was especially influenced by the publication in 1841 of Ludwig Feuerbach's *Das Wesen des Christentums* (The Nature of Christianity). He had intended to teach philosophy at the university, but that quickly proved to be unrealistic. He then turned towards journalism, both to propagandize his ideas and to gain a livelihood. He became editor of the *Rheinische Zeitung*, a liberal newspaper of Cologne, in May 1942. His interest turned more and more to political and social questions, which he treated in an increasingly radical way. The paper was banned by the Prussian authorities a year later.

Karl Marx then planned to publish a magazine called *Deutsch-Französische Jahrbücher* in Paris, in order to escape Prussian censorship and to be more closely linked and identified with the real struggles for political and social emancipation which, at that time, were centred around France. He emigrated to Paris with his wife and met there his lifelong friend Friedrich Engels.

Marx had become critical of Hegel's philosophical political system, a criticism which would lead to his first major work, *Zur Kritik des Hegelschen Rechtsphilosophie* (A Critique of Hegel's Philosophy of Right). Intensively studying history and political economy during his stay in Paris, he became strongly influenced by socialist and working-class circles in the French capital. With his ‘Paris Manuscripts’ (*Oekonomisch-philosophische Manuskripte*, 1844), he definitely became a communist, i.e. a proponent of collective ownership of the means of production.

He was expelled from France at the beginning of 1845 through pressure from the Prussian embassy and migrated to Brussels. His definite turn towards historical materialism (see below) would occur with his manuscript *Die Deutsche Ideologie* (1845–6) culminating in the eleven *Theses on Feuerbach*, written together with Engels but never published during his lifetime.

This led also to a polemical break with the most influential French socialist of that period, Proudhon, expressed in the only book Marx would write in French, *Misère de la Philosophie* (1846).

Simultaneously he became more and more involved in practical socialist politics, and started to work with the Communist League, which asked Engels and himself to draft their declaration of principle. This is the origin of the *Communist Manifesto* (1848), *Manifest der Kommunistischen Partei* (1848).

As soon as the revolution of 1848 broke out, he was in turn expelled from Belgium and went first to France, then, from April 1848 on, to Cologne. His political activity during the German revolution of 1848 centred around the publication of the daily paper *Neue Rheinische Zeitung*, which enjoyed wide popular support. After the victory of the Prussian counter-revolution, the paper was banned in May 1849 and Marx was expelled from Prussia. He never succeeded in recovering his citizenship. Marx emigrated to London, where he would stay, with short interruptions, till the end of his life. For fifteen years, his time would be mainly taken up with economic studies, which would lead to the publication first of *Zur Kritik der Politischen Oekonomie* (1859) and later of *Das Kapital*, Vol. I (1867). He spent long hours at the British Museum, studying the writings of all the major economists, as well as the government Blue Books, Hansard and many other contemporary sources on social and economic conditions in Britain and the world. His reading also covered technology, ethnology and anthropology, besides political economy.
Marx, Karl Heinrich (1818–1883) : The New Palgrave Dictionary of Economics

and economic history; many notebooks were filled with excerpts from the books he read. But while the activity was mainly studious, he never completely abandoned practical politics. He first hoped that the Communist League would be kept alive, thanks to a revival of revolution. When this did not occur, he progressively dropped out of emigré politics, but not without writing a scathing indictment of French counter-revolution in Der 18. Brumaire des Louis Bonaparte (1852), which was in a certain sense the balance sheet of his political activity and an analysis of the 1848–52 cycle of revolution and counter-revolution. He would befriend British trade-union leaders and gradually attempt to draw them towards international working class interests and politics. These efforts culminated in the creation of the International Working Men's Association (1864) – the so-called First International – in which Marx and Engels would play a leading role, politically as well as organizationally.

It was not only his political interest and revolutionary passion that prevented Marx from becoming an economist pure and simple. It was also the pressure of material necessity. Contrary to his hope, he never succeeded in earning enough money from his scientific writings to sustain himself and his growing family. He had to turn to journalism to make a living. He had initial, be it modest, success in this field, when he became European correspondent of the New York Daily Tribune in the summer of 1851. But he never had a regular income from that collaboration, and it ended after ten years.

So the years of his London exile were mainly years of great material deprivation and moral suffering. Marx suffered greatly from the fact that he could not provide a minimum of normal living conditions for his wife and children, whom he loved deeply. Bad lodgings in cholera-stricken Soho, insufficient food and medical care, led to a chronic deterioration of his wife's and his own health and to the death of several of their children; that of his oldest son Edgar in 1855 struck him an especially heavy blow. Of his seven children, only three daughters survived, Jenny, Laura and Eleanor (Tussy). All three were very gifted and would play a significant role in the international labour movement, Eleanor in Britain, Jenny and Laura in France (where they married the socialist leaders Longuet and Lafargue).

During this long period of material misery, Marx survived thanks to the financial and moral support of his friend Friedrich Engels, whose devotion to him stands as an exceptional example of friendship in the history of science and politics. Things started to improve when Marx came into his mother's inheritance; when the first independent working-class parties (followers of Lassalle on the one hand, of Marx and Engels on the other) developed in Germany, creating a broader market for his writings; when the IWMA became influential in several European countries, and when Engels’ financial conditions improved to the point where he would sustain the Marx family on a more regular basis.

The period 1865–71 was one in which Marx's concentration on economic studies and on the drafting of Das Kapital was interrupted more and more by current political commitments to the IWMA, culminating in his impassioned defence of the Paris Commune (Der Bürgerkrieg in Frankreich [The Civil War in France] 1871). But the satisfaction of being able to participate a second time in a real revolution – be it only vicariously – was troubled by the deep divisions inside the IMWA, which led to the split with the anarchists grouped around Michael Bakunin.

Marx did not succeed in finishing a final version of Das Kapital vols II and III, which were published posthumously, after extensive editing, by Engels. It remains controversial whether he intended to add two more volumes to these, according to an initial plan. More than 25 years after the death of Marx, Karl Kautsky edited what is often called vol. IV of Das Kapital, his extensive critique of other economists: Theorien über den Mehrwert (Theories of Surplus Value).

Marx's final years were increasingly marked by bad health, in spite of slightly improved living
conditions. Bad health was probably the main reason why the final version of vols II and III of *Capital* could not be finished. Although he wrote a strong critique of the Programme which was adopted by the unification congress (1878) of German social democracy (*Kritik Des Gothaer Program*), he was heartened by the creation of that united working-class party in his native land, by the spread of socialist organizations throughout Europe, and by the growing influence of his ideas in the socialist movement. His wife fell ill in 1880 and died the next year. This came as a deadly blow to Karl Marx, who did not survive her for long. He himself died in London on 14 March 1883.

**Historical materialism**

Outside his specific economic theories, Marx's main contribution to the social sciences has been his theory of historical materialism. Its starting point is anthropological. Human beings cannot survive without social organization. Social organization is based upon social labour and social communication. Social labour always occurs within a given framework of specific, historically determined, social relations of production. These social relations of production determine in the last analysis all other social relations, including those of social communication. It is social existence which determines social consciousness and not the other way around.

Historical materialism posits that relations of production which become stabilized and reproduce themselves are structures which can no longer be changed gradually, piecemeal. They are modes of production. To use Hegel's dialectical language, which was largely adopted (and adapted) by Marx: they can only change qualitatively through a complete social upheaval, a social revolution or counter-revolution. Quantitative changes can occur within modes of production, but they do not modify the basic structure. In each mode of production, a given set of relations of production constitutes the basis (infrastructure) on which is erected a complex superstructure, encompassing the state and the law (except in classless society), ideology, religion, philosophy, the arts, morality etc.

Relations of production are the sum total of social relations which human beings establish among themselves in the production of their material lives. They are therefore not limited to what actually happens at the point of production. Humankind could not survive, i.e. produce, if there did not exist specific forms of circulation of goods, e.g. between producing units (circulation of tools and raw materials) and between producing units and consumers. A priori allocation of goods determines other relations of production than does allocation of goods through the market. Partial commodity production (what Marx calls ‘simple commodity production’ or ‘petty commodity production’ – ‘einfache Warenproduktion’) also implies other relations of production than does generalized commodity production.

Except in the case of classless societies, modes of production, centred around prevailing relations of production, are embodied in specific class relations which, in the last analysis, overdetermine relations between individuals.

Historical materialism does not deny the individual's free will, his attempts to make choices concerning his existence according to his individual passions, his interests as he understands them, his convictions, his moral options etc. What historical materialism does state is: (1) that these choices are strongly predetermined by the social framework (education, prevailing ideology and moral ‘values’, variants of behaviour limited by material conditions etc); (2) that the outcome of the collision of millions of different passions, interests and options is essentially a phenomenon of social logic and not of individual
psychology. Here, class interests are predominant. There is no example in history of a ruling class not trying to defend its class rule, or of an exploited class not trying to limit (and occasionally eliminate) the exploitation it suffers. So outside classless society, the class struggle is a permanent feature of human society. In fact, one of the key theses of historical materialism is that ‘the history of humankind is the history of class struggles’ (Marx, Communist Manifesto, 1848).

The immediate object of class struggle is economic and material. It is a struggle for the division of the social product between the direct producers (the productive, exploited class) and those who appropriate what Marx calls the social surplus product, the residuum of the social product once the producers and their offspring are fed (in the large sense of the word; i.e. the sum total of the consumer goods consumed by that class) and the initial stock of tools and raw materials is reproduced (including the restoration of initial fertility of the soil). The ruling class functions as ruling class essentially through the appropriation of the social surplus product. By getting possession of the social surplus product, it acquires the means to foster and maintain most of the superstructural activities mentioned above; and by doing so, it can largely determine their function – to maintain and reproduce the given social structure, the given mode of production – and their contents.

We say ‘largely determine’ and not ‘completely determine’. First, there is an ‘immanent dialectical’, i.e. an autonomous movement, of each specific superstructural sphere of activity. Each generation of scientists, artists, philosophers, theologists, lawyers and politicians finds a given corpus of ideas, forms, rules, techniques, ways of thinking, to which it is initiated through education and current practice, etc. It is not forced to simply continue and reproduce these elements. It can transform them, modify them, change their interconnections, even negate them. Again: historical materialism does not deny that there is a specific history of science, a history of art, a history of philosophy, a history of political and moral ideas, a history of religion etc., which all follow their own logic. It tries to explain why a certain number of scientific, artistic, philosophical, ideological, juridical changes or even revolutions occur at a given time and in given countries, quite different from other ones which occurred some centuries earlier elsewhere. The nexus of these ‘revolutions’ with given historical periods is a nexus of class interests. Second, each social formation (i.e. a given country in a given epoch) while being characterized by predominant relations of production (i.e. a given mode or production at a certain phase of its development) includes different relations of production which are largely remnants of the past, but also sometimes nuclei of future modes of production. Thus there exists not only the ruling class and the exploited class characteristic of that prevailing mode of production (capitalists and wage earners under capitalism). There also exist remnants of social classes which were predominant when other relations of production prevailed and which, while having lost their hegemony, still manage to survive in the interstices of the new society. This is for example the case with petty commodity producers (peasants, handicraftsmen, small merchants), semifeudal landowners, and even slave-owners, in many already predominantly capitalist social formations throughout the 19th and part of the 20th centuries. Each of these social classes has its own ideology, its own religious and moral values, which are intertwined with the ideology of the hegemonic ruling class, without becoming completely absorbed by that. Third, even after a given ruling class (e.g. the feudal or semi-feudal nobility) has disappeared as a ruling class, its ideology can survive through sheer force of social inertia and routine (custom). The survival of traditional ancien régime catholic ideology in France during a large part of the 19th century, in spite of the sweeping social, political and ideological changes ushered in by the French revolution, is an
illustration of that rule. 

Finally, Marx's statement that the ruling ideology of each epoch is the ideology of the ruling class – another basic tenet of historical materialism – does not express more than it actually says. It implies that other ideologies can exist side by side with that ruling ideology without being hegemonic. To cite the most important of these occurrences: exploited and (or) oppressed social classes can develop their own ideology, which will start to challenge the prevailing hegemonic one. In fact, an ideological class struggle accompanies and sometimes even precedes the political class struggle properly speaking. Religious and philosophical struggles preceding the classical bourgeois revolutions; the first socialist critiques of bourgeois society preceding the constitution of the first working-class parties and revolutions, are examples of that type.

The class struggle has been up to now the great motor of history. Human beings make their own history. No mode of production can be replaced by another one without deliberate actions by large social forces, i.e., without social revolutions (or counter-revolutions). Whether these revolutions or counter-revolutions actually lead to the long-term implementation of deliberate projects of social reorganization is another matter altogether. Very often, their outcome is to a large extent different from the intention of the main actors.

Human beings act consciously, but they can act with false consciousness. They do not necessarily understand why they want to realize certain social and (or) political plans, why they want to maintain or to change economic or juridical institutions; and especially, they rarely understand in a scientific sense the laws of social change, the material and social preconditions for successfully conserving or changing such institutions. Indeed, Marx claims that only with the discovery of the main tenets of historical materialism have we made a significant step forward towards understanding these laws, without being able to predict ‘all’ future developments of society.

Social change, social revolutions and counter-revolutions are furthermore occurring within determined material constraints. The level of development of the productive forces – essentially tools and human skills, including their effects upon the fertility of the soil – limits the possibilities of institutional change. Slave labour has shown itself to be largely incompatible with the factory system based upon contemporary machines. Socialism would not be durably built upon the basis of the wooden plough and the potter's wheel. A social revolution generally widens the scope for the development of the productive forces and leads to social progress in most fields of human activity in a momentous way. Likewise, an epoch of deep social crisis is ushered in when there is a growing conflict between the prevailing mode of production (i.e. the existing social order) on the one hand, and the further development of the productive forces on the other. Such a social crisis will then manifest itself on all major fields and social activity: politics, ideology, morals and law, as well as in the realm of the economic life properly speaking.

Historical materialism thereby provides a measuring stick for human progress: the growth of the productive forces, measurable through the growth of the average productivity of labour, and the number, longevity and skill of the human species. This measuring stick in no way abstracts from the natural preconditions for human survival and human growth (in the broadest sense of the concept). Nor does it abstract from the conditional and partial character of such progress, in terms of social organization and individual alienation.

In the last analysis, the division of society into antagonistic social classes reflects, from the point of view of historical materialism, an inevitable limitation of human freedom. For Marx and Engels, the real measuring rod of human freedom, i.e. of human wealth, is not ‘productive labour’; this only creates the
material pre-condition for that freedom. The real measuring rod is leisure time, not in the sense of ‘time for doing nothing’ but in the sense of time freed from the iron necessity to produce and reproduce material livelihood, and therefore disposable for all-round and free development of the individual talents, wishes, capacities, potentialities, of each human being.

As long as society is too poor, as long as goods and services satisfying basic needs are too scarce, only part of society can be freed from the necessity to devote most of its life to ‘work for a livelihood’ (i.e. of forced labour, in the anthropological/sociological sense of the word, that is in relation to desires, aspirations and talents, not to a juridical status of bonded labour). That is essentially what represents the freedom of the ruling classes and their hangers-on, who are ‘being paid to think’, to create, to invent, to administer, because they have become free from the obligation to bake their own bread, weave their own clothes and build their own houses.

Once the productive forces are developed far enough to guarantee all human beings satisfaction of their basic needs by ‘productive labour’ limited to a minor fraction of lifetime (the half work-day or less), then the material need of the division of society in classes disappears. Then, there remains no objective basis for part of society to monopolize administration, access to information, knowledge, intellectual labour. For that reason, historical materialism explains both the reasons why class societies and class struggles arose in history, and why they will disappear in the future in a classless society of democratically self-administering associated producers.

Historical materialism therefore contains an attempt at explaining the origin, the functions, and the future withering away of the state as a specific institution, as well as an attempt to explain politics and political activity in general, as an expression of social conflicts centred around different social interest (mainly, but not only, those of different social classes; important fractions of classes, as well as non-class social groupings, also come into play).

For Marx and Engels, the state is not existent with human society as such, or with ‘organized society’ or even with ‘civilized society’ in the abstract; neither is it the result of any voluntarily concluded ‘social contract’ between individuals. That state is the sum total of apparatuses, i.e. special groups of people separate and apart from the rest (majority) of society, that appropriate to themselves functions of a repressive or integrative nature which were initially exercised by all citizens. This process of alienation occurs in conjunction with the emergence of social classes. The state is an instrument for fostering, conserving and reproducing a given class structure, and not a neutral arbiter between antagonistic class interests.

The emergence of a classless society is therefore closely intertwined, for adherents to historical materialism, with the process of withering away of the state, i.e. of gradual devolution to the whole of society (self-management, self-administration) of all specific functions today exercised by special apparatuses, i.e. of the dissolution of these apparatuses. Marx and Engels visualized the dictatorship of the proletariat, the last form of the state and of political class rule, as an instrument for assuring the transition from class society to classless society. It should itself be a state of a special kind, organizing its own gradual disappearance.

We said above that, from the point of view of historical materialism, the immediate object of class struggle is the division of the social product between different social classes. Even the political class struggle in the final analysis serves that main purpose; but it also covers a much broader field of social conflicts. As all state activities have some bearing upon the relative stability or instability of a given social formation, and the class rule to which it is submitted, the class struggle can extend to all fields of
politics, from foreign policy to educational problems and religious conflicts. This has of course to be proven through painstaking analysis, and not proclaimed as an axiom or a revealed truth. When conducted successfully, such exercises in class analysis and class definition of political, social and even literary struggles become impressive works of historical explanation, as for example Marx's *Class Struggles in France 1848–50*, Engels’ *The German Peasant War*, Franz Mehring's *Die Lessing-Legende*, Trotsky's *History of the Russian Revolution*, etc.

**Marx's economic theory — general approach and influence**

A general appraisal of Marx's method of economic analysis is called for prior to an outline of his main economic theories (theses and hypotheses). Marx is distinct from most important economists of the 19th and 20th centuries in that he does not consider himself at all an ‘economist’ pure and simple. The idea that ‘economic science’ as a special science completely separate from sociology, history, anthropology etc. cannot exist, underlies most of his economic analysis. Indeed, historical materialism is an attempt at unifying all social sciences, if not all sciences about humankind, into a single ‘science of society’.

For sure, within the framework of this general ‘science of society’, economic phenomena could and should be submitted to analysis as specific phenomena. So economic theory, economical science, have a definite autonomy after all; but is only a partial and relative one. Probably the best formula for characterizing Marx's economic theory would be to call it an endeavour to explain the social economy. This would be true in a double sense. For Marx, there are no eternal economic laws, valid in every epoch of human prehistory and history. Each mode of production has its own specific economic laws, which lose their relevance once the general social framework has fundamentally changed. For Marx likewise, there are no economic laws separate and apart from specific relations between human beings, in the primary (but not only, as already summarized) social relations of production. All attempts to reduce economic problems to purely material, objective ones, to relations between things, or between things and human beings, would be considered by Marx as manifestations of mystification, of false consciousness, expressing itself through the attempted reification of human relations. Behind relations between things, economic science should try to discover the specific relations between human beings which they hide. Real economic science has therefore also a demystifying function compared to vulgar ‘economics’, which takes a certain number of ‘things’ for granted without asking the question: Are they really only what they appear to be? From where do they originate? What explains these appearances? What lies behind them? Where do they lead? How could they (will they) disappear? *Problembblindheit*, the refusal to see that facts are generally more problematic than they appear at first sight, is certainly not a reproach one could address to Marx's economic thought. Marx's economic analysis is therefore characterized by a strong ground current of *historical relativism*, with a strong recourse to the genetical and evolutionary method of thinking (that is why the parallel with Darwin has often been made, sometimes in an excessive way). The formula ‘genetic structuralism’ has also been used in relation to Marx's general approach to economic analysis. Be that as it may, one could state that Marx's economic theory is essentially geared to the discovery of specific ‘laws of motion’ for successive modes of production. While his theoretical effort has been mainly centred around the discovery of these laws of motion for capitalist society, his work contains indications of such laws —
different ones, to be sure – for precapitalist and postcapitalist social formations too.

The main link between Marx's sociology and anthropology on the one hand, and his economic analysis on the other, lies in the key role of social labour as the basic anthropological feature underlying all forms of social organization. Social labour can be organized in quite different forms, thereby giving rise to quite different economic phenomena ('facts'). Basically different forms of social labour organization lead to basically different sets of economic institutions and dynamics, following basically different logics (obeying basically different 'laws of motion').

All human societies must assure the satisfaction of a certain number of basic needs, in order to survive and reproduce themselves. This leads to the necessity of establishing some sort of equilibrium between socially recognized needs, i.e. current consumption and current production. But this abstract banality does not tell us anything about the concrete way in which social labour is organized in order to achieve that goal.

Society can recognize all individual labour as immediately social labour. Indeed, it does so in innumerable primitive tribal and village communities, as it does in the contemporary kibbutz. Directly social labour can be organized in a despotic or in a democratic way, through custom and superstition as well as through an attempt at applying advanced science to economic organization; but it will always be immediately recognized social labour, in as much as it is based upon a prior assignment of the producers to their specific work (again: irrespective of the form this assignation takes, whether it is voluntary or compulsory, despotic or simply through custom etc.).

But when social decision-taking about work assignation (and resource allocation closely tied to it) is fragmented into different units operating independently from each other – as a result of private control (property) of the means of production, in the economic and not necessarily the juridical sense of the word – then social labour in turn is fragmented into private labours which are not automatically recognized as socially necessary ones (whose expenditure is not automatically compensated by society). Then the private producers have to exchange parts or all of their products in order to satisfy some or all of their basic needs. Then these products become commodities. The economy becomes a (partial or generalized) market economy. Only by measuring the results of the sale of his products can the producer (or owner) ascertain what part of his private labour expenditure has been recognized (compensated) as social labour, and what part has not.

Even if we operate with such simple analytical tools as ‘directly social labour’, ‘private labour’, ‘socially recognized social labour’, we have to make quite an effort at abstracting from immediately apparent phenomena in order to understand their relevance for economic analysis. This is true for all scientific analysis, in natural as well as in social sciences. Marx's economic analysis, as presented in his main books, has not been extremely popular reading; but then, there are not yet so many scientists in these circumstances. This has nothing to do with any innate obscurity of the author, but rather with the nature of scientific analysis as such.

The relatively limited number of readers of Marx's economic writings (the first English paperback edition of *Das Kapital* appeared only in 1974!) is clearly tied to Marx's scientific rigour, his effort at a systematic and all-sided analysis of the phenomena of the capitalist economy.

But while his economic analysis lacked popularity, his political and historical projections became more and more influential. With the rise of independent working-class mass parties, an increasing number of these proclaimed themselves as being guided or influenced by Marx, at least in the epoch of the Second and the Third Internationals, roughly the half century from 1890 till 1940. Beginning with the Russian
revolution of 1917, a growing number of governments and of states claimed to base their policies and constitutions on concepts developed by Marx. (Whether this was legitimate or not is another question.) But the fact itself testifies to Marx’s great influence on contemporary social and political developments, evolutionary and revolutionary alike. Likewise, his diffused influence on social science, including academic economic theory, goes far beyond general acceptance or even substantial knowledge of his main writings. Some key ideas of historical materialism and of economic analysis which permeate his work – e.g. that economic interests to a large extent influence, if not determine, political struggles; that historic evolution is linked to important changes in material conditions; that economic crises (‘the business cycle’) are unavoidable under conditions of capitalist market economy – have become near-platitudes. It is sufficient to notice how major economists and historians strongly denied their validity throughout the 19th century and at least until the 1920s, to understand how deep has been Marx's influence on contemporary social science in general.

**Marx's labour theory of value**

As an economist, Marx is generally situated in the continuity of the great classical school of Adam Smith and Ricardo. He obviously owes a lot to Ricardo, and conducts a current dialogue with that master in most of his mature economic writings.

Marx inherited the labour theory of value from the classical school. Here the continuity is even more pronounced; but there is also a radical break. For Ricardo, labour is essentially a numeraire, which enables a common computation of labour and capital as basic elements of production costs. For Marx, labour is value. Value is nothing but that fragment of the total labour potential existing in a given society in a certain period (e.g. a year or a month) which is used for the output of a given commodity, at the average social productivity of labour existing then and there, divided by the total number of these commodities produced, and expressed in hours (or minutes), days, weeks, months of labour.

Value is therefore essentially a social, objective and historically relative category. It is social because it is determined by the overall result of the fluctuating efforts of each individual producer (under capitalism: of each individual firm or factory). It is objective because it is given, once the production of a given commodity is finished and is thus independent from personal (or collective) valuations of customers on the market place; and it is historically relative because it changes with each important change (progress or regression) of the average productivity of labour in a given branch of output, including in agriculture and transportation.

This does not imply that Marx's concept of value is in any way completely detached from consumption. It only means that the feedback of consumers’ behaviour and wishes upon value is always mediated through changes in allocation of labour inputs in production, labour seen as subdivided into living labour and dead (dated) labour, i.e. tools and raw materials. The market emits signals to which the producing units react. Value changes after these reactions, not before them. Market price changes can of course occur prior to changes in value. In fact, changes in market prices are among the key signals which can lead to changes in labour allocation between different branches of production, i.e. to changes in labour quantities necessary to produce given commodities. But then, for Marx, values determine prices only basically and in the medium-term sense of the word. This determination only appears clearly as an explication of medium and long-term price movements. In the shorter run, prices fluctuate around values.
as axes. Marx never intended to negate the operation of market laws, of the law of supply and demand, in determining these short-term fluctuations.
