In 2005, only 20 out of the 184 member countries of the International Monetary Fund (IMF) declined to accept the obligations to current account convertibility. But in a large number of countries various types of restrictions limited convertibility in some way or created differences in the exchange rates applying to exports and imports. Non-unified exchange rates lead to inefficient allocation of resources, as previously documented by Bhagwati (1978). For example, 70 countries required repatriation and surrender of proceeds of exports or invisible transactions, 57 countries had payments arrears of one kind or another, and 11 countries maintained either dual or multiple exchange rates for different types of transactions. With respect to capital account transactions, the situation is much more restrictive: 126 countries had controls on international transactions in capital market securities, and 143 countries maintained controls on direct investment flows.

**Reserve assets**
In order to guarantee convertibility of the domestic currency into other convertible currencies, monetary authorities hold stocks of reserve assets, which are liquid assets held in readily accepted international media of exchange, such as dollars, euros, and a few other currencies. In addition, IMF member countries have access to unconditional borrowing rights to obtain additional reserve assets in the form of their reserve positions in the Fund and Special Drawing Rights. These, together with reserve asset holdings, make up international liquidity.

Since most international payments are handled by inter-bank transactions, banks have sought to minimize transactions costs by channelling their foreign exchange transactions through one or more vehicle currencies, the pound sterling in earlier days, but more recently the US dollar and to some extent the euro. Because the dollar is so widely used in private exchange transactions, monetary authorities also find it convenient to operate in dollars to ensure the convertibility of their currencies.

Adjustment mechanisms

The existence of different national currencies and the need to maintain convertibility of the different currencies lead to the concept of balance of payments adjustment mechanism. At a given exchange rate, as long as the amount of foreign exchange earned through exports of goods and services and capital inflows just pays for imports and capital outflows, no external imbalance exists. If international capital markets were perfect and if investors were risk neutral so that assets denominated in different currencies were perfect substitutes for one another in private portfolios, there would in practice be a single world interest rate for short-term borrowing. Then imbalances between foreign exchange earnings and payments could simply be financed by borrowing in the international capital market. There would be no real distinction between the convertibility characteristics of the official liabilities of different borrowers. But, in fact, countries face very real limits on the amount of foreign currency they can borrow abroad in exchange for domestic currency because of exchange rate risk, which limits the willingness of risk-averse foreign lenders to acquire domestic currency assets. According to the doctrine of original sin, countries with a history of convertibility problems are unable to issue foreign debt in their own currency (Eichengreen and Hausmann, 2005). The ability to repay foreign currency debt is dependent on balance of payments adjustment. Political risk involves the possibility that exchange controls may be imposed in the future, preventing the repayment of foreign currency debt on the promised terms. Thus it is desirable for countries to have access to a variety of adjustment mechanisms to eliminate external imbalances, as well as a variety of sources of official financing in the form of international liquidity. The primary mechanisms of balance of payments adjustment are through movements in exchange rates and adjustments of income and price levels via monetary and fiscal policies. The need for adjustment can be postponed by imposition of tariffs and subsidies, quantitative restrictions on current account or capital account transactions, or controls over the allocation of foreign exchange. But tariffs, quantitative restrictions, and exchange controls generally involve inefficiencies in the allocation of resources, including in the latter case loss of convertibility of the domestic currency. Changes in monetary and fiscal policies or exchange rates have their own costs in terms of domestic policy objectives forgone.

Financing
Thus, a mixture of adjustment policies and financing mechanisms is provided in a system of international monetary arrangements. Official financing is provided either by drawing on holdings of official reserve assets or by borrowing from international institutions. Private financing can be arranged by a monetary authority borrowing from foreign banks or the international bond market. Either provides the ability to postpone adjustment. The optimum mix of adjustment and financing for an individual country depends on the costs of the various alternatives. By setting the costs of these alternatives, international monetary arrangements influence the behaviour of the world economy.

A model of adjustment versus financing

In the theory of adjustment versus financing, a country is faced with random balance of payments deficits and surpluses, which it may either finance by drawing on reserve assets or adjust by one of the adjustment mechanisms mentioned above. In one branch of the theory, due to Heller (1966) and others, the cost of adjustment is assumed to be a linear function of the size of the adjustment, so that any adjustments are postponed to the last minute, at which time full adjustment takes place. Alternatively, one may assume a nonlinear cost of adjustment, leading to a theory of partial adjustment. Kelly (1970) and Clark (1970) assume that the country's welfare function depends on the mean and variance of income, so that gradual adjustments are preferred. The analysis determines both the optimum level of reserve holdings, $R^*$, and the optimum rate of adjustment $\alpha$ to that level, according to the equation

\[ \Delta R = \alpha [R^* - R_{-1}] + u, \]

where $u$ is normally distributed with mean zero and variance $\sigma^2$ and $R_{-1}$ is the stock of reserves at the end of the previous period. This equation assumes that changes in the stock of reserves arise from both the random shocks in the balance of payments and the desired rate of adjustment to the optimal level of reserves. From eq. (1) we find that the variance of reserve holdings decreases as the speed of adjustment $\alpha$ increases from zero to one. Tchebychev's inequality then enables one to show that, for a given probability of not exhausting reserves and given opportunity cost $r$ of holding reserves, the optimum reserve holding $R^*$ decreases with increasing $\alpha$. As $\alpha$ increases, the need for more frequent adjustments raises the variance of income. Therefore the speed of adjustment should be chosen such that the welfare loss from increased variance in income due to a small increase in $\alpha$ is just counterbalanced by the welfare saving due to holding slightly smaller reserves.

According to this theory, international monetary institutions will strongly affect the behaviour of national policies concerning balance of payments adjustment and acquisition of reserves. Specifically, international money institutions will determine the opportunity cost of holding reserves, the penalty attached to running out of reserves, and the availability of different types of adjustment policies. By influencing countries’ balance of payments adjustment policies, international institutions will also
influence their domestic policies, since there is a trade-off between internal and external objectives of policy.

The role of markets and institutions

An optimal design for the international monetary system depends on balancing among a group of conflicting objectives: growth of real income and employment, stable prices, efficient allocation of resources, maintenance of convertibility of currencies, improving the distribution of income, and growth of world trade. The relevant trade-offs can be understood in the context of an economic model.

According to the model of adjustment and financing outlined above, reductions in the opportunity cost of holding reserves will lead to increased reserve holdings, a reduction in the speed of adjustment to imbalances, increased use of financing, and a decline in the variability of income. The slowdown in the speed of adjustment implies a change in the allocation of resources among countries. The increased use of financing may imply an increase in the rate of inflation. An optimal international system should balance these various considerations. For discussion of efforts to design such a system, see Solomon (1982) and the documents of the IMF's Committee of Twenty (IMF, 1974).

In a purely laissez-faire system, market borrowing instead of official reserves would be the source of financing to postpone adjustment. Fluctuations in market interest rates would determine the terms of trade between adjustment and financing. As is usual in market solutions, the wealthy are in a better position to negotiate terms on loans. By contrast, a more institutionalized system provides access to financing at lower rates to those with a weaker market position, with more conditions on the use of the funds. Evaluating the difference between two such systems is a complex task. For an attempt, see Jones (1983).

The evolution of international monetary institutions

Between the close of the Napoleonic Wars and 1880, the international monetary system gradually moved onto the gold standard, which was fully achieved during the period 1880–1914. Under the leadership of Great Britain, sterling operated as a vehicle currency during this period, allowing an efficient international payments mechanism to develop. The increasing substitution of bank deposits for currency allowed an ever-larger volume of payments to be supported by a gradually rising supply of gold. Despite the best efforts of the Bank of England and other central banks, periodic crises interfered with the continued convertibility of individual currencies. And the system was characterized by substantial fluctuations in employment and prices, albeit about a rising trend of employment with no trend in prices.

Following the First World War, gold convertibility was resumed on a limited basis, until the Great Depression of 1929–33 brought it to an end. A period of fluctuating exchange rates, competitive devaluations, and increasing use of trade restrictions to promote domestic employment ensued. It is generally believed that the economic difficulties of the interwar period were major factors bringing on the Second World War.

The Bretton Woods system
The United States and Great Britain took the lead in constructing the post-war international monetary institutions, with Harry Dexter White and John Maynard Keynes drawing up rival designs for the new system agreed at the Bretton Woods Conference in 1944. The Articles of Agreement of the International Monetary Fund provided for a system based on pegged, but adjustable, exchange rates and an institution which would lend reserve assets to countries that were having temporary difficulties in maintaining convertibility. Resort to floating exchange rates, competitive devaluations, and trade restrictions to promote domestic employment were explicitly to be avoided, in the light of the problems of the 1930s. Convertibility for current account transactions was promoted, while capital account convertibility was required only for those transactions necessary for financing current payments.

The lending power of the IMF was based on quotas of gold and domestic currency contributed by each member country. Only the gold was to be paid in initially, but, if the Fund needed convertible currency to lend out, it would obtain it from any member whose currency was considered strong enough to be usable. Members could borrow automatically up to the amount of the gold portion or tranche of the quota, but only on demonstration of balance of payments need, and thereafter they could borrow more subject to meeting conditions on economic and financial policies. For further discussion of IMF policies, see Williamson (1983), Kenen (2001), and Truman (2006).

The initial post-war problem involved the establishment of a payments system that would promote economic recovery and the growth of trade among the former combatants. The International Monetary Fund limited itself to establishing a set of agreed par values for pegged exchange rates which could promote the growth of trade, leaving the provision of loans and grants for economic recovery to the United States, the strongest economy. Under this system, which was a form of gold exchange standard, countries declared their par values in terms of the US dollar, which in turn was convertible into gold at $35 an ounce. Thus the dollar became the key currency of the system, and most foreign exchange reserves came to be held in the form of dollars. Within Europe, convertibility remained limited until 1958, and the European Payments Union was established to facilitate intra-European payments. The re-establishment of convertibility led to fears that the IMF might have inadequate resources to deal with the problems of large member countries. In 1962 the General Arrangements to Borrow were created, to enable the Fund to mobilize additional resources from its largest members, the Group of Ten.

With the recovery of the European economies in the 1950s and the achievement of convertibility in 1958, the US dollar became gradually overvalued relative to gold and other currencies. As Robert Triffin (1960) pointed out, the key currency system required the United States to continue to run balance of payments deficits in order to supply other countries with increased foreign exchange reserves. As it did so, the gold reserve of the United States became increasingly inadequate to guarantee gold convertibility of growing US official dollar liabilities at $35 an ounce.

A variety of solutions to this problem were proposed, including the creation of an artificial reserve asset to substitute for dollars, an increase in the dollar price of gold, and the adoption of floating exchange rates. In 1968 the First Amendment to the Articles of Agreement of the International Monetary Fund permitted the creation of Special Drawing Rights (SDRs), which have twice been allocated to member countries in proportion to their existing quotas in the Fund. SDRs, when utilized, permit the user to acquire convertible currencies from other members, upon the payment of interest. They represent a centralized mechanism for increasing the stock of reserves. By the early 1970s the gold convertibility of the dollar was under increasing pressure, for a variety of reasons. In August 1971 the dollar was
unilaterally set loose from gold. The Smithsonian Agreement of December 1971 attempted to save the
Bretton Woods system by multilateral realignment of exchange rates, including a devaluation of the
dollar against gold and a widening of the narrow bands of fluctuation permitted around the newly fixed
values. Some members of the European Communities (EC) agreed to maintain narrower margins of
fluctuations versus each other’s currency, in an arrangement that became known as the ‘EC Snake’.
Despite these efforts, the revised Bretton Woods system lasted only a little more than a year.

Floating exchange rates

In March 1973, exchange rates of most of the major industrial countries began floating. At the same
time, most developing countries continued to peg their currencies to the dollar or another developed
country currency, and the EC maintained the ‘Snake’. About this time, a major effort to reconstruct
international monetary institutions on the basis of pegged exchange rates began under the auspices of the
IMF’s Committee of Twenty. This effort collapsed in 1974, in part under the impact of the quadrupling
of world oil prices by the Organization of Petroleum Exporting Countries.
In Jamaica in January 1976, the Interim Committee of the Board of Governors of the International
Monetary Fund agreed on a Second Amendment to the Fund’s Articles of Agreement, ratifying the
system of floating exchange rates. First, stability of exchange rates was to be sought through stability of
underlying monetary and fiscal policies rather than through pegging. Second, floating rates should be
subject to a process of ‘firm surveillance’ by the IMF. Third, it was hoped that the SDR would ‘become
the principal reserve asset’, with the role of gold and the dollar being reduced. Fourth, the fixed official
price of gold was abolished and one-third of the IMF’s gold was disposed of. Acceptance of the status
quo was all that could be accomplished. The result, according to Corden (1983), was an international
laissez-faire system.
In 2005 some 88 countries made use of floating exchange rates, while 51 had pegged exchange rates of
one type or another and 48 operated within currency unions with other countries.

Increased capital mobility, the Asian crisis and reform proposals

Beginning in the 1970s, international capital mobility increased significantly, as middle-income
developing countries found new access to foreign borrowing and industrialized countries increasingly
opened production facilities in each others’ markets. In the early 1990s, the IMF began discussions of a
possible amendment that would promote capital account convertibility as an additional goal of the
international monetary system, on the argument that improved allocation of capital would lead to
increased economic growth. But a series of crises in emerging market economies interfered with this
project, most notably the Asian financial crisis of 1997, followed by the Russian crisis of 1998 and the
Argentine crisis of 2001. Each of these events was preceded by substantial capital inflows seeking
higher returns, which overwhelmed under-regulated and underprepared domestic economies and
financial systems. The convertibility of affected currencies was often temporarily impaired (Black,
Christofides and Mourmouras, 2006). In some cases the IMF was seen as creating a permissive
environment prior to the crisis, followed by harsh demands for domestic reforms subsequently, in
attempts to restore confidence and bring an end to capital outflow.
A substantial body of criticism on one side argued that, by its willingness to provide large amounts of financing to countries in crisis, the Fund had created ‘moral hazard’, encouragement to over-borrowing and over-lending in expectation of a bailout (International Financial Institution Advisory Commission, 2000). On the other side, others claim that the Fund by its harsh requirements for reform was stifling economic recovery and growth (Stiglitz, 2002). Both of these viewpoints may have had some validity, but in a sense they cancel each other out (see Kenen, 2001). The Fund itself proposed creation of an international Sovereign Debt Restructuring Mechanism to assist defaulting countries in negotiations with creditors (Krueger, 2003). This was rejected in favour of a more modest approach encouraging the use of collective action clauses in bond indentures requiring minority bondholders to accept terms of repayment agreed to by a majority.

Another criticism of the IMF is that its voting shares and representation appear outdated, as compared with the changing economic importance of different groups of countries (Truman, 2006). In particular, large emerging market economies such as China, India, and Brazil are under-represented, while the European Union countries with 32 per cent of the voting power are over-represented. Obviously, changes in representation are extremely difficult to achieve, but will still be necessary to remedy a situation in which the rich creditor countries that do not utilize the Fund's resources have disproportionate voting power relative to the debtor nations that have greater need for use of its facilities.

The ‘new’ Bretton Woods and Asian monetary cooperation

Following recovery from the Asian crisis of 1997, countries such as Korea, China, Malaysia, Taiwan and India sharply increased their accumulations of international reserves, as developing Asian countries in total raised their reserves (minus gold) from SDR 414 billion to SDR 1,039 billion between the ends of 1998 and 2004. China, Hong Kong and Malaysia in particular sought to maintain exchange rates pegged to the US dollar, while the other countries managed their floating exchange rates so as to avoid undue appreciation against the US dollar, accumulating enormous reserves in the process. An influential paper by Dooley, Folkerts-Landau and Garber (2004) argued that this relationship was a new version of the old Bretton Woods system, whereby other countries pegged their exchange rates to the US dollar, enabling the United States to run large current account deficits, while the creditor nations increased their exports to the United States. Alternatively, the vastly increased reserve holdings of Asian countries could be regarded as a precautionary response to insure the availability of financing to avoid the prospect of another sharp adjustment, following the unpleasant experiences of the 1997 Asian crisis. The combination of increased regional reserve holdings and recent bad experience with internationally supervised adjustment has led Asian countries to embark on steps towards regional monetary cooperation, culminating in the so-called Chiang Mai Initiative for regional currency swaps among the Association of South East Asian Nations (ASEAN) plus China, Japan, and Korea (see Park and Wang, 2005). ASEAN members realized that the industrial countries of the Group of Ten had previously used currency swaps among central banks to lend each other money in times of crisis and thus avoid the need for borrowing from the IMF with its conditionality. With growing availability of reserves in Asia, the ASEAN+3 concluded that they might similarly help each other out in future. Under the leadership of the Asian Development Bank, further steps are contemplated, possibly including an Asian Monetary Fund and an Asian Currency Unit.
The European Monetary Union

The enlargement and strengthening of the EC ‘Snake’ in 1978, which was in the process renamed the European Monetary System (EMS), gradually led to the creation of the European Monetary Union with a unit of account, the European Currency Unit (ECU). The objectives of the enlarged EMS were to reduce intra-European exchange rate fluctuations, to promote convergence of macroeconomic policies within Europe, and to reduce European dependence on US monetary policies. Over a period of 15 years, the EMS succeeded in these objectives, at the cost of a series of exchange rate realignment crises culminating in a major collapse of the system in 1992–3, when the narrow margins (plus or minus $\frac{21}{4}$ per cent) were expanded (to plus or minus 15 per cent). The crisis was brought on by a combination of increasingly rigid exchange rates within the system, increased capital mobility as a component of the Single Market programme of the European Union, and stresses brought on by the unification of East and West Germany.

In response to these factors, and to further strengthen the integration of European markets and achieve a more symmetrical sharing of decision making in monetary policy, the Maastricht Treaty ratified in 1993 brought into being in 1999 the European Monetary Union, with a single currency, the euro, with monetary policy controlled by a European Central Bank (ECB) in Frankfurt, Germany, replacing the currencies of the 12 member countries of the eurozone. While the euro has been quickly accepted as an international currency, in both the member countries and their neighbours, the relatively conservative operations of the ECB together with the constraints on member countries’ fiscal policy embodied in the Stability and Growth Pact have proven controversial in the light of slow economic growth in the eurozone.

The euro is gradually becoming more important in international transactions and in the foreign exchange market as a rival to the US dollar. In 2006 the IMF redefined the SDR currency basket reflecting the importance of currencies in international trade and finance to be composed of 44 per cent US dollars, 34 per cent euro, 11 per cent Japanese yen and 11 per cent pound sterling, as compared with the previous weights of 45 per cent US dollars, 29 per cent euro, 15 per cent yen and 11 per cent pound sterling.

International outsourcing involves the import of intermediate inputs or services from unaffiliated foreign suppliers. While it implies that the production of a final product involves production activities in more than one country, this trade in intermediate inputs can be explained by traditional theories of international trade where countries have comparative advantage in different stages of production. However, since outsourcing relationships involve interaction with foreign partners, the choice of organizational form for these transactions is also influenced by industrial organization factors, such as search costs or contract incompleteness. This article discusses these issues and the effects of outsourcing on the international economy.

Keywords
comparative advantage; factor price equalization; foreign direct investment; hold-up problem; incomplete contracts; intermediate inputs; international outsourcing; matching; North–South economic relations; offshoring; search costs; sunk costs; trade costs; thick markets; transport costs; vertical integration

Article
In complex production processes firms face a classic make-or-buy question: should they purchase parts, assembly or services from an outside vendor, or perform those tasks themselves? In the domestic context, the benefits and costs of vertical integration are already well understood. However, declines in international transport costs, advances in remote management technologies and improved communications technologies have brought an international dimension to this question, as they have enabled an increasing number of firms to engage in international outsourcing, purchasing parts, assembly or services from unaffiliated international suppliers. As with trade in final products, international trade in intermediate inputs is shaped by international
differences in comparative advantage that reflect cross-country differences in factor costs, or relative productivities for different stages of production. Hence, when firms decide where to complete the production activities required for the creation of a final product – design, materials extraction, parts production, and assembly – comparative advantage influences the ideal country placement for each production stage. However, if there are international frictions, such as international transport costs or tariffs, outsourcing imports will emerge only when the international outsourcing benefits stemming from comparative advantage exceed the costs associated with these international frictions.

Broad examination of international trade data, such as that of Hummels, Ishii and Yi (2001), or Yeats (2001) indicates that international trade in intermediate inputs has grown even more rapidly than the generally large growth in international trade since 1960. This trade in intermediate inputs represents both outsourcing purchases from unrelated suppliers and ‘offshoring’, which is the import of parts or services from related overseas suppliers, such as foreign subsidiaries. Yi (2003) argues that two key economic factors explain why recent declines in international trading costs have generated such an exceptional increase in intermediates trade. First, trade in intermediates increases along an extensive margin as declines in trade costs enable products that were previously produced domestically to be more profitably produced through an internationally integrated production process. Second, the effects of declining frictional costs are magnified when intermediates trade involves multiple border crossings, since the benefits of falling tariff or transportation charges apply to each border crossing involved in the creation of the final product.

Nonetheless, while international differences in international factor costs provide an incentive for international outsourcing, differences in international factor costs are not sufficient in themselves to guarantee that outsourcing relationships will develop. Thus, there are two strands in the literature on international outsourcing that explain firm choices. The first emphasizes limits on outsourcing that relate to search costs and matching, while the second focuses on the firm's choice of organizational form when contracts are incomplete.

When the search for an appropriate outsourcing partner is costly, firms will search for a foreign partner if the expected increase in profit generated by the search exceeds the sunk costs of searching for an international partner. Thus, Grossman and Helpman (2005) demonstrate that, when the cost of foreign search is particularly high, firms may choose domestic outsourcing in the high-wage home country over foreign outsourcing in the lower-cost foreign country. In addition, if the appearance of potential outsourcing partners is endogenous, the increased demand for partners in a particular location generates a market thickness externality. Since the entry of potential partners increases the likelihood that searches will be successful, the increase in expected profits in thick markets increases the equilibrium number of searches in the market that becomes more densely populated with suppliers. As a result, search cost frictions, and the market thickness externalities they generate support an international equilibrium in which firms may be indifferent between searching for partners at home and searching for them abroad, even though wages and factor costs are not equalized across countries. In support of these ideas, Swenson (2005) finds that, while costs matter for some US outsourcing decisions, the cost sensitivity is largest for industries that are less capital intense and for industries that have thicker international markets for suppliers. The quality of country institutions, such as the strength and efficacy of a country's legal system, also influence the strength of market thickness externalities, since favourable country institutions increase demand for international outsourcing partnerships, thus increasing entry by outsourcing suppliers.
Even when comparative advantage is sufficiently strong to favour the overseas purchase of intermediate inputs, problems caused by contract incompleteness present a second reason why firms may not choose to engage in international outsourcing. In this case, firms may alternatively choose to integrate vertically with their foreign suppliers, or to set up foreign subsidiaries to conduct and support their purchase of overseas inputs and supplies. Firms are particularly likely to choose such ‘offshoring’ arrangements when problems arising from contract incompleteness are present in an industry that requires significant relationship-specific investments (Head, Ries and Spencer, 2004; Qui and Spencer, 2002). Antras (2003) argues that contract incompleteness will be more problematic in capital-intensive industries: an idea that finds empirical support in his observation that the fraction of US imports that are intra-firm is higher for capital-intensive industries and for trade with more capital-abundant countries.

Since the set-up of a foreign affiliate often involves substantial foreign direct investment expenditure, not all firms will choose offshoring over outsourcing for their international purchases of intermediate inputs. In this vein, Antras and Helpman (2004) show that, when firms are heterogeneous in their productivity, different sourcing strategies will coexist in equilibrium, as each firm chooses the sourcing method that maximizes its profits. Feenstra and Hanson (2005) provide further evidence of heterogeneous organizational choices in the case of Chinese processing trade, where organizational variation across Chinese industries and Chinese provinces supports their model of firm organization which is based on a property-rights description of the firm. Finally, thick market externalities may generate multiple outsourcing equilibria, as McClaren (2000) describes in a setting where independent input suppliers face a hold-up problem when they develop special components for a specific foreign purchaser of intermediate inputs. Here, an increase in market thickness, due to an increase in the number of final goods firms who search for suppliers, reduces the hold-up problem, since the bid of the next-closest purchaser increases.

Cross-country cost differences influence firms’ international outsourcing decisions. In turn, the growth of international outsourcing may lead to changes in the international equilibrium. First, if country endowments differ dramatically, ordinary trade in final goods may narrow cross-country differences in factor rewards, but fail to bring about factor price equalization. Using traditional trade models, Deardorff (2001) shows that outsourcing may facilitate factor price equalization. Deardorff also shows that outsourcing may reduce a country's welfare if changes in international prices cause a terms of trade loss which reduces a country's gains from trade, as compared with the gains it reaped from trade in final goods only. However, outsourcing will not harm, and may even help, country welfare when international prices are unaffected.

The effect of outsourcing on international factor rewards depends crucially on the nature of the production process. In a three factor world where production of intermediate inputs involves the combination of capital with skilled and unskilled labour, Feenstra and Hanson (1996) demonstrate how outsourcing may exacerbate income inequality in all countries, where income inequality is measured by the compensation of high-skilled relative to low-skilled workers. Intermediate goods are ordered according to their relative use of skilled to unskilled labour, while all intermediate inputs have equal capital cost shares. The production of the final good involves the costless assembly of the full range of intermediate inputs. In this framework, outsourcing brought about by capital flows from the Northern country to the Southern country reduces the relative cost of capital in the south, thus lowering the relative cost of producing each intermediate input in the south. This causes the skill intensity of southern
production to rise as the country begins to produce an expanded range of intermediate inputs, which were previously completed in the North. From the South’s perspective, the activities are more skilled-labour intense than their previous set of activities, while the activities were the least skilled-labour intense activities of those that the North produced. Thus, the shift in intermediates production increases the compensation of high-skill relative to low-skill workers in both locations since the relative demand for skilled workers rises in both the North and the South. At a firm level, Head and Ries (2002) observe that the skill level of Japanese workers in Japanese multinationals rose especially rapidly when the Japanese firms imported an increasing portion of their products from low-income, presumably labour-abundant countries. In the end, the fact that international outsourcing provokes such strong political concern reflects the fact that outsourcing, like international trade, has the potential to influence relative factor rewards.

Coordination among national governments as they formulate macroeconomic policies has been proposed as a response to global integration among national markets. Policy coordination may be beneficial by preventing the externalities created by policy spillovers, as well as by promoting international risk sharing. The usefulness of coordination depends upon numerous characteristics of an economy, including the degree of openness in goods and asset markets.

Article
Coordination among national governments as they formulate macroeconomic policies has been proposed as a response to global integration among national markets. Awareness has grown over time of how national macroeconomies are interconnected in a global marketplace. Rising trade volumes indicate international integration among goods markets, large international financial flows indicate integration in asset markets, and highly visible immigration flows reflect increasing integration in national labour markets. Progressive globalization in the private economic sphere has prompted the question of whether public policy likewise should be global. Should the policies that nations use to manage their national macroeconomies be coordinated jointly with other nations? This is not a new question, and economists have voiced a variety of opinions and theories. Most
academic economists have tended to be sceptical about the need for explicit international policy coordination.

To date there is limited coordination of macroeconomic policies in practice. Under the Bretton Woods arrangement of fixed exchange rates following the Second World War II until 1973, the monetary policies of member countries were constrained by the need to maintain an exchange rate target. If a national central bank were to attempt to increase the domestic money supply or lower domestic interest rates as a means of stimulating domestic production, this would tend to lower the value of its national currency relative to others and violate the fixed exchange rate agreement. Since the dissolution of this system in the 1970s, many nations learned to appreciate the resulting freedom to use their monetary policy to pursue domestic objectives.

Nonetheless, over the decades since the end of the Bretton Woods system, economic officials of major industrial countries periodically have met to discuss exchange rate intervention and options for monetary and fiscal policies. Examples include the Plaza and Louvre accords in the 1980s. Without binding public agreements, it is not clear how much coordination takes place at such meetings, and the function served by them may simply be sharing information regarding policy intentions. In some regions of the world, a subset of countries have taken steps on their own to more formally coordinate their policies. The most dramatic form of international macroeconomic policy coordination of late has been the formation of the European Monetary Union in 1999. Eleven initial member countries ceded sovereignty over national monetary policy to a European Central Bank, where a single monetary policy must be agreed upon for the whole region.

The opinions of academic economists on the advisability of policy coordination have varied over time, largely in response to the introduction of new tools of economic analysis. Milton Friedman (1953) and others recommended against explicit coordination, suggesting that private market forces could be trusted to achieve a desirable outcome. In particular, exchange rate movements could serve a useful function of insulating countries against the macroeconomic shocks of their neighbours. In contrast, economists of the 1970s and 1980s were able to find theoretical rationales for policy coordination, using Keynesian models that featured frictions that prevented economic markets from operating efficiently on their own. Finally a renewed interest in the subject since 2000, employing models with more microeconomic foundations, has produced new theoretical reasons to question the usefulness of policy coordination. The rest of this article considers two primary motivations for policy coordination: preventing policy spillovers and promoting pooling of international risk. The article discusses each motivation in turn along with its limitations.

Policy spillovers

One motivation for policy coordination is the possibility that the effects of policy spill over national borders to affect the macroeconomies of trading partners. For example, suppose there is a global shock that lowers global demand below some desirable level, such as a wave of pessimistic expectations that lowers investment expenditure. This might be undesirable, to the degree the excess inventories may lead to recession, with a scaling back of production and lower levels of employment. Keynesian theory indicates that one way policymakers can combat such a shortfall in demand is through expansionary fiscal policy, with a rise in government expenditure or a cut in taxes to stimulate private consumption demand. However, globalization affects this policy prescription. National policymakers may fail to
respond if they fear that some of the benefit will leak abroad: a fiscal expansion may lead to a currency appreciation, making domestic goods less competitive than foreign goods. As a result, some of the increase in demand generated by domestic government debt will be used to purchase foreign goods and employ foreign workers.

Coordination of policymakers across countries may provide a way of eliminating the problem created by this externality. If a mechanism of coordination existed to make sure that all countries symmetrically expanded government spending, each government could be reassured that it would benefit from spillovers of demand from abroad, to compensate for the negative spillover of demand leaking abroad. A coordinated global fiscal expansion, the theory says, is an effective way of combating a global shortfall in demand.

Externalities also apply to monetary policy. Monetary expansions tend to cause currency depreciations that make domestic goods more competitive compared to foreign goods. The use of such policy to shift demand from foreign goods toward home goods to raise domestic production at the expense of lower foreign production is labelled ‘beggar-thy-neighbour’. One might imagine repeated rounds of such policies, with each country progressively increasing money supply to regain competitiveness. In the end competing policies will have no net effect on the exchange rate and competitiveness, but the net rise in the money supply of each country would produce the undesirable outcome of excessive inflation. Coordination agreements may commit countries to avoid such policy outcomes; they may agree to forswear beggar-thy-neighbour policies if there is a credible commitment from other countries to do the same. The end result is a better outcome for all.

The spillover argument in favour of coordination clearly depends on the degree to which the private economies are interdependent internationally. Consider goods market integration. If exports tend to be a small fraction of a country's GDP, a currency depreciation raising exports a certain percentage will have a small effect on GDP in absolute terms. The international implications of any policy just wouldn't matter very much. Asset market integration also has been found to be important. If asset markets do not view government debt issued by different countries as equivalent, then a fiscal expansion that raises the issue of debt in one currency could cause a currency depreciation rather than an appreciation, reversing the direction of the fiscal spillovers described above.

Policy spillovers and strategic interactions of policymakers are topics introduced in research by Hamada (1974), Oudiz and Sachs (1984), and Canzoneri and Gray (1985). When a Keynesian theoretical model embodying the spillover arguments above was quantified by Oudiz and Sachs (1984), it was found that the gains from coordination were too small to justify the effort. US merchandise exports to Europe at the time amounted only to 1.6 per cent of US GNP. As a result, the gains from coordination were estimated at only about 0.5 percentage points of GDP for the United States. The lesson was that since international integration was actually quite low, there was little or no role for policy coordination. A question that is addressed later in this article is whether this conclusion continues to hold in a progressively more globalized and integrated world.

**Policymaker objectives**

The relevance of policy spillovers has been qualified by recent research that studies the objectives of policymakers; see Obstfeld and Rogoff (2002), Corsetti and Pesenti (2005), and Canzoneri, Cumby and
Diba (2005). This research features microeconomic foundations to describe the behaviour of consumers, workers, and producers. One benefit of deriving consumer behaviour from assuming they are trying to maximize a particular utility function is that this utility function provides a natural metric by which to evaluate the benefits of alternative policies. Further, it facilitates predictions about how policymakers will act, on the assumption that their behaviour is driven by the goal of improving the welfare of private consumers. For example, one might assume that the policymakers of each country act independently to maximize the utility of citizens in their own country. This ‘Nash’ solution can be contrasted with a coordinated solution, where an international coordinator chooses the policies of all the countries jointly to maximize the sum of utility of citizens across countries. Only if the outcome of the latter coordinated solution supersedes that of the independent Nash solution is there a clear motivation for international policy coordination.

Consider a simplified theoretical world of two countries populated by representative agents that consume and produce. Production involves labour supplied by these agents, combined with technology that is subject to uncertain shocks each year. Suppose these economies exhibit a market imperfection in the form of prices that must be set ahead of time and that cannot change in response to surprise fluctuations in productivity. Given this environment, imagine there is a negative productivity shock that lowers the level of output. In contrast to the argument of the previous section, it no longer is clear that a policymaker should respond by trying to restore output to its previous level by stimulating demand. This would make the welfare of the citizens even worse, because it would force them to work harder during periods where their labours are less rewarded. Instead, utility is made highest by using monetary policy to replicate the outcome of an economy that is free from the sticky-price market imperfection. In this flexible-price version of the world, citizens would choose to work and consume less during periods of low productivity, and choose to work more and acquire wealth during periods when productivity shocks are favourable.

Although it may seem counter-intuitive, a policymaker wishing to maximize the welfare of his or her citizens in such an economy often will contract the money supply when output falls due to the productivity shock. This has the effect of raising the relative price of home goods and reducing demand and hence production. The outcome of this Nash game differs from the outcome described in the previous section, and does not involve any beggar-thy-neighbour strategy. The domestic policymaker is perfectly capable of replicating the flexible price outcome by the appropriate application of domestic policy. Under certain conditions to be discussed below it turns out that the coordinated solution is identical to that for the Nash solution above. If policy in the two countries were dictated by a central coordinator trying to eliminate all externalities, the set of policies he would prescribe for each country would be identical to the policies that each country would have chosen independently. In this world the spillover argument fails to apply, and there is no benefit from international policy coordination.

International risk sharing

A second type of motivation offered for international policy coordination is the possibility that countries can benefit by mutually insuring each other against the effects of shocks. Ideally private asset markets would include trade in securities contingent on the incidence of shocks, which households could use to insure themselves. For example, in the case of a fall in productivity and output in just one country, such securities would require a transfer of wealth from abroad to this country as a way of buffer...
of consumption despite the fall in domestic production. International trade in equities could serve this function. Suppose the residents of two countries each own half of the firms in the other country's stock market, and they thereby have claim to half of the output of each other's total production. If a productivity shock lowers the output of the home country but leaves the foreign country unaffected, when each country sends half of its respective production to the other country, this implies a net payoff from the foreign country to the home country. This transfer effectively spreads the impact of the productivity shock over the consumption levels of both countries and acts as a type of insurance. However, in the absence of a private market for such securities, there may be a role for policy coordination to replicate these insurance benefits.

For example, consider again the story above of a negative shock to productivity in one country. Another motivation for the policymaker to employ a contractionary monetary policy is to raise the value of the domestic currency, in order to raise the relative price of its exports to imports, the terms of trade. By making home goods more valuable, he or she raises the revenue from export sales abroad, transferring wealth to the affected country. The ability to manipulate the exchange rate to transfer wealth from the foreign to home country clearly could present a temptation to pursue beggar-thy-neighbour policies. But in the hands of a central policy coordinator, this becomes a means of making transfers between countries when useful for insurance purposes.

Note that a coordinated policy motivated by the objective of risk sharing might in principle conflict with the motivation for coordination laid out in previous sections. There is no reason to suppose that the degree of monetary contraction needed to transfer enough wealth to pool risk is also that degree needed to discourage production to the level consistent with flexible prices. That is, it may not be possible to use policy coordination to offset two economic distortions at the same time, the sticky-price and imperfect risk-sharing distortions. This is a point emphasized in the influential work of Obstfeld and Rogoff (2002).

Extensions to more realistic economies

While recent research has noted additional theoretical rationales for coordination, this may not change the conclusion that the gains are too small quantitatively to justify the effort. When Obstfeld and Rogoff (2002) calibrate with reasonable parameter values a model that combines imperfect risk sharing with nominal rigidities, it does find there is some positive gain from a coordinator choosing a policy as opposed to each country optimizing separately. But the additional benefit from coordination is small. As long as policymakers act wisely to replicate flexible price outcomes in their domestic economy, the benefit of coordinating with foreign countries is smaller by an order of magnitude. Several features of the theoretical economic environment are key to this result. Clearly key is the supposition that policymakers will act in a manner to maximize the welfare of their residents when given the freedom to do so. But also essential are assumptions about the behaviour of consumers, such as the willingness to substitute across home and foreign goods to maintain their level of utility, and a desire to smooth consumption levels over time.

As progressively more realistic economic environments are explored, the list is augmented of economic features that affect the decision to coordinate. One such feature is the nature of price stickiness. When exporting firms set their prices, many will set them in the currency of the buyer's market. If prices are
sticky in the local currency, any fluctuations in the nominal exchange rate will have no effect on the price that consumers face in the market. So any attempt to use monetary policy to manipulate the terms of trade as an insurance device will fail. As demonstrated in Devereux and Engel (2003), local currency pricing kills off a primary motivation for policy coordination as well as the temptation to pursue beggar-thy-neighbour policies in a sticky-price world.

On the other hand, some other realistic economic features tend to augment the benefits of coordination. These include the reliance on imported goods as intermediates in the domestic production process, in which case random fluctuations in the exchange rate can severely disrupt domestic production. Such issues are likely to be most important for small economies, especially those that specialize in assembly operations of imported components for final export. Another relevant feature is the presence of nontraded goods. If the productivity shocks hitting the nontraded sector differ from the traded sector, it can become difficult for international trade in asset markets to insure against them. Calibrating and simulating models with these more realistic features indicates that it is possible for some economies to benefit substantially from policy coordination (see Tchakarov 2004).

In sum, the size of benefits from coordination depends on a number of key characteristics of economies. These include how developed asset markets are, how responsive trade flows are to relative prices, how important it is to households to smooth their consumption levels over time, how imports are used, and how sticky prices are set. Whether policy coordination is worthwhile for a country depends largely on the individual characteristics of that country.

Openness reconsidered

While the discussion above has offered two motivations for policy coordination, namely, risk sharing and price stickiness, a revealing distinction between the two is how they are affected by openness and globalization. Consider first openness in the form of international economic integration in goods markets. Goods trade itself may have built-in mechanisms that can help insure a country against country-specific output shocks. For example, if a country is hit by a fall in its production, the relative scarcity of home goods would induce a rise in their relative price. Depending on consumer preferences, such as a type implying constant expenditure shares over home and foreign goods, this terms-of-trade effect will be able to compensate home agents for the fact they have a smaller quantity of home goods. In particular, they will be able to import more foreign goods in exchange for the smaller quantity of home exports, and thereby enjoy a comparable level of overall consumption and utility as the foreign country. This means that goods markets potentially can do the job of pooling risk internationally without the need for an international policy coordinator.

This conclusion stands in sharp contrast to earlier literature. Recall that Oudiz and Sachs (1984) concluded that the need for coordination was small precisely because the degree of goods trade was small. But here we conclude that the need for coordination is small when goods market integration is high.

Consider also the implications of integration in asset markets. In the limiting case where asset markets were complete, with assets to insure against all shocks, private agents would be able to pool the risk of asymmetric shocks internationally on their own. Again, if private markets pool risk, there is no need for policy coordination to serve this function. Clearly the world remains far from complete asset markets, but international trade in equities is definitely on the rise, and international capital flows of various types
have ballooned. One gets the impression that international integration has progressed faster in asset markets than in goods markets, so that this type of integration may be more important. Nevertheless, integration in both markets works in the same direction here. A high level of integration, be it in either asset markets or goods markets, indicates there is less need for explicit international policy coordination to pool national risks. Contrary to the predictions of some analysts, as the age of globalism progresses we might see less pressure for international policy coordination rather than more.

international real business cycles

Mario J. Crucini
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

International business cycle research seeks to summarize the statistical properties of worldwide economic fluctuations and model them as the outcome of purposeful decisions by individuals, firms and policymakers who react to changes in their economic environment and an uncertain future. The focus is on identifying the sources of fluctuations and how interactions of economic actors play out in terms of cyclical movements in variables such as gross domestic product. The term ‘real’ indicates a sub-area of the research programme that focuses on non-monetary dimensions such as changes in productivity and fiscal policy rather than in the money supply and monetary policy.

Article

1 International real business cycles

Business cycles are the recurrent fluctuations of national output relative to its long-term growth trend. The qualitative features of these fluctuations are common to virtually all economies, with their quantitative properties differing somewhat across countries and time periods. Modern research seeks to summarize the statistical properties of business cycles and formally model them as the outcome of purposeful decisions by individuals and firms who react to changes in their economic environment and an uncertain future. Whereas closed-economy analysis focuses on responses to domestic shocks and policy actions, open economy analysis adds to this international policy interaction and spillovers of foreign shocks to the domestic economy. The term ‘real’ indicates a sub-area of the business cycle research programme that focuses on non-monetary dimensions such as changes in productivity, taxes and government spending, rather than changes in the money supply and monetary policy.

2 Measuring international business cycles

What may be surprising to the uninitiated is the controversy surrounding business cycle measurement itself. Measures most often cited in the press are the calendar dates of business cycle peaks and troughs. In the United States, these dates are identified by the Business Cycle Dating Committee at National Bureau of Economic Research. A committee affiliated with the Center for Economic Policy Studies serves the same function for Europe. The logic of the methods used by both committees dates back to the classic contribution of Burns.
and Mitchell (1946), pioneers of formal business cycle measurement.

In academic work, economists favour econometric methods in which the logarithm of real gross domestic product, $y_t$, is decomposed into a growth trend, $y_{g,t}$, and a business cycle component, $y_{c,t}$:

$$y_t = y_{g,t} + y_{c,t}$$

(2.1)

A large applied econometrics literature achieves trend and cycle decompositions by applying identifying assumptions on the innovations to the trend and cycle components of aggregate output. See, for example, Beveridge and Nelson, 1981; Cochrane, 1994; Crucini and Shintani, 2006; Stock and Watson, 2005. Here we employ the Hodrick–Prescott (1997) filter to achieve this decomposition since it is widely used in the literature. The Hodrick–Prescott filter provides a smooth estimate of the growth trend, $y_{g,t}$, and the cycle is computed as the difference between the growth trend and the original series.

Figure 1 displays the business cycle component of the logarithm of gross domestic product for eight industrialized countries: Australia, Canada, France, Germany, Italy, Japan, the United Kingdom, and the United States. As is evident, business expansions and contractions are persistent. One also sees common features such as the emergence of a recession in the 1980s simultaneously in most countries.

Figure 1
We organize our discussion of business cycle facts around two equations. The first is the national income and product accounts (NIPA) accounting identity. (The OECD data satisfy this identity when changes in inventories and a statistical discrepancy are included. We subtract these two items from output when we perform the variance decomposition of output from the expenditure side.)
In words: the amount of output produced in the home country equals the sum of its uses in domestic private consumption and investment, \( C_t \) and \( I_t \), government spending, \( G_t \), and exports, \( X_t \). Imports are deducted to avoid double counting since they are already counted in the other expenditure components. The variables have been ordered in terms of the fraction of output accounted for by each component. Averaged across time periods and countries, consumption accounts for about 58 per cent of output and investment accounts for 23 per cent, while the percentages for government consumption, exports and imports are almost identical, at 18 per cent, 19 per cent, and 19 per cent, respectively. With the exception of exports and imports, the ratios differ modestly across industrialized countries when long-time averages are taken. We use eq. (2.2) below to perform an \textit{expenditure-side} decomposition of output variability.

The second relationship is a theoretical construct. The prototype model assumes that output is produced with two inputs, capital and labour. The production function relating inputs to outputs usually takes the form:

\[
Y_t = A_t K_t^\alpha N_t^{1-\alpha}
\]

where \( A_t \) is total factor productivity, \( K_t \) is the stock of physical capital in place at time \( t \), and \( N_t \) is total hours of input at time \( t \). The exponent \( 1-\alpha \) measures the share of national income paid to labour (salaries and wages) since labour is paid its value marginal product in the model.

Taking logarithms of eq. (2.3) provides the basis for the second variance decomposition:

\[
Y_t = a_t + \alpha k_t + (1 - \alpha)n_t
\]

We compute \( a_t \) as a residual, setting \( \alpha = \frac{1}{3} \) (the share of capital income in national income) and using standard measures of physical capital and aggregate hours, as the inputs on the right-hand-side of the equation. We call this our \textit{production-side} decomposition.

Table 1 contains business cycle statistics for each country using data from the first quarter of 1970 to the first quarter of 2005. Beginning with the variance of the cycle itself, we see that the United States has the most variable business cycle, with a standard deviation of 1.58 per cent per quarter, while France, at the other end of the scale, has a standard deviation of only 0.91 per cent. Australia, Canada, Germany, Italy, Japan and the UK have remarkably similar volatility, in the range of 1.32–1.48 per cent.

**Notes:** All variables except the net export ratio are the Hodrick-Prescott cycle components. All nominal variables are deflated by the Gross Domestic Product Deflator. *Source:* OECD Quarterly National Accounts, CD-ROM.

Turning to the details, we see that investment and trade flows are much more variable than output; consumption is less variable than output while government spending is the least variable. There are some quantitative differences across countries, but the rankings are robust. The correlation of variables with output indicates the cyclicality of a variable. If the correlation is positive, the variable is said to be pro-cyclical: on average, it rises when the economy is in an expansionary phase and falls when the economy is in a contractionary phase. All variables except government spending and the net export ratio are strongly pro-cyclical, consumption and investment particularly so. In a statistical sense, government spending seems to provide some stabilization by virtue of its low variability and near-zero correlation with the cycle. Imports are consistently more highly correlated with domestic output than are exports. This makes economic sense since import demand is influenced by domestic income while export demand depends on potentially diverse income developments across a country’s trading partners.

On the production side of the equation, capital is less cyclically variable than either productivity or labour input (a notable exception is France). The ranking of the variability of labour input relative to productivity is ambiguous.

### 2.1 Variance decompositions

The variance decomposition of output from the expenditure side or production side is computed as:

\[
\text{std}(y) = \sum_{z} s_z \cdot \text{std}(z) \cdot \text{corr}(z, y)
\]

where \(s_z\) is either the expenditure share or the production share for variable \(z\) (productivity gets a weight of one), \(\text{std}(z)\) is the standard deviation of component \(z\) over the cycle and \(\text{corr}(z, y)\) is the correlation between component \(z\) and income. The variance decomposition is exact in levels, but approximate in logs, because the NIPA identity involves levels.
international real business cycles: The New Palgrave Dictionary of Economics

2.2 International dimensions of the business cycle

We turn, now, to key international facets of business cycles: (a) the current account balance, (b) international business cycle co-movement and (c) relative price determination.

2.2.1 The current account

An important goal of international business cycle research is to improve our understanding of the time path of the current-account balance or the trade balance. International trade focuses on the direction and composition of trade and often assumes balanced trade. International finance focuses on the current account, modelling the dynamics of savings and investment over time. Since the business cycle involves time variation, it is natural to emphasize the international finance perspective.

The current account equals the difference between savings and investment. National savings is the sum of private savings and public savings. Private savings is the difference between disposable income and private consumption while public savings is the difference between tax revenue and government expenditure.

\[
CA_t = S_t - I_t = (I_t - T_t - C_t) + (T_t - G_t)
\]

(2.6)

In a closed economy, of course, the current account is identically equal to zero – each dollar of savings must be allocated to domestic investment. An open economy, freed from this constraint, rarely finds itself with a current account balance; when current savings fall short of (or exceed) current investment levels, a current account deficit (or surplus) obtains. Feldstein and Horioka (1980) vividly demonstrated that, when the data are averaged over long periods of time, savings and investment rates are highly positively correlated – countries with higher than average savings rates tend to have higher than average investment rates. Business cycle correlations of saving and investment tend to be lower than the
Feldstein–Horioka values, suggesting that large deviations in the current account are transitory. The correlation of national saving and national investment over the cycle ranges from a high of 0.80 in Italy to a low of 0.44 in both Australia and Germany (see Table 1).

2.2.2 International business cycle co-movement

International co-movement may be expressed in different ways. Kose, Otrok and Whiteman, 2003, among others, use state space models in which there are world, country and idiosyncratic factors in the income process as well as in each component of aggregate demand. This method avoids an arbitrary choice of numeraire and helps to identify what economists refer to as the ‘world business cycle’. Here we use the correlation of a foreign variable with its US counterpart. As is evident in Table 2, positive movements of foreign variables with their US counterparts are the rule rather than the exception. In terms of rankings, output tends to be more correlated than the components of aggregate demand; investment and government spending have particularly low international correlations. The rankings are more ambiguous in a statistical sense and for a broader range of countries than Table 2 suggests; see Ambler, Cardia and Zimmerman (2004).

Source: Author's calculations.

To turn to the production side, we see that US labour input has the highest correlation with its counterpart abroad, ranging from 0.60 with the UK to a low of minus 0.17 with Italy. International productivity levels also tend to be positively correlated, though not to the extent of labour input. Changes in capital formation have a low international correlation, consistent with other facets of this input documented above. The highest international business cycle correlations are between Canada and the United States, geographic neighbours with similar institutions and extensive trade relations.

2.2.3 Real exchange rates and the terms of trade

The two key international relative prices are the real exchange rate and the terms of trade. The real exchange rate is:

\[ R_t = \ln \left( \frac{E_t^* P_t^*}{P_t} \right) \] (2.7)

where $E_t$ is the nominal exchange rate between the home and foreign country and $P_t$ and $P_t^*$ are home and foreign price indices (usually the consumer price index), respectively. In words: $Q_t^R$ is the cost of the foreign consumption basket relative to the domestic consumption basket after converting to a common currency. According to the purchasing power parity proposition, the dollar goes just as far in foreign countries as it does in the United States in terms of purchasing power. This implies that $Q_t^R = 1$ at each point in time. In practice, however, the real exchange rate is highly variable and very persistent. High variability suggests large absolute departures from parity, while high persistence implies that, when a price gap opens up internationally, it tends to remain open for many months rather than days or weeks. In terms of the time series measurement of this property, at business cycle frequencies, it appears that the real and nominal exchange rates have approximately the same variance while the price ratio term ($P_t^* / P_t$) is very stable. For example, the standard deviation of the nominal exchange rate between the United States and France is about 8.52, close to the standard deviation of their bilateral real exchange rate at 7.95, while the price ratio has a standard deviation of only 1.17 (see Table 3). These numbers are typical of US bilateral real exchange rates with respect to other industrialized countries. One also finds that the real exchange rate is not highly correlated with quantity variables such as output or even net exports (not shown).

Sources: Terms of trade moments are from Table 1 in Backus and Crucini (2000). Sample periods are as follows: Canada, the United Kingdom and the United States, 1955Q1–1990Q3; Australia, 1960Q1–1990Q3; France, 1970Q1–1990Q3; Germany, 1968Q1–1990Q3; Italy, 1970Q1–1990Q2; Japan, 1955Q2–1990Q3. Real exchange rate moments are from Chari, Kehoe and McGrattan (2002); sample period is 1973Q1–2000Q1.

To turn to the terms of trade, it is defined as:

$$Q_t^T = \frac{P_t^m}{P_t^*}$$

(2.8)

where $P_t^m$ and $P_t^*$ are import and export price indices for a particular country. Since these price indices are domestic deflators, they are already expressed in the home currency terms, and the spot exchange rate is not needed to convert them to common units. Unlike the real exchange rate, economic theory does not place strong restrictions on the time series or cross-country behaviour of the terms of trade. Given the presumption that countries import different goods from those they export, we expect the terms of trade to be different from unity, and it should fluctuate, too. Australia and Japan have the highest terms-of-trade variability, about twice that of the other countries, with the exception of France, which experiences terms-of-trade variability between these extremes. The terms of trade does not have a robust correlation with either output or net exports.
Quantitative theoretical investigations of business cycles seek to account for business cycle facts using models in which consumers are thoughtful and informed, firms employ workers and utilize capital efficiently, and policymakers use a combination of rules and discretion to achieve various economic objectives. The key dimensions of study are those unique to international economics: matching the international character of the world business cycle and the business cycle properties of the current account, the real exchange rate and the terms of trade.

3.1 The current account

The most rudimentary model of current account behaviour is one in which a small open economy faces an exogenous world interest rate and income stream. To fix ideas, think of a small country that produces mostly oil with perfect access to international capital markets. If the country is always producing at capacity, all of its income variation is due to changes in the price of oil in world markets. What does the intertemporal approach to the current account predict in this circumstance?

The theory reduces the NIPA identity to: \( S_t = Y_t - C_t \), so that consumption decisions effectively determine saving decisions. Investment is absent since we are abstracting from changes in production capacity and its utilization. While this model seems simplistic, the identity is deceptive since it suggests that only current income enters into the current consumption–savings decision. In fact, the most widely used set-up has its roots in the seminal contribution of Friedman (1957), with individuals assumed to be able to draw upon the entire present discounted value of their future labour income. Whereas current income is the traditional argument in the Keynesian consumption function, wealth plays this role in modern macroeconomics. Since wealth is the sum of the market value of financial assets and all future anticipated flows of income, expectations play a central role in the modern consumption function. (There are many extensions to this basic framework that prevent individuals from drawing upon their lifetime wealth for present consumption: collateral requirements, limits on debt-to-income ratios and credit histories. Discussion of these extensions is beyond the scope of this survey.)

Much of the intuition for the impact of a changing income profile on the current account of a small open economy is available from Quah’s (1990) formulation of the permanent-income hypothesis. He assumes a constant interest rate, quadratic preferences and rational expectations. He allows income to contain both permanent and transitory shocks. If we assume income follows a first-order autoregressive process: \( Y_{t+1} = \rho Y_t + \nu_{t+1} \), where \( \nu_{t+1} \) is news about income (that is, under rational expectations, news about income is:

\[
E_{t+1} Y_{t+1} = Y_t + 1 = \nu_{t+1},
\]

the predicted change in consumption in response to this news is:

\[
\Delta C_{t+1} = \frac{r}{1 + r - \rho} \nu_{t+1}
\]

(3.1)

and the change in the current account on impact, on the assumption it was in balance initially, is:

\[
\Delta CA_{t+1} = \Delta Y_{t+1} - \Delta C_t = \nu_{t+1} - \frac{r}{1 + r - \rho} \nu_{t+1}.
\]

(3.2)

Since output deviations from trend (the business cycle) are persistent, it is safe to assume, \( \rho > 0 \). A plausible value for \( r \) is 0.05 (a five per cent real interest rate). Note that the consumption response depends positively on persistence since wealth effects are rising in the persistence of the income change. As persistence moves from zero toward unity, the effect on the current account rises from close to unity toward zero. This algebra delivers a key prediction of the intertemporal approach, that consumption smoothing leads to current account surpluses during booms unless the income change is viewed as permanent (that is, \( \rho = 1 \)) in which case the current account is predicted to remain unchanged.

While there is evidence to suggest an interest rate channel on consumption, it does not help to resolve the counterfactual prediction of a pro-cyclical current account from the consumption side, just established. There are two reasons for this. First, if interest rates are higher during a boom in the home country, individuals would tend to tilt consumption from current to future periods (that is, postpone durable goods purchases) – the intertemporal substitution effect. This would reinforce rather than overturn our prediction that the current...
account moves into surplus during a boom. If real interest rates actually fell during a boom, the intertemporal substitution effect would operate in the right direction, but the evidence on the cyclicality of the real interest is ambiguous. Second, when we move to a general equilibrium setting, incorporating home and foreign responses, the increase in the real interest rate is shared by the two countries and therefore incapable of delivering the asymmetric consumption responses necessary to move the current account balance. This leaves us with the need to look elsewhere for a channel that moves the current account in a countercyclical direction.

To return to the algebra of the current account identity, it would appear that what is needed for a countercyclical current account is for domestic investment to rise more than domestic savings during a business cycle expansion:

\[
\Delta CA_t = \Delta S_t - \Delta I_t = (\Delta Y_t - \Delta C_t) - \Delta I_t.
\]

The identity reveals the tension between the consumption smoothing channel, whereby a transitory change in income is mostly saved, pushing the current account towards surplus and the investment channel, which pulls in the opposite direction, towards a deficit.

In a model with only one good, the consumption smoothing channel wins the contest unless the shocks are highly persistent (see, for example, Backus, Kehoe and Kydland, 1992; Baxter and Crucini, 1993; Mendoza, 1991). Persistence, by increasing the impact response of consumption due to the larger wealth effect, helps to push the current account towards balance, leaving the investment channel to produce a deficit. Extensive empirical investigations of the intertemporal approach to the current account may be found in Glick and Rogoff (1995) and Nason and Rogers (2006). (Sachs (1981) provides early evidence on the investment channel.)

Extensions of the model to multiple goods help avoid this unpleasant arithmetic because individuals want to increase consumption of both the domestic good and the foreign good, increasing import demand and reinforcing the tendency towards a deficit from a traditional trade channel. Demonstrations of this effect under complete and incomplete risk sharing are found in Backus, Kehoe and Kydland (1994) and Arvanitis and Mikkola (1996), respectively. (JoAnne Feeney (1994) provides an insightful exposition of this issue.)

To summarize, early developments of the intertemporal approach to the current account emphasized the consumption smoothing channel and predicted that current account surpluses would occur when output was temporarily above trend. Current account surpluses are often described as good based on the idea that surpluses flow from good economic times. The identity reveals the tension between the consumption smoothing channel, whereby a transitory change in income is mostly saved, pushing the current account towards surplus and the investment channel, which pulls in the opposite direction, towards a deficit.

3.2 The world business cycle

Conceptually, the world business cycle is simple to define: the deviation of world output from its growth trend. The practical difficulty is the measurement of world output because national output is denominated in domestic currency. Converting nominal output into a common currency using spot nominal exchange rates greatly exaggerates fluctuations in output because nominal exchange rates are much more volatile than either real production or price levels. Moreover, prices vary considerably across nations even after conversion to a common currency, making it difficult to construct an appropriate deflator to convert nominal gross international product into real gross international product. Here we follow much of the existing literature and use real gross domestic product of each country, and compute correlations across them. If real output is highly correlated across countries, we have evidence of a world business cycle. As we documented earlier, most macroeconomic aggregates are positively correlated across countries, indicative of a world business cycle. How do business cycle researchers account for this fact?

There are two channels through which positive economic co-movement may arise: endogenous propagation and exogenous propagation. Positive endogenous propagation refers to a situation in which a disturbance originating in one country has a positive impact on both home and foreign output levels. For example, rapid development in China drives up demand for crude petroleum and fuels economic expansions in countries that are specialized in oil production. Positive exogenous propagation refers to the correlation of shocks across countries. For example, the Second World War witnessed dramatic increases in national output in most industrialized countries as government spending rapidly expanded during the conflict. In practice, endogenous propagation and exogenous propagation are difficult to distinguish, presenting one of the key challenges of business cycle research.

Real business cycle researchers have devoted most of their effort to measuring total factor productivity, which has been found to be highly persistent and positively correlated across countries. Correlations over the business cycle are typically lower than correlations over long periods of measurement, suggesting more commonality in the technological trend than in the productivity cycle. (When analysis extends to small developing countries the business cycle correlations sometimes exceed the growth correlations.) Given the lower
A classic contribution in the former category is Backus, Kehoe and Kydland (1994) (BKK), who develop a two-country, two-good model. Each country specializes in the production of goods they themselves do not produce. Examples of work along these lines include an extension of the multisector model with intermediate inputs of Long and Plosser (1983) to the open economy by Ambler, Cardia and Zimmerman (2002), a model of the North–South business cycle by Michael Kouparitsas (1996) which emphasizes trade of intermediate inputs, and a model of the international relative price of intermediate inputs by Prescott (1982) and King, Plosser and Rebelo (1988) quite closely. Despite the similarity, however, international economists were immediately confronted with two key modelling issues. The first had to do with factor mobility across countries, which is obviously absent in the closed economy setting. The mobility of labour across countries seemed minor enough to ignore, physical capital mobility was not. Since physical capital takes real resources to reallocate, the standard approach has been to subject capital accumulation to adjustment costs (or time to build as in Backus, Kehoe and Kydland, 1992). Without some cost of physical capital mobility, capital would be predicted to move rapidly and in large amounts across national boundaries in response to persistent changes in productivity or taxes. Such factor movements generate strongly negative correlations of output from the supply side and unrealistically volatile investment over the business cycle.

The second issue model builders were confronted with was asset market structure. Much of aggregative economics is predicated on the basis that idiosyncratic shocks are irrelevant to macroeconomic fluctuations. In an economy with millions of individual agents and thousands of firms, the law of large numbers combined with not-too-objectionable restrictions of preferences and technology provided a compelling argument to abstract from idiosyncratic variation. At the aggregative international level, the number of shocks is small (in many models it equals the number of countries), and countries are large and few in number. Thus, it makes little sense to rely on the law of large numbers, so researchers adopted the assumption that agents pool nation-specific risks, avoiding the need to track the wealth distribution across countries.

Unfortunately, complete risk pooling in the one-sector model leads to a presumption that output is negatively correlated across countries while consumption is close to perfectly positively correlated. In the data, the reverse rankings of correlation tend to prevail, and the absolute level of consumption correlations is well below unity. The prediction of near-perfect consumption co-movement across countries derives from the risk-pooling assumption and the fact that agents face common prices and interest rates. The negative correlation of income is driven by cost-minimizing production decisions where firms allocate plants and equipment to the most productive location. Thus, an increase in home productivity increases domestic output relative to foreign output directly, and this is reinforced by the flow of capital from the less productive country to the more productive country. Risk pooling also enhances the supply-side response by neutralizing the wealth redistribution effects on home and foreign labour supplies.

Debate continues as to what the appropriate asset market structure should be and how to incorporate changes in asset diversification in business cycle models. Baxter and Crucini (1995) and Kehoe and Perri (2002) show that, when risk pooling is limited, positive output co-movements are more likely to arise the more persistent are the deviations to relative international productivity. Also, consumption correlations may actually fall below output correlations if the shocks are close to permanent, a feature that is prevalent in the data and difficult to explain from a number of standard theoretical paradigms.

Researchers have had more success accounting for positive international output co-movement in models where countries depend on their trading partners for final goods or intermediate inputs they themselves do not produce. Examples of work along these lines include an extension of the multisector model with intermediate inputs of Long and Plosser (1983) to the open economy by Ambler, Cardia and Zimmerman (2002), a model of the North–South business cycle by Michael Kouparitsas (1996) which emphasizes trade of manufactures for primary inputs across these two regions, and the introduction of home production by Canova and Ubide (1998). A contribution that extends the incomplete markets model developed by Baxter and Crucini (1995) to the two-good setting is Arvanitis and Mikkola (1996).

### 3.3 Real exchange rates and the terms of trade

Multiple sectors take centre stage when one considers the real exchange rate and the terms of trade. Approaches to international relative price determination may be usefully placed into two categories. One category focuses on the determination of international relative prices of different goods. A second category focuses on deviations from the law of one price, meaning identical goods trade at different prices in different countries.

A classic contribution in the former category is Backus, Kehoe and Kydland (1994) (BKK), who develop a two-country, two-good model. Each country specializes in the production of one of the two goods and the two goods are combined in production, via an Armington aggregator, to create a composite final good which is, in effect, the single final good in each economy.

The Armington aggregator is a function that describes how substitutable the two goods are in achieving a particular output level of the final good. To match low trade shares with the specialization-in-production assumption, home bias is assumed in the aggregator function. This means that the home country uses more of the home good when producing the...
composite good, and the foreign country behaves symmetrically. This is an elegant model that ties in nicely with the one-sector two-country framework. The key difference between this model and the one-sector model is that specialization provides a motivation for keeping production levels more nearly equal across locations, since individuals have demands for each type of good. The model allows us to study the terms of trade, a key international relative price absent from the one-sector model, by construction. In the BKK model, the terms of trade and trade ratio are related as follows:

$$q_t = \ln \left( \frac{p_{yt}}{p_{xt}} \right) = \omega + \frac{1}{\sigma} \ln \left( \frac{a_t}{b_t} \right).$$

In words: an increase in production of the home good, $a$, drives down its relative price. The home terms of trade turn against the country experiencing the expansion, a pro-cyclical terms of trade, as BKK define it. In the data, the correlation varies substantially across countries in magnitude and sign. The model has difficulty matching both the observed volatility of the terms of trade and the quantity ratio; as the Euler equation makes clear, there is a trade-off between terms of trade and quantity ratio variability as the elasticity is altered. If we view $a$ and $b$ as the final consumption levels of each good, the quantity ratio is not nearly volatile enough, given a plausible degree of elasticity, to generate the terms of trade variation we see in the data. Backus and Crucini (2000) add an oil producing region (and sector) and find that the model does better in matching the cyclicality of the terms of trade and the trade balance than the original BKK model. Kose (2002) provides an extensive quantitative analysis of the variation of international relative prices and their role in the business cycles of small open economies.

Models that consider deviations from the law of one price differ in the source of the price deviations and their duration. Sticky-price models consider the deviations to be transitory, with nominal prices responding with a lag to changes in the economic environment. These models also assume trade in an infinite number of varieties, which allows individual firms to charge a markup of price over marginal cost. Key contributions in this area are Svensson and van Wijnenbergen (1989) and Obstfeld and Rogoff (1995). Trade cost models treat price deviations as a consequence of a real resource cost of trading, or operating businesses, in different locations. The simplest version allows prices to vary across locations by a shipping cost, usually treated as proportional to the marginal cost of the producer/supplier. The seminal contribution is Samuelson (1952), with more recent contributions by Eaton and Kortum (2002) and Sercu, Uppal and van Hulle (1995). An alternative variant is to distinguish traded and non-traded goods with traded goods not subject to trade costs and non-traded goods assumed to be subject to prohibitive trade costs, as in the original Salter (1959) and Swan (1960) models. Stockman and Tesar (1995) conduct a quantitative investigation of the business cycle predictions of this class of model.

Recent efforts have focused on quantifying the role of sticky prices, imperfect competition and trade costs in accounting for international relative price deviations and their business cycle implications. Chari, Kehoe and McGrattan (2002) conduct a quantitative evaluation of the sticky-price, imperfect-competition model and find that it can account for only a small part of the persistence and somewhat more of the volatility of the real exchange rate. (See also Betts and Devereux, 2000; Bergin and Feenstra, 2000.) Corsetti, Dedola and Leduc (2005) and Ravì and Mazzenga (2004) show the promise of models that combine imperfect competition with real trading costs.

What is missing from existing models is a clear distinction between economic activities that take place at the dock and exchange in retail markets. Transportation costs alone cannot account for all of the retail price dispersion we observe. Presumably, this is because much of what the retail market entails are local inputs of land, labour and infrastructure (some of it publicly provided). Models and empirical evidence are just now being developed to make these distinctions, such as Burstein, Neves and Rebelo (2003) and Crucini, Telmer and Zachariadis (2005), respectively.

international reserves

Joshua Aizenman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Developing countries, particularly in East Asia, account for most of the large increase in international reserves–GDP ratios in recent decades. Possible explanations include self-insurance against the output costs of sudden stops; precautionary fiscal demand by countries with inelastic fiscal outlays, sovereign risk, volatile and limited tax capacity; and a modern incarnation of mercantilism. Empirical studies reveal that the 1997–8 East Asian financial crisis triggered a sharp increase in hoarding international reserves. They suggest prominent roles for the precautionary demand and self-insurance motives and conclude that the financial integration of developing countries is associated with greater hoarding of international reserves.

Keywords

Asian miracle; buffer stock model; exchange-rate flexibility; hot money; international capital flows; international reserves; liquidity crises; option pricing theory; self-insurance

Article

International reserves are the liquid external assets under the control of the central bank. An intriguing development since the 1960s has been that, despite the proliferation of greater exchange rate flexibility, international reserves–GDP ratios increased substantially. Flood and Marion (2002) report that reserve holdings have trended upwards; at the end of 1999, reserves were about 6 per cent of global GDP, 3.5 times what they were at the end of 1960 and 50 per cent higher than in 1990. Practically all the increase in reserves-GDP holding has been by developing countries, mostly concentrated in East Asia. These developments stirred lively debate among economists and financial observers. The earlier literature focused on using international reserves as a buffer stock, part of the management of an adjustable-peg or managed-floating exchange-rate regime. Accordingly, optimal reserves balance the macroeconomic adjustment costs incurred in the absence of reserves with the opportunity cost of
international reserves: The New Palgrave Dictionary of Economics

holding reserves (see Frenkel and Jovanovic, 1981). The buffer stock model predicts that average reserves depend negatively on adjustment costs, the opportunity cost of reserves, and exchange rate flexibility; and positively on GDP and on reserve volatility, driven frequently by the underlying volatility of international trade. Overall, the literature of the 1980s supported these predictions; see Frenkel (1983), Edwards (1983), and Flood and Marion (2002) for a recent review.

While useful, the buffer stock model has limited capacity to account for the recent development in hoarding international reserves – the greater flexibility of the exchange rates exhibited in recent decades should work in the direction of reducing reserve hoarding, in contrast to the trends reported above. As an indication of excess hoarding, observers noted that developing countries frequently borrow at much higher interest rates than the one paid on reserves.

The recent literature provided several interpretations for these puzzles, focusing on the observation that the deeper financial integration of developing countries has increased exposure to volatile short-term inflows of capital (dubbed ‘hot money’), subject to frequent sudden stops and reversals (see Calvo, 1998; Edwards, 2004). Looking at the 1980s and 1990s, Aizenman and Marion (2003a) pointed out that the magnitude and speed of the reversal of capital flows throughout the 1997–8 crisis surprised most observers. Most viewed East Asian countries as being less vulnerable to the perils associated with hot money than Latin American countries. After all, East Asian countries were more open to international trade, had sounder fiscal policies, and much stronger growth performance. In retrospect, the 1997–8 crisis exposed hidden vulnerabilities of East Asian countries, forcing the market to update the probability of sudden stops affecting all countries.

The above observations suggest that hoarding international reserves can be viewed as a precautionary adjustment, reflecting the desire for self-insurance against exposure to future sudden stops. Self-insurance has several interpretations. The first focuses on precautionary hoarding of international reserves needed to stabilize fiscal expenditure in developing countries (see Aizenman and Marion, 2003b). Specifically, a country characterized by volatile output, inelastic demand for fiscal outlays, high tax collection costs and sovereign risk may want to accumulate both international reserves and external debt. External debt allows the country to smooth consumption when output is volatile. International reserves that are beyond the reach of creditors would allow such a country to smooth consumption in the event that adverse shocks trigger a default on foreign debt. Political instability, by taxing the effective return on reserves, can reduce desired current reserve holdings. The tests reported by Aizenman and Marion (2003b) are consistent with this interpretation. Another version of self-insurance and precautionary demand for international reserves follows the earlier work of Ben-Bassat and Gottlieb (1992), viewing international reserves as output stabilizers (see Aizenman and Lee, 2005; see Lee, 2004, for insurance perspectives of international reserves applying the option pricing theory). Accordingly, international reserves can reduce the probability of an output drop induced by a sudden stop and/or the depth of the output collapse when the sudden stop materializes (see Kaminsky and Reinhart, 1999).

The views linking the large increase in hoarding reserves to deeper financial integration face a well-known contender in a modern incarnation of mercantilism: international reserves accumulations triggered by concerns about export competitiveness. This explanation has been advanced by Dooley, Folkerts-Landau and Garber (2003), especially in the context of China. They interpret reserves accumulation as a by-product of promoting exports, which is needed to create better jobs, thereby absorbing abundant labour in traditional sectors, mostly in agriculture. While intellectually intriguing,
this interpretation remains debatable. Some have pointed out that high export growth is not the new kid on the block – it is the story of East Asia since the 1950s. Yet the large increase in hoarding reserves happened mostly after 1997. This issue is of more than academic importance: the precautionary approach links reserves accumulation directly to exposure to sudden stops, capital flight and volatility, whereas the mercantilist approach views reserves accumulation as a residual of an industrial policy, a policy that may impose negative externalities on other trading partners. Aizenman and Lee (2005) test the importance of precautionary and mercantilist motives in accounting for the hoarding of international reserves by developing countries. While variables associated with the mercantilist motive (like lagged export growth and deviation from purchasing power parity) are statistically significant, their economic importance in accounting for reserve hoarding is close to zero and is dwarfed by other variables. Overall, the empirical results are in line with the precautionary demand. The effects of financial crises have been localized, increasing reserve hoarding in the aftermath of crises mostly in countries located in the affected region, but not in other regions. A more liberal capital account regime is found to increase the amount of international reserves, in line with the precautionary view. These results, however, do not imply that the hoarding of reserves by countries is optimal or efficient. Making inferences regarding efficiency would require having a detailed model and much more information, including an assessment of the probability and output costs of sudden stops, and the opportunity cost of reserves. To conclude, greater exposure of developing countries to sudden stops and reversals of hot money as well as growing trade openness go a long way towards accounting for the observed increase in international reserves–GDP ratios by developing markets.

Empirical studies of production units within sectors have reported a massive amount of heterogeneity in various performance measures (most notably, size and productivity). This heterogeneity, within sectors, matters for theoretical and empirical models of trade. Trade, or trade liberalization more generally, induces important reallocations between heterogeneous producers in a sector: the smallest, least productive producers are forced to exit, and market shares are further reallocated between less productive producers (who do not export) towards larger, more productive exporters. These reallocations generate a new channel for productivity and welfare gains from trade.

Article

Census-wide ‘micro’ level studies of production units for a wide range of countries at all levels of development have documented substantial heterogeneity in virtually all relevant performance measures across these production units. For example, across all US manufacturing plants in 1992, a plant one standard deviation above the mean plant size is 167 per cent bigger, and a plant one standard deviation above the mean plant productivity level (value-added per worker) is 75 per cent more productive (Bernard et al., 2003). (More precisely, the standard deviation of log sales is 1.67 and that of labour productivity is 0.75.) These represent massive differences in performance outcomes, which are also reflected in differences in other key plant characteristics. Furthermore, the extent of this heterogeneity does not diminish much when looking within narrowly defined sectors. In the case of the US plants, the
75 per cent productivity difference mentioned above only drops to a 66 per cent difference when controlling for productivity differences across more than 400 different sectors. These large differences in firm performance are also strongly correlated with the firm decision to engage in international transactions (such as exporting, importing intermediate goods from foreign suppliers, or investing in foreign subsidiaries): only a small proportion of firms report any such activities, even within narrowly defined sectors; and those firms are substantially larger and more productive than their counterparts with no international contacts in the same sector. (This pattern has been documented at both the firm and the plant level for a very wide range of countries. From here on out, I will mostly focus on differences between exporting and non-exporting firms, although similar differences have also been documented concerning multinational firms and firms that import intermediate goods from foreign suppliers.) For the United States, Bernard et al. (2006) report that manufacturing plants are more than twice as large (value of shipments) as and 14 per cent more productive (value-added per worker) than their non-exporting counterparts in the same sector. (Bernard et al., 2006, provide an extensive description of firm-level differences related to international trade based on US manufacturing data and also survey the related empirical and theoretical literatures.) Bernard et al. (2006) also report how these exporting firms exhibit other different characteristics relative to non-exporters: they are more capital- and skill-intensive, and pay higher wages.

This strong correlation between export status and firm characteristics (notably higher productivity) naturally leads to the follow-up question of causality. A very large number of studies have examined this question, usually focusing on a firm's productivity trajectory over time relative to its export market entry decision. Virtually all these studies find a strong self-selection effect: firms are relatively more productive prior to their entry into export markets. (Two early influential papers in this area are Bernard and Jensen, 1999, and Clerides, Lach and Tybout, 1998.) Several of these studies further reject the hypothesis of firm-level productivity growth following export market entry, although some studies, especially for developing countries, do report such a link. (See, for instance, Loecker, 2007; Topalova, 2004; Biesebroeck, 2005; and the survey by Girma, Greenaway and Kneller, 2004.) However, this distinction – based on the timing of the export market entry – has been blurred given the evidence from some recent studies that firms make innovation/technology use decisions based on current or anticipated export market participation, as highlighted by Bustos (2006), Verhoogen (2007), and Trefler and Lileeva (2007). In such a case, productivity and exporting decisions are both endogenous with respect to one another, and the timing of the export market entry can no longer be used to identify causality. (Yeaple, 2005, theoretically studies this joint technology adoption and export decision by firms, and explores the consequences for the return to skill – highlighting how skill-biased technological change may be induced by trade.) Nonetheless, the results obtained clearly indicate that it is initially more successful firms that make the joint decisions concerning innovation (or ‘higher’ technology use) and export status. In other words, the least successful firms overwhelmingly tend to undertake neither activity.

Another part of the recent empirical literature using micro-level data has examined the consequences of this link between export status and productivity when the exposure to trade is changing (predominantly because trade costs are decreasing over time). In such a case, trade liberalization induces some reallocations between exporters and non-exporters competing in the same sectors (see Tybout, 2003, for a survey of this literature). One influential such study by Pavcnik (2002) finds that most of the 25 per
productivity increase in export-competing sectors in Chile between 1979 and 1986 is explained by realloccations between producers (generated by entry, exit, export market entry, and market share realloccations). However, since significant changes in trade regimes are also part of a larger set of substantial macroeconomic changes for the involved countries (as was the case for Chile), it nevertheless remains difficult to associate this type of reallocation-induced productivity growth to the direct effects of trade liberalization. One notable exception is Bernard, Jensen and Schott (2006), who show that reductions in trade costs for US plants substantially increase both the probability of exit and that of exporting among non-exporters. Given the productivity advantage of exporters, this induces reallocations in favour of the more productive exporting plants and hence increases average industry productivity (which is also confirmed by Bernard et al., 2006, as a result of the decrease in trade costs). Clearly, these empirical patterns cannot be addressed by trade models based on representative firms. Such models, by construction, predict that trade affects all firms in a sector in similar ways. (Note that extensive firm-level heterogeneity per se is not necessarily problematic for a representative firm model of trade so long as firms, on average, respond in similar ways to trade. However, the evidence reviewed clearly shows that this is not the case.) In response to this empirical evidence, theoretical models of trade have been developed to incorporate firm-level productivity differences, and analyse the consequences for the effects of trade liberalization. One class of models, developed by Bernard et al. (2003) and Eaton and Kortum (2008), introduce stochastic firm productivity into the multi-country Ricardian model analysed in Eaton and Kortum (2002). In this class of models, there is a fixed number of products that can be produced by competing firms in all countries. All these firms (both in the same country but also across countries) use different technologies to produce the same good (based on a stochastic productivity draw) – hence the Ricardian framework. Consumers in any given country buy each good from the lowest-cost producer across all countries. Due to trade costs, several firms producing the same good can survive if they are located in different countries (although each firm is the sole supplier to any given destination). This model thus emphasizes the resulting competition between firms to be this exclusive supplier. Bernard et al. (2003) show how such a model can be calibrated to fit both micro-level data on US producers and macro-level data on cross-country trade and aggregate production across countries. The calibrated model can then be used to analyse many counterfactual predictions involving the consequences of trade liberalization. Another class of models developed in Melitz (2003) and Melitz and Ottaviano (2005) eschews the analysis of the direct competition between firms to produce the same good by using a monopolistic competition framework: each firm produces its own distinctive differentiated good. These models incorporate firm heterogeneity into the one-sector models of intra-industry trade (the ‘new’ trade theory) developed in Krugman (1979; 1980). In this type of model, the product variety available to consumers in any given country varies endogenously with the characteristics of the country and the trade costs linking it to its trading partners (these affect the endogenous number of varieties produced domestically, as well as the endogenous fraction of firms from all trading partners that export to that country). Firms face sunk costs of entry, along with uncertainty concerning their future productivity (or also possibly the quality of the differentiated good that is under development). Upon entry, each firm instantaneously learns about its productivity level, modelled as a draw from a known distribution. Due to the sunk nature of the entry costs, firms with heterogeneous productivity levels remain active and produce. The least productive firms face negative profits and therefore exit. As exporting is costly, only the relatively more productive
firms (among those surviving) choose to export, while the remaining firms only serve their domestic market. Exporting is not profitable for these firms, either because it involves fixed or sunk costs, or because import demand is driven to zero at prices below the firms’ delivered cost.

Both classes of models predict that trade liberalization induces the type of reallocations between firms that was previously described: the least productive firms are constrained to exit, new firms enter the export market, and market shares are reallocated towards more productive firms. These reallocations generate both aggregate productivity and welfare gains. Both classes of models also predict an important empirical regularity regarding bilateral trade flows: that differences in these trade flows reflect both differences in the amount of each good traded (the intensive margin of trade) as well as differences in the number of goods traded (the extensive margin of trade). (See Bernard, Jensen and Schott, 2005; Broda and Weinstein, 2006; Broda, Greenfield and Weinstein, 2006; Eaton, Kortum and Kramarz, 2004; and Kehoe and Ruhl, 2003, for some empirical applications.) Helpman, Melitz and Rubinstein (2007) and Chaney (2006) show how the framework of Melitz (2003) can be extended to derive a gravity specification for bilateral trade flows where trade costs affect both the extensive and intensive margins of trade. Both papers highlight the empirical importance of incorporating changes in trade at both margins.

Due to the absence of strategic interactions between firms, the monopolistic competition model of Melitz (2003) provides a convenient framework for the modelling of additional firm-level decisions in an open economy environment – where heterogeneous firms self-select into different types of activities. This framework can thus also explain why only a fraction of firms choose to become multinationals and operate foreign affiliates (horizontal foreign direct investment, FDI) as in Helpman, Melitz and Yeaple (2004) or integrate with their foreign suppliers (vertical FDI) as in Antras and Helpman (2004). (Helpman, 2006, provides a much more extensive review of the related models.) Additionally, other firm-level decisions that are also affected by the exposure to international trade can be incorporated: the choice of technology as in Acemoglu, Antras and Helpman (2007), the level of investment in innovation as in Atkeson and Burstein (2006), or the range of products produced and exported within multi-product firms as in Bernard, Redding and Schott (2006). Lastly, the structure from Melitz (2003) has also been fruitfully integrated into various other types of models that rely on the basic monopolistic competition of trade. This includes extension to two-sector models of trade with comparative advantage and factor proportion differences (Bernard, Redding and Schott, 2007), open economy models of growth (Baldwin and Robert-Nicoud, 2006), and international macro-dynamics (Ghironi and Melitz, 2005). In each case, the addition of firm-level heterogeneity allows the models to explore additional important features upon which a model with representative firms remains silent.

international trade theory

James E. Anderson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

International trade theory provides explanations for the pattern of international trade and the distribution of the gains from trade. The theory convinces most economists of the benefits of liberal trade. But many non-economists oppose liberal trade. Opponents include some who may have encountered trade theory but nevertheless fall prey to fallacious reasoning. This article attempts to convey why trade theory is so persuasive to economists and also to deal with why many non-economists are not persuaded.

Article

Why do nations trade the products they do? Is trade a good thing? The theory of international trade provides answers. The answers are both convincing and elegant; hence, the vast majority of economists agree about the desirability of liberal trade. But the argument is also subtle and often misunderstood or distorted. Thus, a large proportion of the general population tends to oppose liberal trade from confusion. This article attempts to convey why the answers convince most economists and why their liberal trade position is so often misunderstood. The article's focus is theory, but theory convinces when it succeeds in fitting the data. Thus, passing reference will be made to empirical findings, a sensibility much more thoroughly developed in the graduate textbook of Feenstra (2003).
‘Buy low, sell high’ logic leads economists to comparative advantage theory. Comparative advantage means the comparison of relative price differences between nations to explain the pattern of trade. For example, compare the relative price of wheat in terms of cheese at home with the same relative price in the foreign economy in a hypothetical equilibrium with no trade (autarky) or with restricted trade. The country with the lower relative price of wheat is said to have a comparative advantage in wheat while the other country has, symmetrically, a comparative advantage in cheese. Buy low, sell high logic predicts that a country will export the good in which it has a comparative advantage. (In the case of many goods, the prediction is that a country will on average export goods which are relatively cheap in the absence of trade and import goods which are relatively expensive in the absence of trade. The prediction is about correlation. Bernhofen and Brown, 2004, show that Japan's opening to trade in the 1850s reveals data consistent with the prediction.)

Notice that the focus on relative prices tends to cancel out forces (exchange rate manipulations, environmental or labour standards) which cause national differences in levels of non-traded factor (or goods) prices. Note also that by this reasoning a country must have a comparative advantage in some good. Prices of non-traded factors of production adjust in general equilibrium so that each country ends up in the trade equilibrium with a competitive or absolute cost advantage in the good in which it has a comparative advantage. Partial equilibrium thinking takes factor prices as given and does not impose the external budget constraint that requires exports to pay for imports. Partial equilibrium reasoning leads to misunderstandings explored below as the absolute advantage fallacy.

Comparative advantage differences between nations are explained by exogenous differences in national characteristics. Labour differs in its productivity internationally and different goods have different labour requirements, so comparative labour productivity advantage was Ricardo's predictor of trade patterns. Ricardian trade theory is useful in its simplicity and even rather loosely confirmed by empirical evidence. The factor proportions theory added relative factor endowment differences to the exogenous explanation of comparative advantage (Jones, 1987). More capital-abundant countries have higher labour productivity, but the advantage gained relative to the less abundant countries varies with the relative capital intensity of the good's technology. Combining technology and endowment differences appears to account well for actual trade patterns (Davis and Weinstein, 2002).

Trade theory also encompasses endogenous differences between countries. One focus is on economies of scale. The wider market due to trade induces a cost advantage in an industry in one of the countries. Another theory is based on monopolistic competition, whereby the wider markets due to trade increase product variety as buyers seek the special characteristics of foreign brands. Differentiated products trade flows both ways within product categories.

Trade costs also shape the pattern of trade. The economic theory of gravity explains the complex bilateral trade patterns among countries. Actual trade is much lower than gravity predicts in a frictionless world, providing evidence of trade costs much larger than those due to policy or transportation. The costs are well explained by geography and a set of national differences. The stability of the relationships over time suggests that these costs change slowly.

There are gains from trade in all these models. But the division of the gains will be uneven and there will be losers. Distribution matters in two ways, between and within nations. Internationally, with only mild qualifications, gains are shared between nations: some trade is better than none. Each nation can act through trade policy to take more of the gain, however, leading to destructive trade wars with mutual losses. Within national economies, there are gains on average but there are ordinarily losers. National
institutions act to redistribute some of the gains (US Trade Adjustment Assistance) or provide temporary relief from losses due to trade (escape clause protection), at the cost of lowering the overall gain from trade.

The topics of this outline are developed below in more detail. Section 1 examines the causes of comparative advantage. Section 2 exposes the absolute advantage fallacy. Section 3 reviews endogenous advantage. Section 4 sets out the economic theory of gravity and its implications. The concluding section examines the gains from trade.

1. Comparative advantage

Ricardo explained comparative advantage as due to differences in labour productivity. Suppose that it takes two hours of labour to produce a bushel of wheat in the home country, while it takes four hours of labour to produce a bushel of wheat in the foreign country. Also, it takes three hours of labour to produce a pound of cheese in the home country while it takes eight hours of labour to produce a pound of cheese in the foreign country.

Ricardo saw that the world trade equilibrium would result in the home country exporting cheese and the foreign country exporting wheat. This is because, in the absence of trade, a pound of cheese is worth 1.5 bushels of wheat (three hours per pound of cheese divided by two hours per bushel of wheat) in the home country while a pound of cheese is worth two bushels of wheat in the foreign country. The labour market equilibrium which accompanies such a trade equilibrium must have a foreign wage of at most one-half of the home wage (since, with a foreign wage equal to one-half the home wage, a bushel of wheat costs the same amount in each country, allowing production in both). If we consider a low-wage foreign economy, the labour market equilibrium accompanying the trade equilibrium could have a foreign wage no lower than three-eighths of the home wage (since in this case a pound of cheese costs the same amount in each country).

Notice that countries export the good in which they have the comparative labour productivity advantage, cheese for the home country and wheat for the foreign country. The numbers chosen make no difference to the logic; what is essential is that comparative labour productivities differ. One special aspect of the numbers deserves emphasis, however: the home country has an absolute labour productivity advantage in both goods yet trade occurs regardless.

Subsequent developments of trade theory generalized the production model. The essence of comparative advantage theory remains: trade is due to differences in relative prices that would obtain in the absence of trade, and an average of each country's citizens gain from such trade. The Heckscher–Ohlin analysis of the factor proportions model predicted that a country would have a comparative advantage in the good which made relatively intensive use of its relatively abundant factor. Thus, if the home country were relatively abundant in capital (which would explain why its labour was so much more productive in the preceding example), it would have a comparative advantage in the good which used capital relatively intensively (cheese in the preceding example). Conversely, the foreign country is relatively abundant in labour and has a comparative advantage in the good which uses labour relatively intensively (wheat in the example above).

Trade in goods compensates for the international immobility of factors. The factor content extension of Heckscher–Ohlin trade theory predicts that trade patterns permit each country to consume factor services as if it were in a completely integrated world, smoothing out differences in national factor endowments.
Recent empirical work has met with striking success in combining factor endowment differences with technology differences as an explanation of observed trade patterns (Davis and Weinstein, 2002). Comparative advantage theory is much more general than the preceding discussion of special cases (Deardorff, 1984), but predictions about the pattern of trade weaken with generality. On average a country will import goods that would be relatively expensive in the absence of trade. See the Appendix for a technical statement. See Bernhofen and Brown (2004) for confirming evidence based on Japan's opening to trade in the 1850s. The assumptions of the general model are that (a) price-taking consumers minimize the expenditure needed to realize any level of utility (real income), and (b) producers behave so as to maximize the national product given the resource endowments. Assumption (a) implies downward-sloping demand curves in the generalized form. Assumption (b) leads to upward-sloping supply curves in the generalized form. Scale economies and imperfect competition, treated below in the section on endogenous advantage, can lead to the violation of assumption (b).

2 The absolute advantage fallacy

Businessmen naturally compare the money cost of the same good in different locations to draw inferences about the direction of trade. Absolute cost advantage appears to imply that a nation imports goods that are cheaper abroad and exports goods that are more expensive abroad. The reasoning is insidious because it makes sense in many contexts. Absolute advantage appropriately addresses the householder's question of which good should be purchased, the businessman's question of how tough his competitors are. The individual businessman can appropriately take all other prices as given when contemplating his own actions, such as entering a new export market.

To see the difference between absolute and comparative advantage reasoning clearly, return to the Ricardian example above. If wages (measured in a common currency) were equal in the two countries prior to the opening of trade, the home country would have a ‘competitive’ or absolute advantage in both goods: it could undersell the foreign country in both wheat and cheese. Foreign businessmen would naturally be worried that they would all be driven from the market. This universal bankruptcy could not be an equilibrium, however, because the foreign workers would have no income to pay for home-produced goods. The imbalance between expenditure and income would also mirror the absence of exports to pay for imports. Market equilibrium would be reached through price changes, lowering the foreign wage or raising the home wage until the foreign workers could be employed in the industry in which the foreign economy has the comparative advantage. (Unless the two currencies were pegged, the exchange rate of the foreign economy could depreciate and create the same effect.) More general models of production lead to the same conclusion: equilibrium costs will adjust to confer absolute advantage in the good in which each country has a comparative advantage.

With many goods, comparative advantage applies to ranges of goods rather than to a single good, and the dividing line between comparative advantage and disadvantage is endogenous. The absolute advantage is weak in the mathematical sense in the case where both countries continue to produce the good.

Another illustration of the absolute advantage fallacy arises in popular concerns about the rapid productivity growth of China compared with that of the United States. A ten per cent improvement in productivity will indeed secure a ten per cent cost advantage for the businessman over his competitor. A
ten per cent improvement in all Chinese productivity relative to the United States is unlikely to change comparative advantage (indeed, in the Ricardian example, comparative labour productivity advantage is unchanged) because Chinese wages will rise relative to US wages. Similarly, a ten per cent drop in all US productivity due to tighter environmental regulations will be unlikely to change comparative advantage because US factor returns will fall.

The widespread practice of making international comparisons of ‘competitive advantage’ is essentially misguided because it suggests the metaphor of a race. The race metaphor is extended in concerns about ‘a race to the bottom’, which supposedly expresses the dilemma of countries seeking to implement pollution or labour standards but being pressured to lower standards by their competition with foreign countries that have low standards. But nations do not ‘compete’ as firms do. A firm may well be unable to survive after implementing pollution reduction when its competitors abroad do not follow suit and no other prices change in the new equilibrium. Nations cannot similarly put themselves out of business because factor prices will change in the new equilibrium. Polluting industries may or may not survive at the new factor prices under the new regulations, but the nation's factors will be productively employed somewhere in the economy. Pollution reduction is costly with or without trade; nothing about the nature of a trading economy makes any essential difference to the nation's ability to implement desired standards. The desirability of trade is an *essentially* separate matter.

### 3 Endogenous advantage

Many goods are traded because they are simply unavailable from local production. Some kinds of availability are exogenous to the interaction of nations – diamonds and oil are found only in a few locations. Endogenous availability is in contrast driven by advantage arising from the economic interaction of nations. Endogenous advantage normally coexists with comparative advantage but it is simpler to consider special cases independent of comparative advantage. Theory focuses on endogenous advantage resulting from economies of scale. (In a formal but trivial sense, oil or diamond trade can be seen as comparative advantage trade – big oil deposits lead to a low relative price of oil where they are found. Moreover, comparative advantage trade is often associated with the disappearance of some industries in some countries. Neither of these associations of comparative advantage with availability is essential to the model, however.)

Trade based on scale economies features the possibility of multiple equilibria – one country will produce a good with scale economies but which nation ends up producing it can be a matter of chance. Since advantage is endogenous, it appears attractive in developing countries to attempt to reverse the historical head start of rich countries by starting up production behind protection and then later being able to compete on world markets. The record of success in such efforts is mixed.

Openness to trade will generally allow economies of scale to be more thoroughly exploited, so this is a new source of gains from trade. Moreover, wider markets may support a wider range of products, still another source of gains from trade. Each country shares in the gains from trade with scale economies under conditions that appear to be met in practice. (This claim is based on the results from numerous simulation models of trading economies that have been developed since the mid-1970s.) The theoretical possibility that a country can lose from trade based on scale economies has drawn a lot of attention from development economists in particular (Ethier, 1982b). (Losses result when a trading equilibrium has a country importing the good with scale economies while still producing it. Since domestic scale is
smaller, unit costs are higher, meaning that market forces perversely ‘choose’ to import a good with higher price than in autarky. Simulation models have not found such equilibria but they are possible.) Gains can be guaranteed if a country expands production in goods with scale economies, so it looks more attractive to use policy to promote production of such goods.

Scale economies come in two forms: external to the firm and internal to the firm. External scale economies are typified by specialized labour markets such as Silicon Valley, where the concentration of the market reduces search costs for computer engineers. External scale economies need not be location-specific, however. Increases in the scale of downstream final production can permit carrying on upstream input production with a specialized process that is cheaper at large enough scale. Such scale economies can operate at the level of the world economy and appear to be bound up with the recent phenomenon of outsourcing (Ethier, 1982a). Global scale economies tend to guarantee mutual gains from trade among countries.

Internal scale economies are associated with imperfect competition when the size of the firm looms large relative to the market size. Trade tends to intensify competition and thus to reduce the inefficiency of monopoly, another gain from trade.

The most fruitful form of imperfect competition for trade theory has been monopolistic competition. Only Ford Motor Co. produces Ford autos (monopoly) but dozens of brands compete for auto buyers. Each design has a fixed cost of design (and marketing) which must be covered by sales net of variable cost. The total market size limits the number of designs which can profitably be produced. A signal accomplishment of trade theory in the 1980s was the embedding of monopolistic competition in a general equilibrium trade model (Helpman and Krugman, 1985; Ethier, 1982a). Progress was enabled by the simplifying assumption of symmetric firms: all brands were equally desirable and all firms’ costs were the same.

Monopolistic competition provides an explanation of the two-way international trade that is found in many products such as autos, and of why two-way trade is more prevalent between similar countries. Trade between rich and poor countries, in contrast, is explained mainly by comparative advantage as autos exchange for agriculture. Relative country size matters too, the home-market effect of Krugman (1980). Here the insight has been rigorously proved only for a two-country example. Start with two equally sized countries, then increase one relative to the other. Trade costs imply that the larger country will have a more than proportionally larger share of brands. Intuitively, with access to foreign markets being costly the home market, being larger, allows scale economies to be more readily exploited, increasing the larger country’s share of differentiated goods production more than its share of world income.

Monopolistic competition theory has recently focused on the heterogeneity of firms. If the symmetry of firms on the demand side is retained, differences in firms’ productivities imply differential responses to trade. The best firms export disproportionately while imports drive out the worst firms. Fixed trade costs add explanatory power; only the best firms choose to incur the cost of trade. A key element of the model is productivity shocks, firms discover their productivity after committing fixed costs. The distribution of surviving firms is related to the distribution of productivity shocks as well as economic determinants. The models of Bernard et al. (2003) and Melitz (2003) deserve special attention. The former focuses on competition within a variety while the latter focuses on competition across varieties. Both models imply new gains from trade in the form of overall productivity gains: opening trade causes the exit of weak firms and the expansion of strong ones.
4 Bilateral trade patterns

The trade theories presented above are focused on explaining the cross-commodity trade pattern of essentially two trading countries. The contemporary world of more than 100 countries (most of which are collections of distinct economic regions) has complex trade patterns. The economic theory of gravity complements the preceding models by providing an explanation of bilateral trade (Anderson and van Wincoop, 2004). Gravity fits the data well and reveals important information. The model is based on four assumptions: expenditure on goods from all sources is equal to income from sales to all sources, markets for all goods clear, (more restrictively) each country or region produces a unique good, and all countries have the same tastes for goods.

The third assumption – products differentiated by place of origin – appears to be the most restrictive. In practice, only models of this type do at all well in fitting bilateral trade patterns. Monopolistic competition provides one explanation for why products appear to be differentiated by place of origin. Eaton and Kortum (2002) show alternatively that productivity shocks in a Ricardian model will select producers within product lines, resulting at the aggregate level in what appears to be two-way trade. In either case, gravity ends up describing trade flows.

In a frictionless world, gravity theory predicts that the bilateral trade in a commodity as a share of world production of the commodity will be equal to the product of the source country's share of world production of the commodity times the consuming country's share of expenditure on the commodity. Alternatively, the model predicts that size-adjusted trade, the bilateral flow divided by the product of source country supply and consuming country expenditure, should be constant across country pairs in a frictionless world.

Actual trade flows are far smaller than the frictionless prediction (while shipments within regions are far larger, home bias). The deviations of actual bilateral trade from the frictionless prediction allows inference about bilateral trade costs. Distance appears to be more costly than can be accounted for by transport costs. Other costs are associated with non-contiguity, language barriers, exchange rate barriers, insecurity and other plausible bilateral characteristics. Just crossing a border imposes a cost which is larger than can be explained by policy variables.

Trade flows in the model are predicted to vary with relative resistance, equal to the ratio of the direct bilateral trade cost to the product of inward and outward multilateral resistance. Multilateral resistance is an index of bilateral trade costs, inward from every source to a particular destination or outward from a particular source to every destination. Multilateral resistance is linked to country size and thus to explaining an important aspect of trade patterns. Since borders are costly, a big country tends to have lower multilateral resistance than does a small country because a smaller fraction of its shipments must cross borders. The size-adjusted internal trade of big countries will be smaller than that of small countries because big countries have higher relative resistance to their internal trade. These differences can be quite dramatic, as shown by studies of US and Canadian trade (Anderson and van Wincoop, 2003), where the United States is about ten times larger than Canada.

5 Division of the gains
Professional economists generally support liberal trade because theory and evidence persuade them that there are gains from trade in an average sense in all these models of the determinants of trade. But the division of the gains will be uneven and there can be losers. Most policy intervention with trade is explained by the policymakers’ desire to alter the distribution of gains.

The gains from trade reasoning is illustrated with comparative advantage-based trade. Focus on a ‘typical’ household. Suppose that in autarky equilibrium, as in the Ricardian numerical example, the Home typical householder is willing to swap 1 unit of cheese for 1.5 units of wheat. That is, he would be indifferent to moving his consumption and production a small distance to offer the market 1 cheese for 1.5 wheat or 1.5 wheat for 1 cheese. Suppose that a typical foreign country household in the autarky equilibrium is willing to swap 2 wheat for 1 cheese. Now allow frictionless trade, and suppose for illustrative purposes that the new equilibrium price is equal to 1.75 wheat per unit of cheese. (Generally the price must lie between 1.5 and 2, always implying mutual gains.) Each Home household offers cheese to Foreign households in exchange for their wheat. Formerly it cost 2 wheat for 1 cheese in Foreign but now the 2 wheat will procure 1 cheese and leave 0.25 wheat left over, a gain from trade. Similarly, each Home household can obtain 1.75 wheat for 1 cheese where formerly this would procure only 1.5 wheat, a gain from trade of 0.25 wheat. Both households and hence both nations gain from trade. The numbers chosen illustrate a general principle: mutual gains result from trade when autarky relative prices differ. See the Appendix for a more formal discussion.

The mutual gains from trade claim may seem dubious because, with the numbers chosen, trade equilibrium requires that foreign wages must be lower than home wages. In effect, trade facilitates an exchange in which more than one unit of foreign labour exchanges for one unit of home labour – the home country is ‘exploiting’ foreign labour. Some anti-trade sentiment on the left in rich countries is based on this observation. (Marxism embeds the observation in a wider system of analysis, but it probably is no longer a basis for much sentiment on the left.) Nevertheless, foreign labour gains from trade, as does home labour. Prior to trade, a pound of cheese cost 1.5 bushels of wheat in the home country while it cost 2 bushels of wheat in the foreign country. By specializing in wheat production and exchanging it for cheese, foreign workers can obtain cheese more cheaply, at a price somewhere between 2 and 1.5 bushels of wheat. This exchange must make them better off. As for home workers, prior to trade, a pound of cheese obtained 1.5 bushels while with trade it obtains somewhere between 1.5 and 2 bushels. This must make home workers better off. Concern about the ‘fairness’ of the exchange in rich countries should lead to policies which might actually help the poor countries. Trade theory shows that anti-trade policies by rich countries will instead on average harm the poor countries.

Scale economies and imperfect competition models of trade suggest further gains. With scale economies, trade implies that the force of wider markets drives costs lower. With imperfect competition, trade stimulates competition and drives profit margins lower. Trade equilibrium with monopolistic competition suggests that consumers and intermediate input users gain from more variety of differentiated products (see Helpman and Krugman, 1985).

The distribution of the gains matters, both between and within nations. Nationalist trade policy can take more of the gains, leading to destructive trade wars with mutual losses. Negotiation of trade agreements and their enforcement through international institutions such as the World Trade Organization (WTO) help to restrain the destructive tendencies of unilateral action. Nations have an incentive to participate in negotiations and to join institutions such as the WTO because some trade is better than none for each nation. Theoretical qualifications to this statement must be entered in models of trade involving scale.

http://www.dictionaryofeconomics.com.proxy.library.csi.c...edu/article?id=pde2008_1000268&goto=B&result_number=855(第 8/12 页)2009-1-2 11:09:15
economies and imperfect competition, but in practice simulation of such models suggests that some trade remains better than none for each nation. Within national economies the division of gains issue is much sharper: some members of a nation ordinarily lose from trade. Ricardo's one-factor trade model submerges income distribution. Multi-factor production models feature groups who must lose from trade. Loosely speaking, these groups are associated with import competing production (see Jones, 1987).

In equilibrium the gains must ordinarily outweigh the losses within each nation, by the preceding national-gains-from-trade argument. For an economy with non-identical households, this implies that there are gains from trade on average. Under special circumstances the gains can be redistributed so that all households gain. In practice, these circumstances are rarely met completely. Even so, most economists tend to favour efficiency-enhancing policies such as liberal trade on the pragmatic grounds that efficiency-reducing policies such as protection also cause gainers and losers, so it is better to go with the larger net gains and supplement them with feasible programmes to compensate the most obvious losers.

(A benevolent and very powerful government can in principle calculate and implement the lump-sum transfers – negative for gainers, positive for losers – that are required to achieve redistribution so that all gain. In practice, information is more limited and implementation more difficult – because households modify their behaviour to reduce their tax or increase their subsidy – than with the lump-sum story. Trade and public economic theory have relaxed the conditions somewhat. Income taxation can in some circumstances achieve redistribution with efficiency, but information limitations rule them out as a practical matter; see Guesnerie, 2001. Dixit and Norman, 1986, show that a system of consumption taxes – differentially taxing each commodity – that sacrifices some of the gains from trade is powerful in achieving gains for all. For a qualification of their argument, see Kemp and Wan, 1986. Again, information limitations vitiate the applicability of this idea. Finally, a government that can discriminate powerfully between households is sure to be lobbied intensively by those able to organize politically, to the detriment of the unorganized.)

What if losers are not compensated? A person taking this question seriously must decide on liberal trade by weighting individual gains and losses. Ethical considerations give more weight to losses or gains to the poor than to the rich. The case for liberal trade is strengthened by ethical considerations because the illiberal trade policies of rich countries hurt the poor disproportionately, as documented by Gresser (2002). Poor countries have comparative advantage based on cheap low-skilled labour, hence discrimination against their exports harms the poor citizens of poor countries. At home in rich countries, protection makes food and clothing more expensive, a regressive tax on poor consumers. Among the poor, losers from protection appear almost surely to outweigh gainers.

On the way to equilibrium, it is theoretically possible that adjustment cost losses may temporarily exceed gains, justifying temporary relief measures. For example, workers displaced by import competition may be unemployed for a time. Extensive investigation of US cases suggests that such adjustment cost losses from trade are small, of short duration, and are swamped by the gains from trade. A typical investigation reports that the net cost to the economy of using protection to re-employ a worker far exceeds the wage the worker would receive in the job, usually several (up to ten) times the wage. In practice, therefore, temporary protection for workers cannot be justified on efficiency grounds, though it remains possible to justify it on equity grounds. Economists in favour of liberal trade point out that protection can be replaced with much less inefficient methods of compensation to displaced workers.
A substantial part of the opposition to liberal trade is based on confusion and ignorance. Confusing absolute advantage with a valid theory of trade sows fear that a nation must protect itself from overwhelming competition. Greatly exaggerated notions of the size of adjustment costs leads to support for protection. Ignorance of the harm done to the world's poor by protection persuades many who support redistribution of income to support protection that harms the majority of those they seek to help. The combination of confusion and ignorance among the ‘disinterested’ with well-organized special interest groups explains the power of protectionism.

Appendix

The general statement of comparative advantage is that on average a country will import goods that are relatively expensive in autarky. Let \( m \) denote the vector of excess demands in equilibrium, positive for imports and negative for exports. Let \( p \) denote the vector of relative prices in autarky in the home country and let \( p^* \) denote the vector of relative prices in autarky in the foreign country. Then the vector inner product \( (p - p^*)' m \geq 0 \).

The key requirement for the proposition is ‘as if’ optimization by consumers and producers, leading downward-sloping demand and upward-sloping supply in the generalized sense (the substitution effects matrix of real income-compensated excess demands, \( m_p \), is negative semi-definite). If the actual trade equilibrium involves trade distortions, the additional requirement is that trade not be on balance subsidized. Let \( t \) be the vector of trade taxes, positive for import taxes and negative for export taxes (and negative for import subsidies and positive for export subsidies). The requirement is \( t' m \geq 0 \).

The ‘buy low, sell high’ logic implies that a surplus is captured by trade, so comparative advantage trade is closely linked to the gains from trade. ‘As if’ optimization means that consumers lower the expenditure required to support given real income by reallocating consumption in trade equilibrium as compared with autarky, while optimization by producers means that income is raised by reallocating production in trade equilibrium as compared with autarky.

Similar comparative advantage statements can be made concerning the factor content of trade; countries tend to import (embodied in goods) the factors that are relatively expensive in autarky (see Neary and Schweinberger, 1986).

Abstract

This article reviews empirical research in international trade, which has undergone a resurgence since the mid-1980s. The article begins with traditional trade empirics, in which cross-country differences in opportunity costs of production (comparative advantage) are the basis for trade, before turning to new trade empirics, in which consumer love of variety and increasing returns to scale give rise to trade in similar goods between similar countries. More recent empirical research has emphasized heterogeneity across products within industries and across individual plants and firms, while other recent work has focused on the political economy of trade policy.

Article

Traditional trade empirics
The idea that comparative advantage provides an explanation for ‘inter-industry trade’ (the international exchange of one set of goods for another) dates back to Ricardo (1817), who emphasized technology differences as the source of cross-country variation in opportunity costs of production. While some early empirical studies adopted a Ricardian perspective (for example, MacDougall, 1951), much of the empirical analysis of traditional trade frameworks has been concerned with the Heckscher–Ohlin (HO) model (Heckscher, 1919; Ohlin, 1924). In contrast to its Ricardian counterpart, the HO model assumes that countries have identical technologies, and instead emphasizes variation in country factor endowments and industry factor intensities as the source of differences in opportunity costs of production.

The stylized version of the HO model assumes two factors of production (capital and labour), two countries (one capital-abundant), and two goods (one capital-intensive at all factor prices). In this stylized case, the model yields four sharp predictions: (a) the HO theorem – the capital-abundant country exports the capital-intensive good; (b) the factor price equalization theorem – with diversified production, international trade equalizes factor prices; (c) the Stolper–Samuelson theorem – with diversified production, an increase in the relative price of the labour-intensive good raises the relative and real return to labour and reduces the relative and real return to capital; (d) the Rybczynski theorem – with diversified production, an increase in the endowment of labour leads to a more than proportionate increase in the output of the labour-intensive good and reduces output of the capital-intensive good. Early empirical examinations of the HO model were loosely motivated by these four theorems. In seeking to test the HO theorem, Leontief (1953) found that US exports were less capital-intensive than US imports, which appeared paradoxical within the confines of the stylized HO model. The key to resolving this paradox in Leamer (1980) was in rigorously deriving the correct empirical predictions directly from the theory. Indeed, a distinguishing feature of recent empirical studies of the HO model has been the derivation of empirical specifications from general equilibrium trade theory and the explicit recognition of the complexity of the model's predictions with many goods and factors of production. With many goods and factors of production, and in the absence of trade costs, the theorems of the HO model are considerably weaker than in the 2×2×2 stylized version, and hold only as averages or correlations. We begin by examining predictions for international trade (the generalization of the HO theorem). The many-good, many-factor version of the model does not predict the pattern of trade in individual goods, but does predict the pattern of trade in individual factor services. A country that is abundant in a factor is predicted to be a net exporter of the factor, where factor abundance is defined as an endowment exceeding the country's share of world consumption times the world factor endowment. Therefore, many empirical studies of the HO model have focused on its predictions for net trade in factor services. Following Leamer's (1984) early and influential treatment, Bowen, Leamer and Sveikauskas (1987) were the first to observe that a full test of the model's predictions for factor service trade requires three sets of separate data on international trade, factor input requirements and factor endowments. Early empirical results were discouraging from the point of view of the explanatory power of the theory. Bowen, Leamer and Sveikauskas (1987) found that the HO model performed no better than a coin toss in predicting the direction of a country's net trade in factor services. In response, Trefler (1993) argued that factor-augmenting technology differences could both explain patterns of trade in factor services and account for cross-country variation in factor prices. Under this hypothesis, first
mooted in Leontief (1953), the HO model's predictions for factor service trade and of factor price equalization hold only after one controls for cross-country differences in the efficiency of factors of production. In subsequent work, Trefler (1995) identified two systematic departures between predicted and measured net trade in factor services: (a) ‘The Case of the Missing Trade’, where measured factor services trade is close to zero and much smaller than predicted by the HO model; and (b) ‘The Endowments Paradox’, where rich countries are scarce in most factors and poor countries are abundant in most factors.

One strand of recent research has argued that the HO model's predictions for factor service trade are much closer to the measured values for trade between regions within countries, where the model's assumptions of identical technologies, factor price equalization and identical and homothetic preferences are more likely to be satisfied. Davis et al. (1997) provide evidence supporting the HO model's predictions using data for trade between Japanese regions. A second strand of research has argued that factor-augmenting technology differences are not enough to explain international trade in factor services, but that a reconciliation between theory and data is ultimately possible. Davis and Weinstein (2001) provide evidence that international trade in factor services can be successfully explained if the HO model's assumptions are relaxed to introduce cross-country differences in technology that vary between industries (‘non-neutral’ technology differences), trade costs and non-factor price equalization. While predicted and measured net factor service trade has been brought into line, the model is radically transformed by relaxing these assumptions.

We now turn to the predictions of the many-good, many-factor HO model for the international location of production (the generalization of the Rybczynski theorem). With an equal number of goods and factors of production and factor price equalization, the HO model implies a linear relationship between production and factor endowments. Estimating this relationship using cross-country data, Harrigan (1995) finds statistically significant coefficients on factor endowments, but large within-sample prediction errors, suggesting that the model performs poorly in explaining the international location of production. Gandal, Hanson and Slaughter (2004) and Hanson and Slaughter (2002) examine the HO model's prediction that, in an equilibrium where factor prices are pinned down by goods prices, changes in factor endowments should be absorbed through changes in output mix. Using immigration data for Israel and US states, they find some evidence in support of the model's prediction. More recent research reinforces conclusions from the analysis of net factor services trade by suggesting that non-neutral technology differences across industries are important in explaining the international location of production. In an influential paper, Harrigan (1997) estimates an equation for the share of sector in GDP derived from the neoclassical model of trade, which relaxes the assumptions of the HO model to allow for cross-country differences in technology. Both differences in factor endowments and differences in technology that are non-neutral across industries are found to be important in explaining cross-country variation in production structure. Other research finds evidence consistent with multiple cones of diversification within the HO model, where countries or regions specialize in a distinct set of goods, and as a result have different relative factor prices (Schott, 2003; Bernard, Redding and Schott, 2005).

We now turn to the relationship between international trade and factor prices, an issue which rose to prominence with the debate about whether the rise in wage inequality in OECD countries since the 1970s is explained by international trade or skill-biased technological change. While the labour economics literature has tended to emphasize the role of skill-biased technological change, the
international trade literature has produced mixed findings, as illustrated by the collection of studies in Feenstra (2000). One approach has examined the net factor content of trade and has typically found a relatively minor role for international trade (see, for example, Krugman, 2000). Another approach has examined the relationship between relative goods and relative factor prices within the many-good, many-factor version of HO model (the generalization of the Stolper–Samuelson theorem). Here the results have been more sanguine about the contribution of international trade. Leamer (1998) shows how zero-profit conditions and the shares of factors in unit costs for a cross-section of industries can be used to estimate the changes in factor prices mandated by observed changes in goods prices. Assumptions are made about the degree to which improvements in technology are passed through into lower goods prices, and some evidence is found that trade-induced changes in goods prices during the 1970s pushed towards increasing wage inequality in the United States. Feenstra and Hanson (1999) extend the analysis to estimate the contribution of measures of technological change and outsourcing to changes in relative goods and hence through the zero-profit conditions to relative factor prices. In their baseline specification, they estimate that computers explain around 35 per cent of the rise in the relative wages of US non-production workers over the period 1979 to 1990, and outsourcing explains around 15 per cent.

One important difference between international trade and other fields, such as development economics, is that general equilibrium is central to many of the field's theoretical predictions. As a result, it has proved hard to find natural experiments that provide plausible sources of exogenous variation to identify relationships of interest. Relatedly, many of the predictions of traditional trade theory with many goods and many factors relate to movements from autarky to international trade, but autarky is rarely observed.

In two creative papers, Bernhofen and Brown (2004; 2005) exploit the dramatic opening of the Japanese economy in the 19th century from a state of near-complete isolation to test some of the most fundamental predictions of general equilibrium trade theory. In their first paper, they find evidence, supporting the general law of comparative advantage, that an economy's net export vector evaluated at autarky prices is negative. In their second paper, they estimate that, during the final years of Japan's isolation during 1851–3, real income would have had to increase by around eight or nine per cent in order to afford the consumption bundle that the economy could have obtained if it were engaged in international trade during that period.

New trade empirics

Although traditional trade theory emphasizes the international exchange of one set of goods for another (inter-industry trade) due to comparative advantage (dissimilar countries), much of international trade involves the two-way exchange of goods within industries (intra-industry trade) between developed nations (similar countries). This apparent disconnect between theory and data was documented in a number of early empirical studies, which examined the extent of intra-industry trade (for example, Grubel and Lloyd, 1975) and the volume of trade between similar countries (for example, Linder, 1961). This empirical evidence was a key motivation for the ‘new trade theory’ literature following Krugman (1979; 1980) that explained these features of international trade in terms of consumer love of variety and increasing returns to scale. Firms manufacture differentiated products and concentrate production in a single location, while consumers spread their expenditure across all firms’ varieties, giving rise to two-way trade even if countries are identical. Although not the only explanation for intra-industry trade
international trade, empirical approaches to: The New Palgrave Dictionary of Economics

Between similar countries (see Davis, 1997), the combination of consumer love of variety and increasing returns to scale provided an entirely new intellectual framework for thinking about the causes and consequences of international trade.

In the HO model, the volume of trade is increasing in the extent of dissimilarity in countries’ factor endowments, whereas in new trade theory the volume of trade is increasing in the similarity of countries’ sizes. Indeed, new trade theory provides rigorous theoretical foundations for the so-called ‘gravity equation’, in which the volume of trade between two countries is proportional to the product of their sizes and measures of extent of trade frictions. Although the gravity equation had been known for some time to provide an extremely successful empirical explanation for bilateral patterns of international trade (classic early treatments include Tinbergen, 1962, and Linnemann, 1966), it initially suffered from a lack of theoretical foundations.

New trade theory's prediction that the volume of trade should be proportional to the similarity of country sizes was examined empirically by Helpman (1987) in specifications derived directly from the theory. Using data from 14 OECD countries over the period 1956 to 1981, both bilateral trade and the share of inter-group trade in total trade were found to be strongly increasing in the similarity of country sizes. While this appeared to strongly confirm the predictions of new trade theory, Hummels and Levinsohn (1995) found that the same patterns existed for trade between non-OECD countries, for which new trade theory's assumptions of differentiated products and identical and homothetic preferences appeared less appropriate. One explanation of why the gravity equation appears to work for such diverse groups of countries is that a number of alternative theoretical frameworks, including the HO model, yield this relationship. As argued by Deardorff (1998), the gravity relationship is a basic implication of specialization combined with identical and homothetic preferences. Therefore, the problem is not a lack but rather a surfeit of theoretical foundations. Consistent with this insight, Evenett and Keller (2002) found that increasing returns and factor endowments both played a role in explaining the empirical success of the gravity equation for a diverse cross-section of developed and developing countries.

The gravity equation has been widely used in empirical work to estimate the impact on trade of a host of frictions, policies and institutions including national borders, transport costs, tariffs, common currencies and the World Trade Organization (WTO). A notable example is McCallum (1995), who finds that trade between Canadian provinces was more than 20 times larger than trade between Canadian provinces and US states, suggesting a surprisingly large impact of national borders on trade. Anderson and Van Wincoop (2002) show, however, that theoretical derivations of the gravity equation imply that bilateral trade depends not only on trade costs between regions themselves (‘bilateral resistance’) but also on trade costs with all locations (‘multilateral resistance’). An implication is that national borders have a larger impact on inter-regional trade than on international trade the smaller a country is and the larger its trade partner. When countries are small, international trade is a large share of overall economic activity. Therefore, the national border has a large effect on multilateral resistance, and so leads to a large reduction in the cost of inter-regional trade relative to international trade. Estimating the gravity equation in a theory-consistent way, Anderson and Van Wincoop (2002) obtain much smaller, though still large, estimates of the trade impact of the Canada–US border.

In the presence of trade costs, an important difference emerges between the predictions of new trade theory and those of traditional trade theory. The combination of consumer love of variety, increasing returns to scale and trade costs in new trade theory generates a ‘home market effect’, whereby an
increase in expenditure leads to a more than proportionate increase in domestic production of a good. The intuition is that increasing returns to scale imply that firms have an incentive to concentrate production, while transport costs imply that they have an incentive to concentrate production close to large markets. In contrast, traditional trade models imply that an increase in expenditure leads at most to a proportionate increase in domestic production if foreign export supply is perfectly inelastic. Otherwise, if the foreign export supply curve is upward sloping, some of the increase in expenditure is satisfied through higher foreign exports and the increase in domestic production is less than proportionate. Using international and Japanese regional data, Davis and Weinstein (1999; 2003) find evidence of home market effects for a number of manufacturing industries, which together account for a substantial share of overall manufacturing activity. Additional evidence in support of home market effects emerges from international trade data in Feenstra, Markusen and Rose (2001) and Hanson and Xiang (2004).

One feature of international trade that appears at first sight hard to reconcile with new trade theory is the large number of zeros between country pairs. The constant elasticity of substitution (CES) preferences and iceberg trade costs in new trade models imply that all country pairs trade a positive quantity of each variety. However, in an analysis of bilateral trade between 161 countries over the period 1970 to 1997, Helpman, Melitz and Rubinstein (2006) find that roughly one half of the country-partner-year observations involve zero trade. A natural explanation for zero bilateral trade flows can be created within new trade theory if firm heterogeneity and fixed trade costs are introduced following Melitz (2003). Depending on the distribution of productivity within countries, firms may or may not find it profitable to incur the fixed costs of exporting to a particular market. Helpman, Melitz and Rubinstein (2006) develop a methodology for estimating the gravity equation that not only controls for multilateral resistance as suggested above, but also controls for the existence of zero bilateral flows and the non-random selection of firms into exporting according to their productivity.

Finally, one key stylized fact about international trade since the Second World War is that it has grown far more rapidly than income. Two potential explanations are reductions in trade barriers following multilateral liberalization or regional integration, and improvements in transportation and communication technologies. Yi (2003) argues that is hard to explain the magnitude of the trade growth using standard trade models, and observed declines in trade barriers unless one assumes implausibly high elasticities of substitution. However, augmenting standard models to include intermediate inputs enables the growth in trade to be explained with a smaller elasticity of substitution. In the augmented model, tariff reductions decrease the cost of shipping both intermediate inputs and final goods, and so have a magnified impact on overall trade volumes. Indeed, the geographical separation of stages of the production process is one of the distinctive features of trade at the end of the 20th century compared with an earlier era of international integration at the end of the 19th century. This geographical separation of stages of production has been variously referred to as vertical specialization, vertical disintegration, the fragmentation of production, the slicing of the value-added chain, geographical production networks and offshoring. Hummels, Ishii and Yi (2001) define vertical specialization as occurring when the following conditions are satisfied: (a) goods are produced in multiple sequential stages; (b) two or more countries provide value-added in the good's production sequence; (c) at least one country uses imported inputs in its stage of the production process and some of the resulting output is exported. The authors provide empirical evidence of the rapid growth in vertical specialization in the closing decades of the 20th century alongside the rapid growth in overall trade.
The empirics of product trade

The dissemination of highly disaggregated data-sets on trade in thousands of individual products (Feenstra, Romalis and Schott, 2002; Feenstra et al., 2005) has contributed towards a shift in focus in empirical trade research towards the micro level. For the United States, data are available for over 7,000 seven-digit products of the Tariff Schedule of the United States (TS7) from 1972 to 1988 and for over 10,000 ten-digit products of the Harmonized System (HS10) from 1989 onwards.

In contrast to the empirical research on the HO model discussed above, which emphasizes specialization across products or industries, Schott (2004) provides compelling evidence of specialization within products. With US manufacturing imports taken as a whole in 1994, and the unit value ratio (UVR) defined as the ratio of value to quantity, the maximum UVR within products across trade partners is a factor of 24 times greater than the minimum UVR. The UVRs are higher for varieties originating in capital- and skill-abundant countries than for those sourced from labour-abundant countries, consistent with HO-based specialization. Similarly, UVRs are positively associated with the capital intensity of the production techniques that exporters use to produce them. Taken together, these and other findings in the paper suggest that comparative advantage operates at a much finer level of detail than customarily considered.

Another insight that emerges from the product-level trade data is the importance of the ‘extensive margin’ of the set of goods traded. Hummels and Klenow (2005) decompose variation in countries’ aggregate exports into the contributions of the following terms: (a) the quantity of each good exported (the ‘intensive margin’); (b) the set of goods exported (the ‘extensive margin’); (c) the quality of goods exported. They find that the extensive margin accounts for around 60 per cent of the greater exports of larger economies, while the remaining intensive margin contribution of 40 per cent consists of higher quantities being exported at modestly higher prices. Kehoe and Ruhl (2004) establish an important role for the extensive margin in explaining the growth of trade following trade liberalizations. The set of goods that accounted for only 10 per cent of trade prior to liberalization are found to account for as much as 40 per cent of trade after liberalization. Using micro data from the U.S. Commodity Flow Survey, Hillberry and Hummels (2005) show that trade frictions such as distance reduce the aggregate value of trade primarily through the number of commodities shipped and the number of establishments shipping commodities (the extensive margin) rather than through the average value of shipments (the intensive margin). Together these findings present a number of challenges to standard trade models. For example, in marked contrast to the data, new trade theory models without firm heterogeneity and fixed costs of trading imply that all of the adjustment to trade frictions occurs through the intensive margin.

Although consumer love of variety is one of the defining features of new trade theory, Broda and Weinstein (2006) were the first to estimate the welfare gains from an increase in the number of varieties imported over time. In their analysis, the product-level trade data is used to measure varieties, defined as the versions of a product supplied by different exporters. The methodology of Feenstra (1994) is extended to estimate separate elasticities of substitution for thousands of products and to evaluate the contribution of new varieties to the US import price index. According to their baseline estimates, conventional price indices that do not correctly control for variety growth overstate the growth in US import prices by around 1.2 percentage points per annum. The estimated contribution to US welfare...
from an increase in the number of varieties imported over the period 1972 to 2001 is around 2.6 per cent of national income.

The empirics of plant and firm trade

The analysis of micro data-sets on plants and firms presents additional empirical challenges to traditional and new trade theory, and prompted a wave of subsequent theoretical research. The first set of empirical challenges relates to producer heterogeneity and persistent reallocation. Whereas traditional and new trade theories typically assume a representative firm, micro data-sets reveal vast heterogeneity across plants and firms within narrowly defined industries, in terms of productivity, capital intensity, skill intensity and other characteristics (see for example the survey by Bartelsman and Doms, 2000). Similarly, whereas traditional trade theory emphasizes net reallocations of resources between industries in response to exogenous shocks such as trade liberalization, micro data-sets reveal persistent job creation and job destruction in all industries even in the apparent absence of exogenous shocks. Additionally, job creation and job destruction are positively correlated across industries, implying that rates of gross job creation and destruction are large relative to the net reallocation emphasized in traditional trade theory. An implication of these findings is that the changes in employment across plants and firms are greater than those required to achieve the observed between-industry reallocation of resources (‘excess job reallocation’), implying substantial within-industry reallocations of resources (see in particular Davis, Haltiwanger and Schuh, 1998).

The second set of empirical challenges relates to the export behaviour of plants and firms. Traditional trade theory predicts net exports in one set of industries and net imports in another set of industries. New trade theory implies that all firms export as a result of consumer love of variety and increasing returns to scale. Yet, in micro data-sets, all manufacturing industries display a mix of exporters and non-exporters (see Bernard and Jensen, 1995). Moreover, exporters are systematically more productive, more capital-intensive and more skill-intensive than non-exporters (see again Bernard and Jensen, 1995). These findings have led to considerable debate as to whether high-performing firms become exporters or whether exporting leads to improved firm performance. The current consensus favours causality running from good firm performance to exporting (selection into export markets): see, for example, Bernard and Jensen (1999), Clerides, Lach and Tybout (1998) and Roberts and Tybout (1997).

The third set of empirical challenges relates to evidence from trade liberalizations in both developed and developing countries. Despite traditional trade theory's emphasis on between-industry reallocations of resources, one of the central findings from empirical studies of trade liberalizations is the importance of within-industry reallocations of resources across plants and firms. In an influential paper, Pavcnik (2002) finds that between-plant reallocations of resources account for around two-thirds (12.4 percentage points) of the 19 per cent increase in aggregate productivity in the Chilean manufacturing sector following the trade liberalization of the late 1970s and early 1980s. Similarly, Trefler (2004) finds an important role for reallocation in accounting for the improvement in aggregate productivity in Canadian manufacturing in the aftermath of the Canada–US free trade agreement. Together these empirical challenges have led to the development of new theoretical frameworks incorporating firm heterogeneity into both traditional and new trade theory (see in particular Bernard, Eaton and Kortum, 2003; Melitz, 2003). The interplay between the econometric analysis of micro data-
A final area of rapid recent progress is the empirical analysis of trade policy. A number of alternative approaches to modelling the political economy of trade policy have been taken, including median-voter theories, models where the government trades off political support from industry against consumer dissatisfaction, theories of lobbying by special interest groups, and models of electoral contribution. One of the most influential lines of research follows the seminal work of Grossman and Helpman (1994). In their model, campaign contributions are designed to influence policy choices. Interest groups move first and offer politicians campaign contributions that depend on their policy stance. Politicians next maximize a political objective function which depends on both campaign contributions and social welfare. The political objective function is derived from microeconomic foundations within a model of electoral competition. The model yields a structural equation in which the level of protection depends on the political organization of the industry, the ratio of domestic output in the industry to net trade, and the elasticity of import demand or export supply. Goldberg and Maggi (1999) estimate the structural relationship implied by the Grossman and Helpman model and find broad empirical support. In particular, the pattern of protection differs markedly between politically organized and non-organized industries, though the implied weight on social welfare relative to political contributions is larger than expected. One of the distinctive features of recent empirical work in this area is again the rigorous derivation of empirical specifications from theoretical predictions. Gawande and Krishna (2003) survey both the recent empirical evidence and the results of earlier and more ad hoc empirical specifications. A related theoretical literature has sought to model the politics of international trade agreements (for example, Grossman and Helpman, 1995; Krishna, 1998; McLaren, 2002). One issue that has attracted particular attention is the extent to which regional preferential trade agreements reinforce or retard multilateral trade liberalization. Theoretical research has also examined the microeconomic foundations for observed features of international trade institutions such as the General Agreement on Tariffs and Trade (GATT) and the World Trade Organization (WTO) (see in particular Bagwell and Staiger, 1999; 2001). Two key features are reciprocity and non-discrimination (the Most Favored Nation, MFN, principle). Empirical work in this area remains in its infancy and offers an exciting prospect for the future. In an analysis of US trade policy, Limao (2006) finds evidence that preferential trading blocs have acted as stumbling blocks for multilateral liberalization.

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We discuss salient economic aspects of the Internet, including the possible abolition of net neutrality by local broadband access networks as well as potential incompatibilities and degradation of connectivity in the Internet backbone.

Keywords

antitrust; cartels; common standards; innovation; interconnection; Internet, economics of the; market power; net neutrality; network effects; network externalities; price discrimination; proprietary standards; switching costs; two-sided pricing; universal connectivity

Article

The Internet is a global network of interconnected networks that connect computers. The Internet allows data transfers as well as the provision of a variety of interactive real-time and time-delayed telecommunications services. Internet communication is based on common and public protocols. Hundreds of millions of computers are presently connected to the Internet. Figure 1 shows the expansion of the number of computers connected to the Internet.

Figure 1
The vast majority of computers owned by individuals or businesses connect to the Internet through commercial ‘Internet service providers (ISPs). Educational institutions and government departments are also connected to the Internet but typically do not offer commercial ISP services. Users connect to the Internet either by dialing their ISP, connecting through cable modems, or residential ‘digital subscriber line’ (DSL), or through corporate networks. Typically, routers and switches owned by the ISP send the caller's packets to a local ‘point of presence’ (POP) of the Internet. Dial-up, cable modem, and DSL access POPs as well as corporate networks dedicated access circuits connect to high-speed hubs. High-speed circuits, leased from or owned by telephone companies, connect the high speed hubs forming an ‘Internet backbone network’.

The Internet is based on three basic separate levels of functions of the network:

- the hardware/electronics level of the physical network;
- the (logical) network level where basic communication and interoperability is established; and
- the applications/services level.

Thus, the Internet separates the network interoperability level from the applications/services level. Unlike earlier centralized digital electronic communications networks, such as CompuServe, AT&T Mail, Prodigy, and early America On Line (AOL), the Internet allows a large variety of applications and services to be run ‘at the edge’ of the network and not centrally.
Users pay ISPs for access to the whole Internet. Similarly, ISPs pay backbones for access to the whole Internet. ISPs pay per month for a pipe of a certain bandwidth, presumably according to their expected use. When digital content, for example, is downloaded by consumer A from provider B, both sides, that is, both A and B, pay. Consumer A pays to his ISP through his monthly subscription, and provider B pays similarly. In turn, ISPs pay to their respective backbones through their monthly subscriptions. The present regime on the Internet does not distinguish in terms of price (or in any other way) between bits or information packets depending on the services that these bits and packets are used for. This regime, called ‘net neutrality’, has prevailed on the Internet since its inception. Presently, a bit or information packet used for ‘voice over Internet protocol’ (VOIP), for search, email, for an image or for a video is priced equally as a part of the large number of packets that correspond to the subscription services of the originating and terminating ISP. Taking advantage of a change in regulatory rules by the Federal Communications Commission that reclassified the Internet as an ‘information service’ rather than a ‘telecommunications service’, AT&T, Verizon and cable TV networks advocate price discrimination based on which application and on which provider the bits they transport come from. These local broadband access networks would like to abolish the regime of non-discrimination which has been called ‘net neutrality’ and substitute for it a complex price discrimination schedule where, besides the basic service for transmission of bits, there will be additional charges by the Internet access network levied to the originating party (such as Google, Yahoo or Microsoft Network, MSN) even when the application provider is not directly connected to the local access network.

The imposition of price discrimination on the provider side of the market and not on the subscriber is a version of two-sided pricing. It is uniquely possible for firms operating within a network structure. Besides traditional networks, such two-sided pricing is also possible for intermediaries in exchange networks (such as the exchanges themselves). There is presently considerable debate on the legality as well as the efficiency properties of the implementation of such complex pricing strategies by broadband Internet access networks, mainly because of the very considerable market power of such firms.

Residential retail broadband Internet access customers may well have difficulty changing ISPs. Ninety-nine per cent of US households are offered Internet access by at most two firms – a telephone company through DSL and a cable TV company through a cable ‘modem’ – and many households are facing a monopoly of either cable or DSL. There are also switching costs to residential customers, such as changing equipment. Finally, residential customers are much more affected by contracts that bundle broadband Internet access with other services such as telecommunications and cable television.

As discussed earlier, the Internet under net neutrality separated the network layer from the applications/services layer. This allowed firms to innovate ‘at the edge of the network’ without seeking approval from network operator(s). The decentralization of the Internet based on net neutrality facilitated innovation resulting in big successes such as Google, MSN, Yahoo, and Skype. Net neutrality also increased competition among the applications and services ‘at the edge of the network’ which did not need to own a network to compete.

Additionally, the existence of network effects on the Internet implies that efficient prices to users on both sides (consumers and applications) should be lower than in a market without network effects. Instead we see an attempt to increase prices that will reduce network effects and innovation.

Abolition of net neutrality raises both horizontal and vertical antitrust issues. To start with horizontal issues, last-mile carriers (who are selling as a duopoly or monopoly to residential consumers) may reduce capacity of ‘plain’ broadband Internet access service and/or degrade it so that they can establish a ‘premium’ service for which they intend to charge content/applications providers whose content or application is used by residential subscribers. Coordinated reduction of capacity in ‘plain’ service is reminiscent of cartel behaviour. In general, the coordinated introduction of price discrimination schemes may reduce output, which would reduce total surplus. Therefore, introduction of coordinated price discrimination may have anti-competitive consequences.

There is also a variety of potentially anti-competitive vertical effects. For example, a carrier may favour its own content or application over the content of a competing carrier or a company that does not have its own network. VOIP provided over broadband Internet competes with traditional circuit-switched service provided by AT&T and Verizon, and could be subject to discrimination. Additionally, both AT&T and Verizon are gearing to distribute video, and could favour their video services over those of others. But the anti-competitive concerns are hardly limited to products and services currently provided by the firms with market power in the access market. The carriers can also leverage market power in broadband access to the content or applications markets through contractual relationships. For example, a carrier can contract with an Internet search engine to put it in ‘premium’ service while searches using other search engines face considerable delays using ‘plain’ service. The question that confronts the US Congress in 2007 is whether it should intervene by imposing non-discrimination restrictions or wait instead for antitrust suits to file and resolve. The crucial role of the Internet in US economic growth argues in favour of preemptive restrictions.

**Backbone issues**

Backbone networks provide transport and routing services for information packets among high-speed hubs on the Internet. Backbone networks vary in terms of their geographic coverage. There is wide variance of ISPs in terms of their subscriber size and the networks they own. However, irrespective of its size, an ISP needs to interconnect with other ISPs so that its customers can reach all computers/nodes on the Internet. That is, interconnection is necessary to provide the universal connectivity on the Internet which is demanded by users. Internet networks interconnect in two ways: (a) private bilateral interconnection, and (b) interconnection at public network access points (NAPs). Private interconnection points and public NAPs are facilities that provide collocation space and a switching platform so that networks are able to interconnect. Interconnection services are complementary to Internet transport. In a sense, the Internet backbone networks are like freeways and the NAPs are like the freeway interchanges.
Internet networks have contracts that govern the terms under which they pay each other for connectivity. Payment takes two distinct forms: (a) payment in dollars for ‘transit’, and (b) payment in kind, that is, barter, called ‘peering’. Connectivity arrangements among ISPs encompass a seamless continuum, including ISPs that rely exclusively on transit to achieve connectivity, ISPs that use only peering to achieve connectivity, and everything in between. Although there are differences between transit and peering in the specifics of the payments method, and transit includes services to the ISP not provided by peering, these two are essentially alternative payment methods for connectivity. The transport and routing that backbone networks offer do not necessarily differ depending on whether cash (transit) or barter (peering) is used for payment.

Under transit, a network X connects to network Y with a pipeline of a certain size, and pays network Y for allowing X to reach all Internet destinations. Under transit, network X pays Y to reach not only Y and its peers, but also any other network, such as network Z by passing through Y, as in the diagram below.

\[ X \rightarrow \ldots \rightarrow \ldots \rightarrow Y \rightarrow \ldots \rightarrow \ldots \rightarrow Z \]

Under peering, two interconnecting networks agree not to pay each other for carrying the traffic exchanged between them as long as the traffic originates and terminates in the two networks. In the diagram above, if X and Y have a peering agreement, they exchange traffic without paying each other so long as such traffic terminating on X originates in Y, and traffic terminating on Y originates in X. If Y were to pass to X traffic originating from a network Z that was not a customer of Y, Y would have to pay a transit fee to X (or get paid a transit fee by X), that is, it would not be covered by the peering agreement between X and Y.

Although the networks do not exchange money in a peering arrangement, the price of the traffic exchange is not zero. If two networks X and Y enter into a peering agreement, it means that they agree that the cost of transporting traffic from X to Y and vice versa that is incurred within X is roughly the same as the cost of transporting traffic incurred within Y. These two costs have to be roughly equal if the networks peer, but they are not zero.

It is a commercial decision whether interconnection takes the form of peering or transit payment. Peering is preferred when the cost incurred by X for traffic from X to Y and Y to X is roughly the same as the cost incurred by Y for the same traffic. If not, the networks will use transit. As I explain below, the decision on whether to peer depends crucially on the geographic coverage of the candidate networks.

Generally, peering does not imply that the two networks should have the same size in terms of the numbers of ISPs connected to each network, or in terms of the traffic that the two networks generate. If two networks, X and Y, are similar in terms of the types of users to whom they sell services, the amount of traffic flowing across their interconnection point(s) will be roughly the same, irrespective of the relative size of the networks. For example, suppose that network X has ten ISPs and network Y has one ISP. If all ISPs have similar features, the traffic flow from X to Y is generally equal to the traffic flow from Y to X.

What determines whether a peering arrangement is efficient for both networks is the cost of carrying the mutual traffic within each network. This cost will depend crucially on a number of factors, including the geographic coverage of the two networks. Even if the types of ISPs of the two networks are the same as in the previous example (and therefore the traffic flowing in each direction is the same), the cost of carrying the traffic can be quite different in network X from network Y. For example, network X (with the ten ISPs) may cover a larger geographic area and have significantly higher costs per unit of traffic than network Y. Then network X would not agree to peer with Y. These differences in costs ultimately would determine the decision to peer (barter) or receive a cash payment for transport.

Where higher costs are incurred by one of two interconnecting networks because of differences in the geographic coverage of the networks, peering would be undesirable from the perspective of the larger network. Similarly, one expects that networks that cover small geographic areas will peer only with each other. Under these assumptions, who peers with whom is a consequence of the extent of a network’s geographic coverage, and may not have any particular strategic connotation. In a theoretical model, Milgrom, Mitchell and Srinagesh (2000) show how peering can emerge under some circumstances as an equilibrium in a bargaining model between backbones.

Structural conditions for Internet backbone services (ease of expansion and entry) ensure low barriers to entry and expansion, and easy conversion of other transport capacity to Internet backbone capacity. As discussed later, raw transport capacity as well as Internet transport capacity have grown dramatically. Transport capacity is almost a commodity because of its abundance. The business environment for Internet backbone services is competitive. Generally, ISPs buying transport services face flexible transit contracts of relatively short duration. This is reflected in competitive pricing. Economides (2006a) shows that AT&T and MCI had almost identical prices for transit in 1999 when AT&T’s backbone business was significantly smaller than MCI’s.

ISPs are not locked in by switching costs of any significant magnitude. Thus, ISPs are in good position to change providers in response to any increase in price, and it would be very difficult for a backbone to profitably increase price. Moreover, a large percentage of ISPs has formal agreements that allow them to route packets through several backbone networks and are able to control the way the traffic will be routed (multi-homing).

When an ISP reaches the Internet through multiple backbones, it has additional flexibility in routing its traffic through any particular backbone. A multi-homing ISP can easily reduce or increase the capacity with which it connects to any particular backbone in response to changes in prices of transit. Thus, multi-homing increases the firm-specific elasticity of demand of a backbone provider. Therefore, multi-homing severely limits the ability of any backbone services provider to profitably increase the price of transport. Any backbone
increasing the price of transport will face a significant decrease in the capacity bought by multi-homing ISPs. Large Internet customers also use multiple ISPs, which is called ‘customer multi-homing’. They have chosen to avoid any limitation on their ability to switch traffic among suppliers even in the very shortest of runs. Customer multi-homing has similar effects as ISP multi-homing in increasing the firm-specific elasticity of demand of a backbone provider and limiting the ability of any backbone services provider to profitably increase the price of transport.

Like any network, the Internet exhibits network effects. Network effects are present when the value of a good or service to each consumer rises as more consumers use it, everything else being equal – see Economides (1996), Farrell and Saloner (1985), Katz and Shapiro (1985), and Liebowitz and Margolis (1994). In traditional telecommunications networks, an additional customer to the network increases the value of a network connection to all other customers, since each of them can now make an extra call. On the Internet, an additional user potentially

- adds to the information that all others can reach;
- adds to the goods available for sale on the Internet;
- adds one more customer for e-commerce sellers;
- adds to the number of people who can send and receive e-mail or otherwise interact in through the Internet.

Thus, the addition of an extra computer node increases the value of an Internet connection to each connection. In networks of interconnected networks, there are large social benefits from the interconnection of the networks and the use of common standards. A number of networks of various ownership structures have harnessed the power of network externalities by using common standards. Examples of interconnected networks of diverse ownership that use common standards include the telecommunications network, the network of fax machines, and the Internet. Despite the different ownership structures in these three networks, the adoption of common standards has allowed each of them to reap huge network-wide benefits.

As the variety and extent of the Internet’s offerings expand, and as more customers and more sites join the Internet, the value of a connection to the Internet rises. Because of the high network externalities of the Internet, consumers on the Internet demand universal connectivity, that is, to be able to connect with every website on the Internet and to be able to send electronic mail to anyone. This implies that every network must connect with the rest of the Internet in order to be a part of it. The demand for universal connectivity on the Internet is stronger than the demand of a voice telecommunications customer to reach all customers everywhere in the world. In the case of voice, it may be possible but very unlikely that a customer might buy service from a long-distance company that does not include some remote country because the customer believes that it is very unlikely that he or she would be making calls to that country. On the Internet, however, one does not know where content is located. If company A did not allow its customers to reach region B or customers of a different company C, customers of A would never be able to know or anticipate what content they would be missing. Thus, consumers’ desire for Internet universal connectivity is stronger than for voice telecommunications. Additionally, because connectivity on the Internet is two-way, a customer of company A would be losing exposure of his or her content (and the ability to send and receive e-mails) to region B and customers of company C. It would be difficult for customer A to calculate the extent of the losses accrued to him or her from such actions of company A. Thus, again, customers on the Internet require universal connectivity.

In networks with network externalities, firms may create bottleneck power by using proprietary standards. A firm controlling a standard needed by new entrants to interconnect their networks with the network of the incumbent may be in a position to exercise market power (see Economides, 2006b). Often a new technology will enter the market with competing incompatible standards. Competition among standards may have the snowball characteristic attributed to network externalities. Economics literature has established that using network externalities to affect market structure by creating a bottleneck requires three conditions (see Economides, 1996; 1989; Farrell and Saloner, 1985; Katz and Shapiro, 1985):

- networks use proprietary standards;
- no customer needs to reach nodes of or to buy services from more than one proprietary network; and
- customers are captives of the network to which they subscribe and cannot change providers easily and cheaply.

First, without proprietary standards, a firm does not have the opportunity to create the bottleneck. Second, if proprietary standards are possible, the development of proprietary standards by one network isolates its competitors from network benefits, which then accrue to only one network. The value of each proprietary network is diminished when customers need to buy services from more than one network. Third, the more consumers are captive and cannot easily and economically change providers, the more valuable is the installed base to any proprietary network. I show below that these conditions fail in the context of the Internet backbone.

For example, if universal connectivity were not offered by a backbone network, a customer or its ISP would have to connect with more than one backbone. This would be similar to the period 1895–1930 when a number of telephone companies run disconnected networks. Eventually most of the independent networks were bought by AT&T, which had a dominant long-distance network. The refusal of AT&T to deal and interconnect with independents was effective for three key reasons: (a) AT&T controlled the standards and
protocols under which its network ran; (b) long-distance service was provided exclusively by AT&T in most of the United States; and (c) the cost to a customer of connecting to both AT&T and an independent was high. None of these reasons applies to the Internet. The Internet is based on public protocols. No Internet backbone has exclusive network coverage of a large portion of the United States. Finally, connecting to more than one backbone (multi-homing) is a common practice by many ISPs and does not require big costs. And ISPs can interconnect with each other through secondary peering, as explained below. Thus, the economic factors that allowed AT&T to blackmail independents into submission in the first three decades of the 20th century are reversed in today's Internet backbone, and therefore would not support a profitable refusal to interconnect by any backbone.

The Internet fails to fulfill any of the three necessary conditions stated above under which a network may be able to leverage network externalities and create a bottleneck. First, there are no proprietary standards on the Internet, so the first condition fails. The scenario of standards wars is not at all applicable to Internet transport, where full compatibility, interconnection and inter-operability prevail. For Internet transport, there are no proprietary standards. There is no control of any technical standard by service providers and none is in prospect. Internet transport standards are firmly public property (Kahn and Cerf, 1999; Bradner, 1999). As a result, any seller can create a network complying with the Internet standards – thereby expanding the network of interconnected networks – and compete in the market.

In fact, the existence and expansion of the Internet and the relative decline of proprietary networks and services, such as CompuServe, can be attributed to the conditions of inter-operability and the tremendous network externalities of the Internet. AOL, CompuServe, Prodigy, MCI and AT&T folded their proprietary electronic mail and other services into the Internet. Microsoft, thought to be the master of exploiting network effects, made the error of developing and marketing the proprietary MSN. After that product failed to sell, Microsoft re-launched the Microsoft Network as an Internet service provider, adhering fully to the public Internet standard. This is telling evidence of the power of the Internet standard and demonstrates the low likelihood that any firm can take control of the Internet backbone by imposing its own proprietary standard.

Second, customers on the Internet demand universal connectivity, so the second condition above fails. Users of the Internet do not know in advance what Internet site they may want to contact or to whom they might want to send e-mail. Thus, Internet users demand from their ISPs, and expect to receive, universal connectivity. This is the same expectation that users of telephones, mail and fax machines have: that they can connect to any other user of the network without concern about compatibility, location, or, in the case of telephone or fax, any concern about the manufacturer of the appliance, the type of connection (wireline or wireless) or the owners of the networks over which the connection is made. Because of the users’ demand for universal connectivity, ISPs providing services to end users or to websites must make arrangements with other networks so that they can exchange traffic with any Internet customer.

Third, there are no ‘captive’ ISPs on the Internet, so the third condition fails, for a number of reasons:

- ISPs can easily and with low cost migrate all or part of their transport traffic to other network providers;
- many ISPs already purchase transport from more than one backbone to guard against network failures and for competitive reasons (ISP ‘multi-homing’);
- many large websites/providers use more than one ISP for their sites (‘customer multi-homing’); and
- competitive pressure from their customers makes ISPs agile and likely to respond quickly to changes in conditions in the backbone market.

Competitive conditions imply that significant price increase, raising rivals’ costs or degrading interconnection are unlikely to be profitable on the Internet backbone. If the large Internet backbone connectivity provider’s strategy were to impose equal increases in transport costs on all customers, the response of other backbone providers and ISPs would be to reduce the traffic for which they buy transit from the large Internet backbone provider (IBP) and to instead re-route traffic and purchase more transit from each other. Thus, in response to a price increase by the large Internet backbone connectivity provider, other IBPs and ISPs would reduce the traffic for which they buy transit from the large IBP down to the minimum level necessary to reach ISPs that are exclusively connected to the large IBP. All other IBPs and ISPs would exchange all other traffic with each other bypassing the large IBP network.

Figure 2 shows the typical reaction of an increase in the price of a large IBP, and illustrates why the strategy of increasing price is unprofitable. Consider, for example, a situation where, prior to the price increase, four ISPs (1 to 4) purchase transit from IBP 0, which considers increasing its price. Two of these ISPs (ISP 2 and ISP 3) peer with each other. ISP 1 and ISP 4 buy transit capacity for all their traffic to IBP 0 and the other three ISPs. ISP 2 and ISP 3 buy transit capacity for all their traffic to IBP 0, ISP 1 and ISP 4.

Figure 2
Traffic flows between ISPs and a backbone
Now suppose that IBP 0 increases its transit price. In response, ISP 1 and ISP 4 decide to reduce the traffic for which they buy transit from IBP 0, and instead to re-route some of their traffic and purchase more transit from ISP 2 and ISP 3 respectively. Because of the peering relationship between ISP 2 and ISP 3, all traffic from ISP 1 handed to ISP 2 will reach ISP 3 as well as ISP 4, which is a customer of ISP 3. Similarly, by purchasing transit from ISP 3, ISP 4 can reach all the customers of ISP 1, ISP 2 and ISP 3. Thus, in response to the price increase of IBP 0, each of the ISPs 1, 2, 3 and 4 will reduce the amount of transit purchased from the IBP 0. Specifically, each of the ISPs buys from IBP 0 only capacity sufficient to handle traffic to the customers of network 0. This may lead to a considerable loss in revenues for IBP 0, rendering the price increase unprofitable. The big beneficiaries of the price increase of IBP 0 are peering ISPs 2 and 3, which now start selling transit to ISPs 1 and 4 respectively and become larger networks.
In response to a price increase by the large IBP, rivals would be able to offer their customers universal connectivity at profitable prices below the large IBP's prices. In the scenario described in the example above, market forces, responding to a price increase by a large network, re-route network traffic so that it is served by rival networks, except for the traffic to and from the ISPs connected exclusively with the large network. The rivals purchase the remaining share from the large IBP in order to provide universal connectivity. Thus, the rivals’ blended cost would permit them to profitably offer all transport at prices lower than the large IBP's prices, but above cost.

A direct effect of the increase in price by the large network is that (a) ISPs that were originally exclusive customers of the large IBP would shift a substantial portion of their transit business to competitors, and (b) ISPs that were not exclusive customers of the large IBP would also shift a significant share of their transit business to competitors’ networks, keeping the connection with the large IBP only for traffic for which alternative routes do not exist or for cases of temporary failure of the rivals’ networks. Similarly, degradation of interconnection to all backbones or sequentially one at a time is likely to be unprofitable. Degradation of interconnection to all backbones is clearly dominated by a price increase (since a price increase directly produces additional revenue to the firm, while interconnection degradation does not directly increase revenue), and, as we have shown above, competitive conditions severely limit price increases. Targeted degradation is also unprofitable for a large network that would initiate it for several reasons.

1. ISP clients of the targeted network are likely to switch to third IBP networks that are unaffected by the degradation; it is very unlikely that any will switch to the degrading IBP network because it is itself degraded and cannot offer universal connectivity; there is no demand reward to the large IBP network.
2. Degradation of interconnection hurts all the ISP customers of the targeting IBP network as well, since they lose universal connectivity; these customers of the large network would now wont to pay less to the large network; this leads to significant revenue and profit loss.
3. After losing universal connectivity, customers of the large IBP network are likely to switch to other networks that are unaffected by degradation and can provide universal connectivity; this leads to even further revenue and profit loss for the degrading network.
4. Multi-homing ISPs would purchase less capacity from the large IBP network, or even terminate their relationship with the large network, which through its own actions sabotages their demand for universal connectivity; this further reduces demand and profits for the degrading network; the same argument applies to multi-homing customers of ISPs.
5. As the large IBP network pursues target after target, its customers face continuous quality degradation while the target's customers face only temporary degradation; this would result in further customer and profit losses for the large IBP network.
6. Prospective victims would seek alternative suppliers in advance of being targeted by the large IBP network; the scheme cannot play out the way it is proposed.
7. The degradation scheme is implausible in its implementation. How large do networks need to be to become serial killers? Why have we not observed this behaviour at all?
8. There is no enduring change to the number of competitors in a market caused by serial degradation in a market with negligible entry barriers; the eliminated rival is likely to be replaced by another.

In conclusion, competition on the Internet backbone is strong, with many carriers and easy entry, and thus presently there are no significant competition concerns for Internet backbone services. However, local broadband access is typically a duopoly or monopoly depending on location. As of 2007, local broadband access networks were proposing to abolish the regime of net neutrality and impose fees on content and applications providers. The legality of this proposed change is questionable, and imposition of such price discrimination may have adverse consequences for consumers’ total surplus.

interpersonal utility comparisons (new developments)

Claude d'Aspremont
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Recent developments on interpersonal utility comparisons rely on various interpretations of ‘utility’ indicators and combine in various degrees the ‘subjective’ appreciation of the social states by each individual and their ‘objective’ evaluation by the ethical observer. In a formal welfarist approach, interpersonal comparisons are specified by invariance conditions on social welfare functionals or on social welfare orderings. Interpersonal comparisons have also been introduced through scoring methods.

Article

Distributive justice, whether in normative economics or in collective choice theory, can hardly be treated without introducing some interpersonal comparisons. But does this mean considering interpersonal utility comparisons? The term ‘utility’ has received so many different interpretations that the distinguishing mark of the utility approach to the evaluation of social states by an ethical observer is simply that it assigns to each member of the collectivity a unidimensional individual indicator. These indicators combine in various ways the ‘subjective’ appreciation of the social states by each individual and their ‘objective’ evaluation by the observer. Bentham introduced an interpersonally summable notion of utility based on the objective property of
things to procure either pain or pleasure, but it is the subjective reinterpretation given by J.S. Mill, for whom utility means ‘pleasure itself’ and ‘exemption of pain’, which has prevailed (Mongin and d'Aspremont, 1998). In Harsanyi’s (1977) reformulation of utilitarianism, the ethical observer is, with equal chance, any one of the individuals and obeys the rationality conditions of decision-making under risk. The criterion is expected utility computed from the individual von Neumann–Morgenstern (NM) utility functions, but ‘corrected’ for factual errors and ‘censored’ for anti-social attitudes.

Pareto has clearly distinguished between the objective notion of utilité (in the Bentham sense) and the subjective notion of ophélimité, as an ordinal measure of actual preference satisfaction. The latter has become the dominant concept in economics (the only concept in the new welfare economics), forbidding interpersonal utility comparisons and, ultimately, reducing preferences to observable individual choices (revealed preference theory). But Samuelson (1947) insisted that welfare economics cannot avoid ethical and interpersonal assumptions, and Arrow (1951) derived an ‘impossibility theorem’. For a set N={1, 2, …, n} of individuals and a set X={x, y, …} of (more than two) social states, there is no acceptable social welfare function, associating every profile of individual preference orderings with one ‘collective’ preference ordering of X, and satisfying weak Pareto (if all strictly prefer one state to another, so should society) and independence of irrelevant alternatives (if individual preferences are modified except for a subset of several alternatives, then the collective preference should not be modified on this subset). Such a social welfare function can only be dictatorial: one individual imposes his strict preference. Since all Arrow’s assumptions concern ‘preference satisfaction’, modifying them and reinterpreting ‘utility’ involve ethical considerations.

Rawls’s (1971) principles of justice are agreed upon in some original negotiation where all irrelevant personal features (including personal conceptions of the good) are ignored. Also chosen behind this ‘veil of ignorance’ is an ‘index of primary goods’ defined as an objective indicator of the fundamental resources (except for liberties and access to occupations, preliminarily and equally divided) allocated to each person to promote his own conception of the good. If such an indicator can be called ‘utility’, it is not in the sense of ‘happiness’ or ‘preference satisfaction’. Desires (however intense) and tastes (however inexpensive) are not relevant per se. A similar view is represented by Sen's (1992) notion of capabilities, that is, the set of doings or ‘functionings’ available to a person, leading to an ‘index of functionings’. What is at stake here, as in other theories concerned by opportunities (for example, Roemer, 1996), are the objectively defined conditions allowing individuals to exercise their freedom.

Extended sympathy, social welfare functionals and welfarism

To formally examine the role of interpersonal utility comparisons in social choice, it is usual to start within the framework introduced by Sen (1970), in which the basic ingredient is a utility profile given by a real-valued function U defined on elements (x,i) of the Cartesian product X×N. The function U can be seen as a vector of individual indicators U_i(x) ≡ U(x,i), or as the extended utility function of an individual, evaluating from a moral viewpoint what it is to be anyone in any social state (exercising ‘extended sympathy’ or ‘empathy’). Moreover, if for individual i one interprets the name i as designating all the characteristics of i, then one could look at the function U as a fundamental utility function (Harsanyi, 1977), itself a representation of ‘human nature’ (Kolm, 1972), which would then justify why every individual, when adopting the viewpoint of an ethical observer, should have the same
extended utility function (or at least the same fundamental preference). Lack of identity could lead to a dictatorial ethical observer (see Suzumura, 1996).

The fundamental utility approach is also used in econometric estimations to define ‘adult-equivalent scales’ and different forms of exact aggregation (Christensen, Jorgenson and Lau, 1975; Blackorby and Donaldson, 1991; Deaton and Muellbauer, 1980). Other measurement techniques, such as that which uses the number of ‘just-noticeable-differences’ between two alternatives (discussed in Arrow, 1951) or the ‘social indicators’ approach using questionnaires about degree of happiness (discussed in Hammond, 1991; Fleurbaey and Hammond, 2004) are differently founded.

The function is a very flexible informational basis to start with. For every , we can denote the utility vector in . Taking all functions in some domain determines the set of all admissible utility vectors. Sen's (1970) concept of social welfare functional (SWFL) associates every admissible extended utility function with one (collective) preference ordering . We denote and the corresponding indifference and strict preference relations. Using this notation, Pareto indifference means ‘ implies ’ and strong Pareto requires in addition that ‘ implies ’. Also, Arrow's independence of irrelevant alternatives can be weakened to binary independence, whereby for any two functions and with equal values on two social states and we have . An alternative framework is to define directly a social welfare ordering (SWO) denoted on the set of admissible utility vectors. If the set of admissible utility vectors is large enough (for example, equal to ), then, under Pareto indifference and binary independence, the two frameworks coincide: and implies . This is called welfarism and is an extreme form of consequentialism. All the information required for social evaluation is contained in the final utility values. Under welfarism, strong Pareto (SP) reduces to the condition that , and implies (P* denoting strict collective preference).

Invariance axioms

Measurement theory (Krantz et al., 1971; Roberts, 1980) associates with different measurement scales the associated meaningful statements. We are interested in meaningful statements about intrapersonal and interpersonal comparisons of utility. For instance, the Arrowian informational basis for SWFLs requires that only intrapersonal level comparisons are meaningful: whenever, for every and all , . Another example (for this and others see Bossert and Weymark, 2004) is to consider meaningful interpersonal comparisons of utility differences: whenever, for all , and all , . The more standard way (for example, Sen, 1977) to specify the measurability and comparability properties of ‘utility’ is to introduce invariance transformations , each , being a real-valued function on . In the Arrowian framework, we get the invariance axiom of ordinality and non-
comparability (ON): if each $\phi_i$ is increasing and if for every $x$, $V(x,i)=\phi_i(U(x,i))$, then $R_U=R_V$.

Corresponding to interpersonal comparisons of utility differences, we get cardinality and unit-comparability (CU): if each $\phi_i$ is a positive affine transformation ($\phi_i(u_i)=a_i + bu_i$, with $b>0$) and if, for all $(x,i)$, $V(x,i)=a_i + bU(x,i)$, then $R_U=R_V$.

But there is a third way of specifying such conditions. We have stated these two axioms as restrictions on SWFLs. Under welfarism, they can be translated into axioms on SWOs, as

$$\text{ON: for any increasing } \phi_i \text{'s, } u^* R^* v \iff (\phi_1(u_1), \ldots, \phi_n(u_n))^* R^* (\phi_1(v_1), \ldots, \phi_n(v_n));$$

$$\text{CU: for any } a_i \text{'s and positive } b_i \text{'s, } u^* R^* v \iff (a_1 + b_1 u_1, \ldots, a_n + b_n u_n)^* R^* (a_1 + b_1 v_1, \ldots, a_n + b_n v_n).$$

Invariance axioms determine the informational basis for social evaluation. They should not be considered as purely factual. By specifying the kind of information that a social evaluation can or cannot use, these axioms are taking an ethical stance. But their strong ethical implications are better measured when combined with other axioms. To illustrate, the following axiom allows for (and only for) comparisons of utility differences that are intrapersonal. It is cardinality and non-comparability (CN): for any $a_i$'s and positive $b_i$'s, if $V(x,i)=a_i + b_i U(x,i)$, for all $(x,i)$, then $R_U=R_V$. Such a SWFL version of this axiom does not exclude interpersonal utility comparisons. It does allow us to compare ratios of utility differences of the sort $(U(w,i)-U(x,i))/(U(y,i)-U(z,i))$ between different individuals, and hence to compare measures of risk aversion in case $X$ is specified as a set of lotteries and each $U_i(x)$ as an NM utility function. But the possibility of such comparisons is erased under welfarism, under which cardinal non-comparability reduces to ordinal non-comparability and, with strong Pareto, implies dictatorship (by Arrow's theorem). Under welfarism, ON becomes equivalent to CN: for any $a_i$'s, positive $b_i$'s,

$$u^* R^* v \iff (a_1 + b_1 u_1, \ldots, a_n + b_n u_n)^* R^* (a_1 + b_1 v_1, \ldots, a_n + b_n v_n).$$

If CN is replaced by CU and dictatorship is excluded by anonymity (any utility vector is socially indifferent to any of its permutations), then the only possibility is the pure utilitarian SWO: $u^* R^* v$ if and only if $\sum_{i\in N} u_i \geq \sum_{i\in N} v_i$ (d'Aspremont and Gevers, 1977).

This characterization of utilitarianism is directly related to Harsanyi's aggregation theorem since, under welfarism (and NM preferences), cardinality and unit-comparability become equivalent to NM-
interpersonal utility comparisons (new developments) : The New Palgrave Dictionary of Economics

independence of the collective preference ordering (Mongin and d'Aspremont, 1998).

By giving priority to liberties and access to occupations, Rawls clearly departs from welfarism, even in a formal sense. However, to allocate other primary goods, a common index $V(x_i)$ is fixed, where $x_i$ is the vector of primary goods to be allocated to individual $i$. Letting, for an allocation $x=(x_1,...,x_n)$, $U(x,i)=V(x_i)$, we can fall again into the welfarist formal framework. Since the index is common to all, the associated invariance axiom is *ordinality and comparability*

$$OC: \text{ for any increasing } \phi, \ u R^* v \iff (\phi(u_1),...,\phi(u_n)) R^* (\phi(v_1),...,\phi(v_n)).$$

Two other axioms are clearly required by Rawls: *anonymity* and *strong Pareto*, the latter being the reason why equal distribution of all primary goods is not the agreed-upon solution. To any $u$ in $\mathbb{R}^N$, one can associate a (re)ordered vector $u_{i(\cdot)}$ with same components in \( \{ v \in \mathbb{R}^N : v_1 \leq v_2 \leq ... \leq v_N \} \), the set of ordered utility vectors. *Minimal equity* requires that one should never give priority to the best-off individual over the worst-off. Then, under *separability* (in choosing between two utility vectors the indifferent individuals should not be taken into account), the solution is the ‘lexicographic maximin’ (leximin) SWO: for any $u, v$ in $\mathbb{R}^N$, $u P^* v$ if and only if, for some $k$, $1 \leq k \leq n$, $u_{i(k)} > v_{i(k)}$, and, $\forall j < k$, $1 \leq j \leq n$, $u_{i(j)} = v_{i(j)}$. Leximin formalizes Rawls’s ‘difference principle’. Other concepts of opportunity equalizations can be so translated into welfarist terms (see Maniquet, 2004).

From a formal viewpoint, in the preceding result only utility levels are both intrapersonally and interpersonally comparable. If we add the same possibility for utility differences we have *full comparability*, that is

$$FC: \text{ for any } a, b > 0, \ u R^* v \iff (a + bu_1, ..., a + bu_n) R^* (a + bv_1, ..., a + bv_n).$$

With this type of invariance and the same other assumptions (Deschamps and Gevers, 1978), the SWO $R^*$ can be either leximin or utilitarianism, but in a weak sense (that is $\sum_{i \in N} u_i > \sum_{i \in N} v_i$ implies $u P^* v$). Many other invariance axioms can be introduced (for example, d'Aspremont, 1985). Let us give only two more, *ratio-scale measurability*, *without* or *with interpersonal comparisons* of utility:

$$RN: \text{ for any positive } b_i, s, \text{ and } u, v \in \mathbb{R}^N, \ u R^* v \iff (b_1 u_1, ..., b_n u_n) R^* (b_1 v_1, ..., b_n v_n);$$
With ratio-scale measurability the origin is fixed, so that, under RN, utility levels are interpersonally comparable if they are of opposite sign (below or above the zero line). Moreover, under RC, all utility levels and differences are comparable. These axioms are most often applied on a positive domain (denoted $\mathbb{R}_+^N$). Under RN, ratios of utilities or percentage changes in utility are interpersonally comparable. If we add SP, then a continuous SWO on $\mathbb{R}_+^N$ can only be the Nash bargaining solution with status quo point normalized to zero: for some positive $\theta_i$'s, $uR^*_v$ if and only if

$$\prod_{i=1}^n u_i^\lambda_i \geq \prod_{i=1}^n v_i^\lambda_i.$$  

Under RC and SP the set of continuous and anonymous SWOs is characterized by all homothetic, increasing, continuous and symmetric functions on $\mathbb{R}_+^N$ (for these and other results, see Bossert and Weymark, 2004).

Beyond welfarism: scoring and fair allocation rules

Even when ‘utility’ simply represents actual preference satisfaction, it can be severely adjusted by the ethical observer (or rule designer). This is the case for various voting rules or more generally for scoring rules. These rules violate binary independence in one way or another, so that welfarism is excluded. Voting methods, such as Borda’s, are generally not acceptable for social evaluation, but some related rules are better candidates (Moulin, 1988). Another ‘scoring’ method is relative utilitarianism (axiomatized by Dhillon and Mertens, 1999). Each $U_i(.)$ is supposed to have both a maximum $U_i^{\text{max}}$ and a minimum $U_i^{\text{min}}$ and to represent a NM preference ordering on $X$ and the observer associates to it a NM utility function $V_i(.)$ ordinally equivalent to $U_i(.)$, and then, through individual affine transformations, defines the scoring function $S_i(x) = (V_i(x) - V_i^{\text{min}}) / (V_i^{\text{max}} - V_i^{\text{min}})$. The score $S_i(x)$ is the same whatever the arbitrarily chosen NM utility function $V_i(.)$ representing the preference ordering underlying the initial utility function $U_i(.)$, and measures of curvatures are preserved. The SWFL $F$ is taken to be pure utilitarianism applied to the scores. It satisfies ordinality and non-comparability with respect to the utility functions $U_i(x)$ representing the individual preferences. Since the scores are defined as ratios of utility differences, they could be interpersonally compared, but, because their aggregation is utilitarian, it relies only on interpersonal comparisons of differences of scores.

Other concepts have been proposed in the literature on fair allocations, excluding welfarism in terms of the initial utility functions, but ending up applying some SWFL to some recalibrated utility. An example
is the Pareto efficient egalitarian-equivalent allocation concept (Pazner and Schmeidler, 1978). To illustrate, let \( \tilde{\omega} \) be the vector of total quantities of \( L \) goods and \( X \) be the set of feasible allocations \( (x_1, \ldots, x_n) \): each \( x_i \) is in \( \mathbb{R}^L_+ \) and \( \sum_{i=1}^n x_i \leq \tilde{\omega} \). If \( U(x,i) = U_i(x_i) \) is increasing in each argument and continuous then one can define an ordinally equivalent function \( V_i(x_i) \) such that \( U_i(x_i) = U_i(V_i(x_i) \tilde{\omega}) \). A Pareto efficient allocation \( \hat{x} \) in \( X \) is egalitarian-equivalent if \( U_i(\hat{x}_i) = U_i(V_i(\hat{x}_i) \tilde{\omega}) \) and \( V_j(\hat{x}_j) = V_j(\hat{x}_j) \) for all \( i,j \). As observed in Fleurbaey and Hammond (2004), if individual preferences are convex, \( \hat{x} \) can be obtained by applying the leximin SWFL on the \( V_i(x_i) \)'s. Again, starting with a concept defined in terms of purely ordinal and non-comparable utilities (the \( U_i \)'s), we end up comparing and equalizing utility levels in terms of the \( V_i \)'s.

interpersonal utility comparisons

John C. Harsanyi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Although we all make interpersonal utility comparisons, many economists and philosophers argue that our limited information about other people's minds renders them meaningless. If they are possible, interpersonal comparisons of utility differences must be distinguished from interpersonal comparisons of utility levels. Utilitarianism must assume the interpersonal comparability of utility differences to maximize a social welfare function, while Rawls's maximin principle requires interpersonal comparability of utility levels. Adopting an ordalist or a cardalist view of utility functions restricts the positions one can consistently take as to interpersonal comparability of utilities.

Keywords

Arrow, K.; interpersonal utility comparisons; maximin; Rawls, J.; Robbins, L.; utilitarianism; utility: cardinal vs. ordinal; von Neumann–Morgenstern utility function

Article

Suppose I am left with a ticket to a Mozart concert I am unable to attend and decide to give it to one of my closest friends. Which friend should I actually give it to? One thing I will surely consider in deciding this is which friend of mine would enjoy the concert most. More generally, when we decide as private individuals whom to help, or decide as voters or as public officials who are to receive government help, one natural criterion we use is who would derive the greatest benefit, that is, who would derive the highest utility, from this help. But to answer this last question we must make, or at least attempt to make, interpersonal utility comparisons.

At the common-sense level, all of us make such interpersonal comparisons. But philosophical reflection might make us uneasy about their meaning and validity. We have direct introspective access only to our own mental processes (such as our preferences and our feelings of satisfaction and dissatisfaction) defining our own utility function, but have only very indirect information about other people's mental processes. Many economists and philosophers take the view that our limited information about other
Comparisons of utility levels vs. comparisons of utility differences

In any case, if such comparisons are possible at all, then we must distinguish between interpersonal comparisons of utility levels and interpersonal comparisons of utility differences (i.e. utility increments or decrements).

It is one thing to compare the utility level $U_i(A)$ that individual $i$ enjoys (or would enjoy) in situation $A$, with utility level $U_j(B)$ that another individual $j$ enjoys (or would enjoy) in situation $B$ (where $A$ and $B$ may not refer to the same situation). It is a very different thing to make interpersonal comparisons between utility differences, such as comparing the utility increment

$$\Delta U_i(A, A') = U_i(A') - U_i(A)$$

that individual $i$ would enjoy in moving from situation $A$ to situation $A'$, with the utility increment

$$\Delta U_j(B, B') = U_j(B') - U_j(B)$$

that individual $j$ would enjoy in moving from $B$ to $B'$. Either kind of interpersonal comparison might be possible without the other kind being possible (Sen, 1970).

Some ethical theories would require one kind of interpersonal comparisons; others would require the other. Thus, utilitarianism must assume the interpersonal comparability of utility differences because it asks us to maximize a social utility function (social welfare function) defined as the sum of all individual utilities. (There are arguments for defining social utility as the arithmetic mean, rather than the sum, of individual utilities (Harsanyi, 1955). But for most purposes – other than analysing population policies – the two definitions are equivalent because if the number of individuals can be taken for a constant, then maximizing the sum of utilities is mathematically equivalent to maximizing their arithmetic mean.) Yet, we cannot add different people's utilities unless all of them are expressed in the same utility units; and in order to decide whether this is the case, we must engage in interpersonal comparisons of utility differences. (On the other hand, utilitarianism does not require comparisons of different people's utility levels because it does not matter whether their utilities are measured from comparable zero points or not.)

Likewise, the interpersonal utility comparisons we make in everyday life are most of the time comparisons of utility differences. For instance, the comparisons made in our example between the
utilities that different people would derive from a concert obviously involve comparing utility differences.

In contrast, the utility-based version of Rawls's *Theory of Justice* (1971) does require interpersonal comparisons of utility levels, but does not require comparisons of utility differences. This is so because his theory uses the *maximin principle* (he calls it the *difference principle*) in evaluating the economic performance of each society, in the sense of using the well-being of the worst-off individual (or the worst-off social group) as its principal criterion. But to decide which individuals (or social groups) are worse off than others he must compare different people's utility levels. (In earlier publications, Rawls seemed to define the worst-off individual as one with the lowest utility level. But in later publications, he defined him as one with the smallest amount of 'primary goods'. For a critique of Rawls's theory, see Harsanyi, 1975.)

**Ordinalism, cardinalism and interpersonal comparisons**

In studying comparisons between the utilities enjoyed by *one* particular individual *i*, we again have to distinguish between comparisons of utility *levels* and comparisons of utility *differences*. The former would involve comparing the utility levels $U_i(A)$ and $U_i(B)$ that *i* assigns to two different situations $A$ and $B$. The latter would involve comparing the utility increment

$$
\Delta U_i(A, A') = U_i(A') - U_i(A)
$$

(3)

that *i* would enjoy in moving from situation $A$ to situation $A'$, with the utility increment

$$
\Delta U_i(B, B') = U_i(B') - U_i(B)
$$

(4)

that he would enjoy in moving from $B$ to $B'$. If *i* has a well-defined utility function $U_i$ at all, then he certainly must be able to compare the utility levels he assigns to various situations; and such comparisons will have a clear behavioural meaning because they will correspond to the preference and indifference relations expressed by his choice behaviour. In contrast, it is immediately less obvious whether comparing utility differences as defined under (3) and (4) has any economic meaning (but see below).

A utility function $U_i$ permitting meaningful comparisons only between *i*'s utility levels, but not permitting such comparisons between his utility differences, is called ordinal; whereas a utility function permitting meaningful comparisons both between his utility levels and his utility differences is called...
cardinal.
As is well known, most branches of economic theory use only ordinal utilities. But, as von Neumann and Morgenstern (1947) have shown, cardinal utility functions can play a very useful role in the theory of risk taking. In fact, utility-difference comparisons based on von Neumann–Morgenstern utility functions turn out to have a direct behavioural meaning. For example, suppose that $U_i$ is such a utility function, and let $\Delta_i^*$ and $\Delta_i^{**}$ be utility differences defined by (3) and by (4). Then, the inequality $\Delta_i^* > \Delta_i^{**}$ will be algebraically equivalent to the inequality

$$\frac{1}{2} U_i(A') + \frac{1}{2} U_i(B) > \frac{1}{2} U_i(B') + \frac{1}{2} U_i(A).$$

(5)

This inequality in turn will have the behavioural interpretation that $i$ prefers an equi-probability mixture of $A'$ and of $B$ to an equi-probability mixture of $B'$ and of $A$. Of course, once von Neumann–Morgenstern utility functions are used in the theory of risk taking, they become available for possible use also in other branches of economic theory, including welfare economics as well as in ethical investigations. (It has been argued that von Neumann–Morgenstern utility functions have no place in ethics (or in welfare economics) because they merely express people's attitudes toward gambling, which has no moral significance (Arrow, 1951, p. 10; and Rawls, 1971, pp. 172 and 323). But see Harsanyi, 1984.)

Note that by taking an ordinalist or a cardinalist position, one restricts the positions one can consistently take as to interpersonal comparability of utilities:

1. (1) An ordinalist is logically free to reject both types of interpersonal comparisons. Or he may admit comparisons of different people's utility levels. But he cannot admit the interpersonal comparability of utility differences without becoming a cardinalist. (The reason is this. If the utility differences experienced by one individual $i$ are comparable with those experienced by another individual $j$, this will make the utility differences experienced by one individual (say) $i$ likewise indirectly comparable with one another, which will enable us to construct a cardinal utility function for each individual.)

2. (2) A cardinalist is likewise logically free to reject both types of interpersonal comparisons. Or he may admit both. Or else he may admit interpersonal comparisons only for utility differences. (Though it is hard to see why anybody might want to reject interpersonal comparisons for utility levels if he admitted them for utility differences.) But he cannot consistently admit interpersonal comparisons for utility levels while rejecting them for utility differences. (This can be verified as follows. If utility levels are interpersonally comparable, then we can find four situations $A, A', B, and B'$ such that $U_i(A) = U_i(B)$ and $U_j(A') = U_j(B')$. But then we can conclude that
which means that at least the utility differences $\Delta_i^*$ and $\Delta_j^*$ are interpersonally comparable. But since $U_i$ and $U_j$ are cardinal utility functions, any utility difference $\Delta_i^*$ experienced by $i$ is comparable with $\Delta_i^*$, and any utility difference $\Delta_j^*$ experienced by $j$ is comparable with $\Delta_j^*$. Yet this means that all utility differences $\Delta_i^{**}$ experienced by $i$ are comparable with all utility differences $\Delta_j^{**}$ experienced by $j$. Thus, cardinalism together with interpersonal comparability of utility levels entails that of utility differences.

**Extended utility functions**

In what follows, I will use the symbols $A_i, B_i, \ldots$ to denote the economic and non-economic resources available to individual $i$ in situations $A, B, \ldots$. Moreover, I will use the symbol $A_j$ to denote an arrangement under which $j$ has the same resources available to him as were available to individual $i$ under arrangement $A_i$. These entities $A_i, B_i, \ldots, A_j, B_j, \ldots$ I will call positions.

Interpersonal utility comparisons would pose no problem if all individuals had the same utility function. For in this case, any individual $j$ could assume that the utility level $U_i(A_i)$ that another individual $i$ would derive from a given position $A_i$ should be the same as he himself would derive from a similar position. Thus, $j$ could write simply

$$U_i(A_i) = U_j(A_j).$$

Of course, in actual fact, the utility of different people are rather different because people have different tastes, that is, they have different abilities to derive satisfactions from given resource endowments. I will use the symbols $R_i, R_j, \ldots$ to denote the vectors listing the personal psychological characteristics of each individual $i, j, \ldots$ that explain the differences among their utility functions $U_i, U_j, \ldots$. Presumably, these vectors summarize the effects that the genetic make-up, the education and the life experience of each individual have on his utility function. This means that any individual $j$ can attempt to assess the utility level $U_i(A_i)$ that another individual $i$ would enjoy in position $A_i$ as

$$U_i(A_i) = V(A_i, R_j),$$
where the function $V$ represents the psychological laws determining the utility functions $U_i, U_j, \ldots$ of the various individuals $i, j, \ldots$ in accordance with their psychological parameters specified by the vectors $R_i, R_j, \ldots$. Since, by assumption, all differences among the various individuals’ utility functions $U_i, U_j, \ldots$ are fully explained by the vectors $R_i, R_j, \ldots$, the function $V$ itself will be the same for all individuals. We will call $V$ an extended utility function. (See Arrow, 1978; and Harsanyi, 1977, pp. 51–60; though the basic ideas are contained already in Arrow, 1951, pp. 114–15.)

To be sure, we know very little about the psychological laws determining people's utility functions and, therefore, know very little about the true mathematical form of the extended utility function $V$. This means that, when we try to use equation (7), the best we can do is to use our – surely very imperfect – personal estimate of $V$, rather than $V$ itself. As a result, in trying to make interpersonal utility comparisons, we must expect to make significant errors from time to time – in particular when we are trying to assess the utility functions of people with a very different cultural and social background from our own. But even if our judgements of interpersonal comparisons can easily be mistaken, this does not imply that they are meaningless.

Ordinalists will interpret both the functions $U_i$ and the function $V$ as ordinal utility functions and will interpret (7) merely as a warrant for interpersonal comparisons of utility levels (cf. Arrow, 1978). In contrast, cardinalists will interpret all these as cardinal utility functions and will interpret (7) as a warrant for both kinds of interpersonal comparison (cf. Harsanyi, 1977).

Limits to interpersonal comparisons

It seems to me that economists and philosophers influenced by logical positivism have greatly exaggerated the difficulties we face in making interpersonal utility comparisons with respect to the utilities and the disutilities that people derive from ordinary commodities and, more generally, from the ordinary pleasures and calamities of human life. (A very influential opponent of the possibility of meaningful interpersonal utility comparisons has been Robbins, 1932.) But when we face the problem of judging the utilities and the disutilities that other people derive from various cultural activities, we do seem to run into very real, and sometimes perhaps even unsurmountable, difficulties. For example, suppose I observe a group of people who claim to derive great aesthetic enjoyment from a very esoteric form of abstract art, which does not have the slightest appeal to me in spite of my best efforts to understand it. Then, there may be no way for me to decide whether the admirers of this art form really derive very great and genuine enjoyment from it, or merely deceive themselves by claiming that they do. Maybe in such cases interpersonal comparisons of utility do reach unsurmountable obstacles. But, fortunately, very few of our personal moral decisions and of our public political decisions depend on such exceptionally difficult interpersonal comparisons of utility. (References additional to those listed below will be found in Hammond, 1977 and in Suppes and Winet, 1955.)

Inter-temporal choice

Christopher F. Chabris, David I. Laibson and Jonathon P. Schuldt
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Decisions that have consequences in multiple time periods are inter-temporal choices. Individuals typically discount delayed rewards much more than can be explained by mortality effects. The most common discount function is exponential in form, but hyperbolic and quasi-hyperbolic functions seem to explain empirical data better. Individual discount rates may be measured in a variety of ways, subject to important methodological caveats. Higher discount rates are empirically associated with a variety of substance abuse and impulsive conditions, including smoking, alcoholism, cocaine and heroin use, gambling, and risky health behaviours. By contrast, low discount rates may be associated with high cognitive ability.

Article

Models of inter-temporal choice

Most choices require decision-makers to trade-off costs and benefits at different points in time. Decisions with consequences in multiple time periods are referred to as inter-temporal choices. Decisions about savings, work effort, education, nutrition, exercise, and health care are all inter-temporal choices. The theory of discounted utility is the most widely used framework for analysing inter-temporal choices. This framework has been used to describe actual behaviour (positive economics) and it has been used to prescribe socially optimal behaviour (normative economics). Descriptive discounting models capture the property that most economic agents prefer current rewards to delayed rewards of similar magnitude. Such time preferences have been ascribed to a combination of mortality effects, impatience effects, and salience effects. However, mortality effects alone cannot explain time preferences, since mortality rates for young and middle-aged adults are at least 100 times too small to generate observed discounting patterns.
Normative inter-temporal choice models divide into two approaches. The first approach accepts discounting as a valid normative construct, using revealed preference as a guiding principle. The second approach asserts that discounting is a normative mistake (except for a minor adjustment for mortality discounting). The second approach adopts zero discounting (or near-zero discounting) as the normative benchmark.

The most widely used discounting model assumes that total utility can be decomposed into a weighted sum – or weighted integral – of utility flows in each period of time (Ramsey, 1928):

\[ U = \int_{t=0}^{\infty} e^{-\rho t} u(t) dt \]

\[ u(t) = \text{utility at time } t \]

\[ \rho = \text{discount rate} \]
In this representation: $U_t$ is total utility from the perspective of the current period, $t$; $T$ is the last period of life (which could be infinity for an intergenerational model); $u_{t+\tau}$ is flow utility in period $t+\tau$ ($u_{t+\tau}$ is sometimes referred to as felicity or as instantaneous utility); and $D(\tau)$ is the discount function. If delaying a reward reduces its value, then the discount function weakly declines as the delay, $\tau$, increases:

$$D'(\tau) \leq 0.$$ 

Economists normalize $D(0)$ to 1. Economists assume that increasing felicity, $u_{t+\tau}$, weakly increases total utility, $U_t$. Combining all of these assumptions implies,

$$1 = D(0) \geq D(\tau) \geq D'(\tau) \geq 0,$$

where $0 < \tau < \tau'$. Time preferences are often summarized by the rate at which the discount function declines, $\rho(\tau)$. For differentiable discount functions, the discount rate is defined as

$$\rho(\tau) = - \frac{D'(\tau)}{D(\tau)}.$$ 

(See Laibson, 2003, for the formulae for non-differentiable discount functions.) The higher the discount rate the greater the preference for immediate rewards over delayed rewards. The discount factor is the inverse of the continuously compounded discount rate $\rho(\tau)$. So the discount factor is defined as

$$f(\tau) = \lim_{\Delta \to 0} \left( \frac{1}{1 + \rho(\tau) \Delta} \right)^{1/\Delta} = e^{-\rho(\tau)}.$$ 

The lower the discount factor the greater the preference for immediate rewards over delayed rewards. The most commonly used discount function is the exponential discount function:

$$D(\tau) = \delta^\tau,$$
with \( 0 < \delta < 1 \). For the exponential discount function, the discount rate is independent of the horizon, \( \tau \). Specifically, the discount rate is \(-\ln(\delta)\) and the discount factor is \( \delta \). Figure 1.

Figure 1
Three calibrated discount functions

The exponential discount function also has the property of dynamic consistency: preferences held at one point in time do not change with the passage of time (unless new information arrives). For example, consider the following investment opportunity: pay a utility cost of \( C \) at date \( t=2 \) to reap a utility benefit of \( B \) at date \( t=3 \). Suppose that this project is viewed from date \( t=1 \) and judged to be worth pursuing. Hence, \(-\delta C + \delta^2 B > 0\). Imagine that a period of time passes, and the agent reconsiders the project from the perspective of date \( t=2 \). Now the project is still worth pursuing, since \(-C+\delta B > 0\). To prove that this is true, note that the new expression is equal to the old expression multiplied by \( 1/\delta \). Hence, the \( t=1 \) preference to complete the project is preserved at date \( t=2 \). The exponential discount function is the only discount function that generates dynamically consistent preferences.

Despite its many appealing properties, the exponential discount function fails to match several empirical regularities. Most importantly, a large body of research has found that measured discount functions decline at a higher rate in the short run than in the long run. In other words, people appear to be more impatient when they make short-run trade-offs – today vs. tomorrow – than when they make long-run trade-offs – day 100 vs. day 101. This property has led psychologists (Herrnstein, 1961; Ainslie, 1992; Loewenstein and Prelec, 1992) to adopt discount functions in the family of generalized hyperbolas:

\[
D(\tau) = (1 + \alpha \tau)^{-\gamma/\alpha}.
\]

Such discount functions have the property that the discount rate is higher in the short run than in the long run. Particular attention has been paid to the case in which \( \gamma = \alpha \), implying...
that \( D(\tau) = (1 + \alpha \tau)^{-1} \).

Starting with Strotz (1956), economists have also studied alternatives to exponential discount functions. The majority of economic research has studied the quasi-hyperbolic discount function, which is usually defined in discrete time:

\[
D(\tau) = \begin{cases} 
1 & \text{if } \tau = 0 \\
\beta \cdot \delta^\tau & \text{if } \tau = 1, 2, 3, \ldots
\end{cases}
\]

This discount function was first used by Phelps and Pollak (1968) to study intergenerational discounting. Laibson (1997) subsequently applied this discount function to intra-personal decision problems. When \( 0 < \beta < 1 \) and \( 0 < \delta < 1 \) the quasi-hyperbolic discount function has a high short-run discount rate and a relatively low long-run discount rate. The quasi-hyperbolic discount function nests the exponential discount function as a special case (\( \beta = 1 \)). Quasi-hyperbolic time preferences are also referred to as ‘present-biased’ and ‘quasi-geometric’.

Like other non-exponential discount functions, the quasi-hyperbolic discount function implies that intertemporal preferences are not dynamically consistent. In other words, the passage of time may change an agent's preferences, implying that preferences are dynamically inconsistent. To illustrate this phenomenon, consider an investment project with a cost of 6 at date \( t=2 \) and a delayed benefit of 8 at date \( t=3 \). If \( \beta = 1/2 \) and \( \delta = 1 \) (see Akerlof, 1991), this investment is desirable from the perspective of date \( t=1 \). The discounted value is positive:

\[
\beta (-6 + 8) = \frac{1}{2} (-6 + 8) = 1.
\]

However, the project is undesirable from the perspective of date 2. Judging the project from the \( t=2 \) perspective, the discounted value is negative:

\[
-6 + \beta(8) = -6 + \frac{1}{2}(8) = -2.
\]

This is an example of a preference reversal. At date \( t=1 \) the agent prefers to do the project at \( t=2 \). At date \( t=2 \) the agent prefers not to do the project. If economic agents foresee such preference reversals they are said to be sophisticated and if they do not foresee such preference reversals they are said to be naive (Strotz, 1956). O’Donoghue and Rabin (2001) propose a generalized formulation in which agents are partially naive: the agents have an imperfect ability to anticipate their preference reversals. Many different microfoundations have been proposed to explain the preference patterns captured by the hyperbolic and quasi-hyperbolic discount functions. The most prominent examples include temptation models and dual-brain neuroeconomic models (Bernheim and Rangel, 2004; Gul and Pesendorfer, 2001; McClure et al., 2004; Thaler and Shefrin, 1981). However, both the properties and mechanisms of time preferences remain in dispute.

**Individual differences in measured discount rates**

Numerous methods have been used to measure discount functions. The most common technique poses a series of questions, each of which asks the subject to choose between a sooner, smaller reward and a later, larger reward. Usually the sooner, smaller reward is an immediate reward. The sooner and later rewards are denominated in the same goods, typically amounts of money or other items of value. For example: ‘Would you rather have $69 today, or $85 in 91 days?’ The subject's discount rate is inferred by fitting one or more of the discount functions described in the previous section to the subject choices. Most studies assume that the utility function is linear in consumption. Most studies also assume no
intertemporal fungibility – the reward is assumed to be consumed the moment it is received. Many factors may confound the analysis in such studies, leading numerous researchers to express scepticism about the conclusions generated by laboratory studies. Table 1 provides a summary of such critiques.

### Potential confounds that may arise in attempts to measure discount rates in laboratory studies

<table>
<thead>
<tr>
<th>Factor</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Unreliability of future rewards</strong></td>
<td>A subject may prefer an earlier reward because the subject thinks she is unlikely to actually receive the later reward. For example, the subject may perceive an experimenter as unreliable.</td>
</tr>
<tr>
<td><strong>Transaction costs</strong></td>
<td>A subject may prefer an immediate reward because it is paid in cash, whereas the delayed reward is paid in a form that generates additional transaction costs. For example, a delayed reward may need to be collected, or it may arrive in the form of a cheque that needs to be cashed.</td>
</tr>
<tr>
<td><strong>Hypothetical rewards</strong></td>
<td>A subject may not reveal her true preferences if she is asked hypothetical questions instead of being asked to make choices with real consequences.</td>
</tr>
<tr>
<td><strong>Investment versus consumption</strong></td>
<td>Some subjects may interpret a choice in a discounting experiment as an investment decision and not a decision about the timing of consumption. For example, a subject might reason that a later, larger reward is superior to a sooner, smaller reward as long as the return for waiting is higher than the return available in financial markets.</td>
</tr>
<tr>
<td><strong>Consumption versus receipt</strong></td>
<td>Rewards, especially large ones, may not be consumed at the time they are received. For example, a $500 reward is likely to produce a stream of higher consumption, not a lump of consumption at the date of receipt. Such effects may explain why large-stake experiments are associated with less measured discounting than small-stake experiments.</td>
</tr>
<tr>
<td><strong>Curvature of utility function</strong></td>
<td>A subject may prefer a sooner, smaller reward to a later, larger reward if the subject expects to receive other sources of income at that later date. In general, a reward may be worth less if it is received during a period of relative prosperity.</td>
</tr>
<tr>
<td><strong>Framing effects</strong></td>
<td>The menu of choices or the set of questions may influence the subject's choices. For example, if choices between $1.00 now and delayed amounts ranging between $1.01 and $1.50 were offered, subjects may switch preference from early to later rewards at an interior threshold – for example $1.30. However, if choices between $1.00 and delayed amounts ranging between $1.51 and $2.00 were offered, the switch might happen at a much higher threshold – for example $1.70 – implying a much higher discount rate.</td>
</tr>
<tr>
<td><strong>Demand characteristics</strong></td>
<td>Procedures for estimating discount rates may bias subject responses by implicitly guiding their choices. For example, the phrasing of an experimental question can imply that a particular choice is the right or desired answer (from the perspective of the experimenter).</td>
</tr>
</tbody>
</table>

Discount functions may also be inferred from field behaviour, such as consumption, savings, asset allocation, and voluntary adoption of forced-savings technologies (Angeletos et al., 2001; Shapiro, 2005; Ashraf, Karlan and Yin, 2006). However, field studies are also vulnerable to methodological critiques. There is currently no methodological gold standard for measuring discount functions.

Existing attempts to measure discount functions have reached seemingly conflicting conclusions (Frederick, Lowenstein and O’Donoghue, 2003). However, the fact that different methods and samples yield different estimates does not rule out consistent individual differences. Dozens of empirical studies have explored the relationship between individuals’ estimated discount rates and a variety of behaviours and traits. A significant subset of this literature has focused on delay discounting and behaviour in clinical populations, most notably drug users, gamblers, and those with other impulsivity-linked psychiatric disorders (see Reynolds, 2006, for a review). Other work has explored the relationship between discounting and traits such as age and cognitive ability. Table 2 summarizes representative studies.

#### Notes

- * These studies used hypothetical rewards; others used real rewards.
- ** Results based on those choices falling within the delay range of 1 week to 25 years. Overall analyses including shorter delays (5 minutes to 5 days) also revealed the same effect, but with smaller magnitude.
- c Gamblers with comorbid substance abuse disorders showed a greater effect than gamblers without such disorders.

---

**Smoking.** A number of investigations have explored the relationship between cigarette smoking and discounting, together providing strong evidence that cigarette smoking is associated with higher discount rates (Baker, Johnson and Bickel, 2003; Bickel, Odum and Madden, 1999; Kirby and Petry, 2004; Mitchell, 1999; Ohmura, Takahashi and Kitamura, 2005; Reynolds et al., 2004).

**Excessive alcohol consumption.** While the association with alcoholism has received relatively little attention, the available data suggest that problematic drinking is associated with higher discount rates. Heavy drinkers have higher discount rates than controls (Vuchinich and Simpson, 1998), active alcoholics discount rewards more than abstinent alcoholics, who in turn discount at higher rates than controls (Petry, 2001a), and detoxified alcohol-dependents have higher discount rates than controls (Bjork et al., 2004).

**Illicit drug use.** Recent studies document a positive association between discount rates and drug use for a variety of illicit drugs, most notably cocaine, crack-cocaine, heroin and amphetamines (Petry, 2003; Coffey et al., 2003; Bretteville-Jensen, 1999; Kirby and Petry, 2004).

**Gambling.** Pathological gamblers have higher discount rates than controls, both in the laboratory (Petry, 2001b) and in a more natural setting (Dixon, Marley and Jacobs, 2003), and among a population of gambling and non-gambling substance abusers (Petry and Casarella, 1999). Moreover, Alessi and Petry (2003) report a significant, positive relationship between a gambling severity measure and the discount rate within a sample of problem gamblers. Petry (2001b) finds that gambling frequency during the previous three months correlates positively with discount rate.

**Age.** Patience appears to increase across the lifespan, with the young showing markedly less patience than middle-aged and older adults (Green, Fry and Myerson, 1994; Green et al. 1996; Green, Myerson and Ostaszewski, 1999). Read and Read (2004) report that older adults (mean age=75) are the most patient age group when delay horizons are only one year. However, this study also finds that older adults are the least patient group when delay horizons are from three to ten years. This reversal probably reflects the fact that 75-year-olds face significant mortality/disability risk at horizons of three to ten years.

**Cognitive ability.** Kirby, Winston and Santiesteban (2005) report that discount rates are correlated negatively with grade point average in two college samples. Benjamin, Brown and Shapiro (2006) find an inverse relationship between individual discount rates and standardized (mathematics) test scores for Chilean high school students. Silva and Gross (2004) show that students scoring in the top third of their introductory psychology course have lower discount rates than those scoring in the middle and lower thirds. Frederick (2005) shows that participants scoring high on a ‘cognitive reflection’ problem-solving task demonstrate more patient intertemporal choices (for a variety of rewards) than those scoring low. Finally, in a sample of smokers, Jaroni et al. (2004) report that participants who did not attend college had higher discount rates than those attending at least some college. All of these empirical regularities are consistent with the neuroeconomic hypothesis that prefrontal cortex is essential for patient (forward-looking) decision-making (McClure et al., 2004). This area of the brain is slow to mature, is critical for general cognitive ability (Chabris, 2007), and is often found to be dysfunctional in addictive and other psychiatric disorders.

More research is required to clarify the cognitive and neurobiological bases of intertemporal preferences. Future research should evaluate the usefulness of measured discount functions in predicting real-world economic decisions (Ashraf, Karlan and Yin, 2006). Finally, ongoing research should improve the available methods for measuring intertemporal preferences.

intertemporal equilibrium and efficiency

E. Malinvaud
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A clear formalization of intertemporal equilibrium not only aids the fundamental conceptualization of economic activity but should also lead to comparative statics properties, which, dealing with intertemporal equilibria, have also been called ‘comparative dynamics properties’. Particular importance has been given to the question of knowing how the interest rate changes from one stationary equilibrium to another when some specific change is being brought to its exogenous determinants. The theory of the optimum allocation of resources can likewise be transposed to the intertemporal framework. Applications of these properties may give insights on the evolution of prices through time.

Article

People, corporations and governments take decisions for the future. What kind of consistency exists between these decisions? What role does the price system play in this respect? Is the resulting evolution efficient? How can economic organization be improved in order to permit a more satisfactory growth? Confronted with such huge questions, economists have often answered quickly. Even when attention is
limited to formal theory, which this article exclusively considers, many statements can be found which, taken as valid for a time, were later disproved. They had been obtained on special models and too easily given a broad validity. Indeed, the preliminary step should have been to find a general formal representation of economic activity through time, but this step was not given sufficient attention until the late 19th century (Böhm-Bawerk, 1888; Fisher, 1907). The central model with reference to which the whole theory can be built and developed clearly emerged only in the 1950s.

A survey on the subject must then start from first principles and note which major features of reality are still today neglected in main-stream theory. The significance of the most far-reaching results and the importance of some big question marks will then have to be assessed.

**Intertemporal decisions**

Households save for future consumption, employees work overtime so as to have enough to enjoy their vacation, students strive to get a diploma so as to hold good jobs later, parents want to leave bequest to their children. Firms produce to inventories in the expectation of future sales, recruit and train staff that will later improve their competitiveness, install equipment to be used for many years, build new factories.

The main theories dealing with intertemporal economic problems see such decisions as parts of plans that the relevant agents make for all their future activities. Any household, for instance, is assumed not only to decide its present supply of labour and demand for goods, but also simultaneously to choose its plan for the labour to be later supplied and the goods to be later consumed, and this up to the end of its existence.

The notion of this plan can in principle be made richer by taking uncertainties into account; the future decisions are then conditional on events to be later observed, but they are already specified for all conceivable combinations of events. In principle again the structure of the plan must then depend on the structure of the information that the agent will receive. In the main intertemporal theories these complications coming from uncertainties and information are, however, neglected, so that the concept of a plan does not appear to be unduly abstract. When the relevance of these theories is assessed, one has to wonder about the consequences of the simplification, as will be seen in the sequel.

Analysis of intertemporal behaviour can adopt the familiar approach: the constraints to which the plan is subject and the objectives that it strives to achieve must be identified; then the optimization problem is solved. The purest of all theories simply transpose the classical analysis of consumer and producer behaviour (Debreu, 1959). They assume the existence of a full system of discounted prices, with one such price for each commodity at each present or future date, a price at which agents will be able to buy or sell as much of this commodity as they may wish. They then directly reinterpret as follows the constraints and objectives that static atemporal theories made familiar.

As between the many plans that he can think of, a consumer is assumed to have a system of preferences that is often conveniently represented by a utility function, whose argument is a consumption vector with as many components as there are commodities and dates. A budget constraint requires that the discounted value of the consumption vector does not exceed a given amount, the consumer initial wealth. The chosen plan maximizes the utility function subject to the budget constraint. It then follows that the consumption of the various commodities (and the supply of labour) depend on what are the discounted prices and the initial wealth. The present saving of the consumer may be said to be equal to
the interest income earned on his initial wealth minus the value of his present consumption (labour income appears negatively in this value). It is immaterial in this theory to know how saving is invested. Hence, the consumption plan and the resulting saving plan are seen as involving the whole future life cycle of the consumer (Modigliani and Brumberg, 1954).

The plan of a producer is subject only to the constraints that technology imposes. The producer acts as a price taker. His objective is to maximize the discounted value of the plan. It follows that demand for inputs and supply of outputs are functions of the discounted prices. The balance between the value of present outputs and present inputs gives the financial surplus if positive or requirement if negative; this is subject to no direct constraint.

Such a theory of consumer and producer behaviour does not claim to apply to all problems concerning this behaviour. Clearly, analysis of the firm in particular must usually go far beyond the stylized description given above, even simply when investment behaviour is being studied (Nickell, 1978). But the theory is supposed to be appropriate for fitting into the discussion of the broad questions raised by intertemporal equilibrium and efficiency.

Even when it is so circumscribed, the intent cannot be considered as fully achieved. Significant limitations must be kept in mind, since they may forbid application of the theory to some of the problems raised by equilibrium and efficiency over time; indeed, some of these limitations have been the motivation for theoretical developments that will not be discussed at length here, but must be mentioned. Full knowledge of the system of discounted prices for purchases of sales at all relevant future dates is of course an abstraction. Forward prices exist for only a few basic commodities and a limited horizon. Whereas the interest rates at which one can borrow or lend for more or less long durations are fairly well defined, with non-negligible transaction costs and fiscal interference, however, prices that will apply to future transactions have to be forecast by the agents. The uncertainties that their forecast necessarily contains are neglected. Among the many consequences of this major simplification, one particularly notes that it rules out fundamental problems concerning the characterization of decision criteria of business firms (Drèze, 1982).

Constraints on individual choices are also reduced to a minimum. No consideration is given to quantitative constraints, such as those following from mass unemployment on individuals looking for jobs or from business depression on firms looking for customers. When such constraints are binding, not only must the plans meet them, but also spillover effects from one period to others occur, according to laws that follow from the theory of individual behaviour under rationing (Samuelson, 1947). In particular, consumers willing but unable to borrow are constrained by their current resources, a phenomenon that gives some justification to the Keynesian consumption function relating current consumption to current income.

Neglect of financial constraints may be considered as following from other theoretical simplifications, lack of uncertainty and full knowledge of discounted prices, which rule out insolvency; but it is often particularly restrictive. The role of financial constraints on investment behaviour indeed play a major part in the development of trade cycle theories (Haberler, 1937).

Another notable feature of the theory is the simplicity of the trading relations that it assumes. Consumers and producers buy from ‘the market’ or sell to ‘the market’. A worker need not establish ties with a particular employer, nor a manufacturing firm to a particular supplier of raw material. Actually, intertemporal decisions are often subject to quite significant irreversibilities. Long-term commitments
are frequent for easily understandable reasons, some of which have to do with the specificities that characterize many production processes (for instance, most equipment, once bought, cannot be resold). Long-term contracts are also predominant on the labour market, even though many of their clauses often remain implicit. This feature motivates significant research nowadays, under the heading of ‘implicit contracts’ (Rosen, 1985).

Limited as it is, the classical theory of individual intertemporal decisions is, however, indispensable as a starting point, from which the study of the many complexities of real life can proceed. It has moreover brought to light some quite relevant results, such as the fact that, contrary to common belief, the saving of a household need not be an increasing function of interest rates or that individual choice is bound to exhibit some degree of impatience (Koopmans, 1960).

An intertemporal economy

The theory of general intertemporal equilibrium can also transpose the more familiar static theory. But clearly when so doing it does not go very far; new complications, specific to intertemporal problems, must be faced.

The simple transposition of the general competitive equilibrium assumes the existence of a terminal date, ‘the horizon’, a given set of consumers and producers whose activities end at this date, if not before. They all decide their plans at the initial date, on the basis of a full system of discounted prices, and acting as price takers. Perfect competition is assumed to imply that discounted prices are such that all markets clear; more precisely for a given date and a given commodity, aggregate supply and demand are defined by addition of corresponding individual supplies and demands contained in individual plans, which may then be considered as fully announced; at equilibrium the aggregate supply is precisely equal to aggregate demand, and this applies for any date and commodity. Hence, all individual plans are, from the initial date, mutually consistent for all future dates.

The usefulness of such an abstract equilibrium concept cannot be judged independently of its application, in particularly for the discussion of properties linking discounted prices to the agents’ individual characteristics. Before facing this discussion, it is enlightening to consider how the model can be revised; this was done in three ways.

First, the hypothesis of a full system of markets, one for each date and commodity, has been relaxed and the notion of a temporary equilibrium made explicit (Hicks, 1939; Arrow and Hahn, 1971; Grandmont, 1977). Markets then exist only for the exchange of commodities at the (initial) present date, as well as for the loans of one numeraire commodity from the present to the next future date. Thus, present prices and the interest rate of the first period are assumed to be determined by the law of supply and demand, individual plans being made mutually consistent for the initial data. But, in deciding their plans, individual agents have to form anticipations about future prices. Nothing guarantees that these anticipations are correct, so that individual plans will be revised with the passage of time, as actual prices are found to differ from what was expected.

Formal properties of this more realistic model will not be discussed here. Cases can be defined in which anticipations are later realized. It is then possible, but not always necessary when the future is unbounded, that the sequence of temporary equilibria coincides with the equilibrium defined from the hypothesis of a full system of markets. Thus, two sources of difficulty can arise: false anticipations and
on the other hand instability following from the myopic functioning of the market system (Hahn, 1968).
Second, coming back to the case of a full system of markets, one has relaxed the assumption of a finite
horizon with a fixed set of agents. The problem of knowing which firms exist has not been considered as
specific to the intertemporal models, and has not been discussed thus far in the framework of these
models, given that infinitely lived firms have been assumed. But since the initial proposals of Allais
(1947) and Samuelson (1958), consumers are more and more assumed to belong to overlapping
generations, each generation living only for a finite time. Such a representation of the consumption
sector is clearly more appropriate for long-term analysis than the assumption of a given set of consumers
living for ever, but it raises new difficulties (Balasko and Shell, 1980–81).
Third, since long-term phenomena are often involved, it has been found natural and convenient to
concentrate attention on specifications in which the exogenous conditions of economic activity, such as
technology, tastes, size of the population, natural resources, remain the same through time or change in a
simple way; for instance, population increasing at a constant rate while technology exhibits constant
returns to scale and natural resources are unbounded. Within such specifications one has dealt with the
particular case of a stationary equilibrium, or else with equilibria in which production and consumption
all increase at the same constant rate, that is, the case of ‘proportional growth’. The analytical usefulness
of this assumption of stationarity was at the centre of an important debate on the building of the theory
of capital during the 1930s (Knight, 1935; Hayek, 1936). It follows from the simple form that has the
price system of a stationary equilibrium: all discounted prices can be computed from the prices of the
present commodities using a single interest rate that applies to all future periods of unit duration. ‘The
interest rate’ is then unambiguously defined (Malinvaud, 1953).

Any general law?

A clear formalization of intertemporal equilibrium not only serves to aid progress in the fundamental
conceptualization of economic activity (hence indirectly in the rigour of the discussions concerning
many particular questions) but should also lead to comparative statics properties, which, dealing with
intertemporal equilibria, have also been called ‘comparative dynamics properties’. Particular importance
has been given to the question of knowing how the interest rate changes from one stationary equilibrium
to another when some specific change is being brought to its exogenous determinants.
The study of this question concentrated on a number of conjectures, which turned out to be about as
many disappointments for whose who had expected to find rigorous proofs of their general validity. It is
now realized that the rate of interest is related in a very complex way to the many exogenous
determinants of equilibrium and that changes of relative prices, which are associated with changes of
interest, may be responsible for paradoxical effects. A brief survey of this theoretical search, that
extended over many years, nevertheless reveals some basic issues.
Does a high preference of individuals for present consumption necessarily imply a high interest rate?
The property was often asserted. When first publishing his Theory of Interest in 1907, Irving Fisher
called it an impatience theory. Only later when he revised the book for the 1930 edition did he add the
subtitle ‘as determined by impatience to spend income and opportunity to invest it’, which recognizes
the role of the productivity of investment (Samuelson, 1967). Quite significant cases have indeed been
found in the overlapping generation model for which changes of impatience leave the interest rate
unchanged (Samuelson, 1958).

Does a decrease of the rate of interest mean a lengthening of the production process? The positive answer was taken for granted, at least as long as technology was given, by many economists and was at the head of the ‘Austrian Theory’ as developed mainly by Böhm-Bawerk (1889) and Hayek (1941).

Actually, description of the production process was usually organized in such a way as to focus on the conjectured property, this being true also with such non-Austrian authors as Wicksell (1901). Final output, available for consumption at some date, was seen as resulting from a number of well-identified primary inputs made at previous dates and having ‘matured’ since then. The notion of an average period of production looked natural; an inverse relationship between this period and the rate of interest was expected. However, it turned out that, even restricting attention to the case of one primary input and one final output, one could not prove the relationship unless a special definition was given to the production period and a special phrasing to the property (Hicks, 1939; 1973). Generalization to many primary inputs, many final outputs and many interdependent production processes raises the fundamental difficulty resulting from induced variations in relative prices; it is quite unlikely that a generalized property could be proved (Sargan, 1955).

A somewhat similar property was expected with another formalization that seems to be much more appropriate for describing technology in modern industry. The property concerns the choice of techniques and the notion that different techniques should be selected at various stages of development, as relative scarcity of the two main factors, labour and capital, changes and the interest rate moves accordingly. Its formal specification actually requires a particular model. The production possibility set is seen as resulting from combination of a number of elementary processes, each one operating at constant returns to scale, with fixed input–output coefficients, and requiring a time just equal to one period. Specifying further this model and applying it to an economy with one primary factor (labour), \( n \) produced goods and no joint production (the ‘Samuelson–Leontief technology’), one defines a technique as a selection of \( n \) processes, one for the production of each good.

In this model, given any value of the interest rate, one can determine one technique that is fully appropriate for production, no matter what is the consumption basket. It then seemed natural to conjecture that techniques thus appearing as efficient at different interest rates were ordered from the less capitalistic (high interest) to the most capitalistic ones (low interest). However, this conjecture is not generally valid, even in this special model: as the interest rate progressively declines, one may have to switch at some point away from some technique but have to switch back to it at a later point: this is the case of ‘reswitching of techniques’ (Morishima, 1966).

Is the interest rate systematically smaller when, with a given technology, one shifts from a stationary equilibrium to another one using the same labour input but more productive capital? Again, this looked like a natural property to be stated. Since in a perfect equilibrium with no uncertainty the net rate of profit must be equal to the interest rate, the property was associated with the notion that capital accumulation must depress profit rates.

The property holds in a purely aggregated model with just one produced commodity, used both for consumption and as productive capital (Solow, 1956). The significance of this model for a more general situation was at the heart of hot debates in the late 1950s and early 1960s, the main opponents being located in the two academic cities named Cambridge (Robinson, 1956; Lutz and Hague, 1961). A side issue was whether one could give unambiguous definitions to such aggregate notions as the volume of
productive capital and the marginal productivity of capital. Eventually, both counterexamples and formal analysis of the problem showed that the property was not generally valid (Burmeister and Turnovsky, 1972).

The significance of these various negative theoretical results should of course not be overstated. While reflecting the basic complexity of the relationship between the full system of discounted prices and its determinants, the results do not prove that ‘pathological cases’ are often empirically relevant.

**Intertemporal efficiency**

In the same way as the classical theory of individual behaviour, the theory of the optimum allocation of resources can be transposed to the intertemporal framework. Pareto efficiency of a ‘programme’ made of a set of individual plans, also called ‘Pareto optimality’, is generalized in an obvious way that need not be spelled out. The two classical duality theorems directly apply as long as the horizon is bounded: the programme resulting from a competitive equilibrium of the type described above is Pareto efficient if no external effect occurs; conversely, under a convexity or atomicity assumption, to any Pareto efficient programme can be associated a set of discounted prices supporting this programme. Properties of this system of prices are similar to those of the competitive price system.

Interesting new applications of these properties may give insights on the evolution of prices through time. In particular it is easily found that, if extraction costs are negligible, the discounted efficiency price of an exploited exhaustible resource is the same for all future dates, which means that the undiscounted price increases at a rate equal to the interest rate of the numeraire (Hotelling, 1931). When forming decisions on the use of exhaustible resources, one should give as much weight to the distant future as to the present; discounting gives no comfort for such decisions.

Theoretical difficulties, however, occur when the more realistic case of an unbounded horizon is being considered. The most relevant of these difficulties concerns the Pareto efficiency of competitive equilibria; efficiency is still proved to hold if the discounted value of the productive capital that exists at date \( t \) decreases to zero when one lets \( t \) increase to infinity (Malinvaud, 1953); but examples of competitive equilibria that do not fulfil this condition and are not Pareto efficient can be found. Such examples may be characterized as cases of overcapitalization, an excessive capital stock being indefinitely maintained without this ever benefiting consumption.

When attention is limited to stationary equilibria, a negative interest rate reveals lack of efficiency, whereas a positive one implies efficiency (if no external effect exists). Similarly, the interest rate of the price system supporting an efficient proportional growth programme cannot be smaller than the rate of growth (Starrett, 1970). The borderline case of an interest rate equal to the growth rate corresponds to what was called ‘the golden rule’. More precisely, a new notion of optimality has been defined as follows for proportional growth programmes: an optimal programme is feasible and no other feasible programme leads to larger consumptions (that is, a larger consumption of some commodity at some date and no smaller consumption of any commodity at any date). This definition neglects the conditions at the initial date since an ‘optimal’ programme can require a large input of capital at this date, a larger than is required by other Pareto efficient proportional growth programmes. It was proved that a price system exists that supports such an optimal programme and contains an interest rate equal to the rate of growth (Desrousseaux, 1961; Phelps, 1961). This is another case in which discounting does not make
the distant future negligible.

When it is considered in the preceding terms, the theory of intertemporal efficiency has a somewhat unrealistic aspect; or rather it seems to be quite partial in its treatment of the various questions that intertemporal efficiency raises both for planning and for the study of actual economic evolution. Indeed, the restrictions mentioned in the first section of this article are often serious.

For the theory of planning, even restricted to the medium and long terms, for which intertemporal choices are particularly important, problems concerning the gathering and exchange of information should not be neglected. If a system of discounted prices is to be used for supporting consistency of individual decisions with national objectives, its determination must be given very serious consideration. Moreover, planning often aims at correcting handicaps, distortions or market failures preventing economic development. Its long-term achievement then depends on how well it deals with problems that are not considered here but have motivated an important literature, dealing in particular with the determination of the best shadow discount rate to be used in project evaluation (Dasgupta, Marglin and Sen, 1972).

Similarly, for assessing the performance of actual economic systems, one has still to face many questions that again often relate to problems of information. Three of them seem to deserve particular attention. First, the vision of agents exchanging in markets abstracts too much from the complexities of actual contractual arrangements, some of which deal precisely with intertemporal choices; one does not yet clearly see how these complexities react on the behaviour of the full economy, nor even how theory could approach the issue.

Second, the notion of an intertemporal competitive equilibrium should be replaced by that of a sequence of competitive temporary equilibria. It is then known that, even if anticipations are self-fulfilling along this sequence, intertemporal efficiency is not guaranteed; more precisely, the short-sightedness of equilibria seems to increase the likelihood of an overcapitalization of the type exhibited by the theory of the golden rule. This may occur because of too high saving propensities, because of risk aversion or because of oligopolistic market structures (Malinvaud, 1981). But the question of knowing whether and when this likelihood will materialize remains obscure.

Third, the dual assumption of permanent market clearing and permanently equilibrating prices rules out of consideration many issues, such as those arising from variations in the degree of unemployment or in the stimulus given by profitability. A rather common view among supporters of the market system sees these variations as negligible from a long-term perspective, economic evolution being supposed simply to oscillate around the long-term path determined by equilibrium analysis. But critics of the market system and some other economists have the opposite view: economic disequilibria would provide the main clue for an understanding of the comparative growth of nations (Schumpeter, 1934; Beckerman, 1966). Theory remains conspicuously weak with respect to solving this major debate.

intrahousehold welfare

Marcel Fafchamps
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article focuses on the allocation of tasks and consumption within the household. We first discuss the role of the household in the production of various self-consumed goods and services. We then turn to the outcome of bargaining between household members, examining the empirical evidence to date. The last section makes the link between intrahousehold welfare and the matching of spouses in the marriage market.

Keywords

Article

There is a voluminous economic literature on intrahousehold issues. This is hardly surprising given the many critical functions that households fulfil. They are the locus of most consumption decisions and human capital investments. By pooling resources, households generate economies of size and shelter members against unemployment and health shocks. Furthermore the formation and dissolution of households play a crucial role in the long-term distribution of income and wealth. Here we focus on intrahousehold welfare which, as Haddad and Kanbur (1990) have shown, is important to our understanding of inequality in general.

Becker was the first economist to become seriously interested in what happens within the household. Becker's contribution, which is nicely summarized in his Treatise on the Family (1981), emphasized three things: the organization of production within the household; the way decisions are made within the
Intrahousehold welfare: The New Palgrave Dictionary of Economics

Household; and the formation of couples. All three have a bearing on intrahousehold welfare.

The household as a production unit

The household is a production and consumption unit, self-providing many services such as food preparation, child care and house chores. In developing countries, households also produce much of their own food and housing and fetch their own fuel and water. Becker (1981) pointed out that the organization of production within the household ought to follow economic principles such as the equalization of marginal returns across activities and the allocation of tasks across household members according to comparative advantage.

These simple observations have far-reaching implications because seemingly small differences between household members can have dramatic consequences. To see why, consider the allocation of wage work and household chores between husband and wife. Assume that the tasks are non-divisible and that the return to education is positive in work outside the home and zero in house chores. It follows that the husband will work outside the home if he is slightly better-educated than his wife. Anticipating this, parents may in turn decide not to invest in daughter education but rather to emphasize learning household chores among girls. This results in a self-fulfilling equilibrium in which women receive less education and are confined to household chores. To the extent that education and independent income affect bargaining within the household, such a traditional division of labour may have dramatic consequences on intrahousehold welfare.

The recent empirical literature has cast some doubt on the efficient organization of production within the household. Using data from West Africa, Udry (1996) showed that households do not equalize returns to labour and organic fertilizer across fields managed by different members. Duflo and Udry (2004) provide similar evidence, showing that household labour resources are not optimally reallocated across activities in response to weather shocks. Fafchamps and Quisumbing (2003) show that comparative advantage alone cannot explain the allocation of tasks within Pakistani households. Their evidence also suggests that most household tasks are easy to learn, contradicting Becker's conjecture that learning-by-doing locks men and women into specific work patterns. Gender differences in career choices and intrahousehold division of labour may reflect different preferences, possibly shaped by social norms, or result from differences in intrahousehold bargaining.

Intrahousehold bargaining

Most consumption takes place within households sharing a common budget. (In some societies, such as the coastal region of West Africa, spouses keep separate finances. However, whenever they both contribute to a household public good, they can be regarded as deciding consumption jointly.) Certain consumption goods are rival in the sense that consumption by one precludes consumption by another. Food is an example of a rival good. Other consumption goods – such as a house – are non-rival: they are consumed jointly by the members of the household. In the context of intrahousehold welfare, non-rival goods are usually referred to as (household) public goods.

When choosing how to allocate a limited budget to various rival and non-rival goods, the household takes into account the preferences of its members. Formally, let $x_i$ denote a vector of rival goods
consumed by individual $i$ and let $X$ denote household public goods. The household's consumption choices can be represented as the solution to an optimization problem of the form:

$$\max_{\{x_1, \ldots, x_N, X\}} \sum_{i=1}^{N} \omega_i U_i(x_i, X) \text{ subject to } \sum_{i=1}^{N} px_i + qX = \gamma$$

where $\omega_i$ is a welfare weight, $N$ is the number of household members, $p$ and $q$ are prices, and $\gamma$ is income. Consumption choices depend not only on individual preferences $U_i(.)$ but also on welfare weights $\omega_i$: individuals with large $\omega_i$ have more weight in the household's decision and hence achieve a higher individual welfare. Understanding intrahousehold welfare thus boils down to understanding the factors that affect $\omega_i$.

In two seminal contributions, Manser and Brown (1980) and McElroy and Horney (1981) model intrahousehold bargaining as depending on threat points: when negotiating over how to allocate consumption expenditures, spouses can threaten to walk away from the couple. How much welfare they can achieve on their own determines how much bargaining power they have within marriage. Intrahousehold welfare is predicted to be determined by rules determining the devolution of assets upon divorce (including alimony, child support and welfare payments).

Lundberg and Pollak (1993) argue that the threat of divorce is too extreme to be credible in most everyday situations. Non-cooperation within marriage is a more realistic threat. In this case, intrahousehold welfare is expected to depend on the financial autonomy of spouses, such as rules determining who receives welfare payments or whether married women have independent access to credit. Lundberg, Pollak and Wales (1997) for instance, show that consumption of women's and children's clothing increased when the UK transferred a substantial child allowance from husbands to wives. McElroy (1990) provides a useful discussion of various factors thought to affect intrahousehold bargaining.

The empirical literature has explored these ideas in terms of ‘unitary’ versus ‘collective’ models of the household. A household model is said to be unitary if choices do not depend on bargaining power; otherwise it is collective. A household may be unitary for a variety of reasons, for instance because all decisions are taken by the household head, or because all household members have the same preferences over household consumption $\{x_1, \ldots, x_N, X\}$. A simple way of testing the unitary model is the income-pooling test: if welfare weights do not depend on bargaining power, consumption choices should depend only on total income, not on bargaining weights. This yields a simple exclusion test that has been widely applied in the literature, often to identify variables affecting intrahousehold bargaining.

Chiappori (1988) has proposed a way of testing the efficiency of the intrahousehold bargaining process. The basic idea is that the solution to optimization problem (1) can be written as a two-step process. The household first decides how much to allocate to household public goods $X$ and to the rival expenditures $V_i = px_i$ of each household member, with $px + \sum_i V_i = \gamma$. Then each member maximizes his or her own
intrahousehold welfare: The New Palgrave Dictionary of Economics

utility $U_i$ subject to $P x_i = V_i$. Intrahousehold bargaining only affects how total expenditures are shared among members, that is, it affects only the share of rival expenditures that goes to each member. This observation yields testable restrictions on cross-equation parameters in a demand system. This is called the ‘sharing rule’ approach. Browning et al. (1994), for instance, apply this approach to Canadian couples without children and show that allocation of expenditures on each partner depend on their relative incomes.

Both the sharing rule and the income-pooling tests raise empirical difficulties. One difficulty arises whenever utility is transferable and all household members contribute to a household public good. In this case, Bergstrom (1997) has shown that changes in individual incomes do not affect intrahousehold welfare allocation. The reason is fungibility: reducing the income of a household member simply reduces his or her contribution to the household public good.

Another empirical difficulty is that individual preferences are not directly observable. Hence, in order to identify the effect of bargaining power on household choices, we must assume that different categories of household members have systematically different preferences over joint household consumption. The empirical literature has relied on two types of identification strategies to deal with this issue. The first strategy is to rely on stereotypes, such as ‘men prefer alcohol and cigarettes’ or ‘women care more about children’. This strategy permits identification whenever the stereotype is correct. For instance, it has been shown that, when the bargaining power of the wife increases, the household spends more on child nutrition and schooling (see Bergstrom, 1997, and the references cited therein). Based on this evidence, it has been argued that increasing the bargaining power of women is a way to improve child welfare. Such interpretation is a double-edged sword, however. It also reinforces a stereotype that could be used to argue that, since women care for children, it is acceptable for society to relegate them to a reproductive role. What we need is empirical evidence based on actual preferences, not stereotypes.

The second identification strategy is to focus on individual consumption of rival goods such as food or clothing. While this is a better strategy, it also has problems. Browning et al (1994), for instance, show that households in which the wife earns more spend more on female clothing. They interpret this result as evidence that higher income raises a woman's bargaining power. The problem is that a spouse with a higher income probably occupies a higher job position and needs better clothes to go to work. This may generate a reverse causation between income and clothing expenditures, thereby weakening inference.

An interesting illustration of how altruism can affect intrahousehold welfare is the so-called rotten kid theorem. In this theorem, Becker (1981) imagines a parent who, for altruistic reasons, transfers money to a child. The child can try to capture part of the household income, for instance by refusing to work or by diverting household resources. Becker shows that, as long as the parent decides the size of the transfer
after capture has taken place, capture only leads to lower household income and hence to a lower transfer. As a result, the child chooses not to capture because doing so ultimately reduces his consumption.

The marriage market

The marriage market is discussed in a separate entry in this dictionary and need not be discussed in detail here. What is important to realize for our purpose is that, if sufficient commitment mechanisms exist, intrahousehold allocation of welfare can be negotiated up front at the time of marriage. For instance, future spouses may anticipate that a wife who earns an independent income has more say in household decisions. As a result, the groom may insist that the bride will never work before agreeing to marry her. Similarly, if devolution of assets upon divorce affects bargaining power, the newlyweds may sign a pre-nuptial agreement that shapes how assets will be divided.

As first pointed out by Lundberg and Pollak (1993), this observation has deep implications regarding policy intervention. If intrahousehold welfare is entirely decided at the time of marriage, then changing the rules applying to married couples affects only those who are already married. Changes to what happens after marriage (for example, devolution of assets upon divorce) have no long-run effect because, once they have been introduced, they are anticipated in the marriage market.

Provided that this reasoning is empirically correct, the policy implication is that the best policy handle to influence intrahousehold welfare is the marriage market itself. The share of household consumption that women can (implicitly or explicitly) negotiate for themselves depends on the assets they bring to marriage. If this is true, helping women then is best achieved in the long run by improving female education and by changing inheritance rules in their favour.

Bibliography

Inventory investment is the change in the stocks of materials, works in process, and finished goods within a firm, industry, or entire economy over a specified period of time. Because in most instances the measure encompasses a variety of goods, it is usually measured in currency units, perhaps deflated (for example, in 1999 dollars). Occasionally, however, when highly disaggregated data are available, it can be measured in physical units (for example, Blanchard, 1983; Kahn, 1992).

In national income accounts, aggregate inventory investment is the difference between Gross Domestic Product (GDP) and final sales of domestic product. As a share of GDP it is tiny but highly volatile in modern industrial economies. In the post-war United States, for example, it averages 0.62 per cent of GDP, but has a standard deviation of 0.83 per cent. By comparison, fixed non-residential investment averages 10.6 per cent of GDP with a standard deviation of 1.2 per cent. (Data for these calculations come from the US National Income and Product Accounts, Table 5.)

Inventory investment is also highly pro-cyclical. For example, its correlation with real GDP growth in post-war US data is approximately 0.4, and very close to the correlation between fixed non-residential investment and real GDP growth. Also, the standard deviation of real GDP growth is substantially higher than that of final sales (4.0 versus 3.3 per cent), notwithstanding the fact that for more than half of the economy GDP and final sales are identical. Thus inventory investment ‘adds’ to the volatility of GDP growth in the accounting (though not necessarily causal) sense. Indeed, interest in inventory behaviour as a contributor to aggregate volatility goes back at least to Keynes (1936), and includes notable contributions by Metzler (1941) and Abramovitz (1950). Blinder (1981, p. 500) writes that ‘to a great extent, business cycles are inventory fluctuations’.

The pro-cyclicality of inventory investment appears inconsistent with standard microeconomic models of inventory behaviour, particularly those that stress ‘buffer stock’ or ‘production-smoothing’ motives, as noted by, among others, Blinder (1986) and West (1986). And this was not the first puzzle brought to light by research on inventory behaviour. Some ten years earlier, Feldstein and Auerbach (1976) noted the persistence of inventory-sales ratios’ deviations around their means (see also Ramey and West, 1999), particularly given the trivial adjustments needed to restore them to a (presumed) fixed target.

Researchers have also found inventory behaviour informative about the fundamental driving forces of business cycles (see West, 1990). For example, Blinder (1986), Eichenbaum...
(1989), Kydland and Prescott (1982) and Christiano (1988) hypothesize supply side disturbances to account for pro-cyclical inventory investment. Others (such as Ramey, 1991; Hornstein and Fischer, 2000) consider non-convexities such as fixed costs or downward-sloping marginal cost. Kashyap, Stein and Wilcox (1994) argue for the importance of credit constraints. By contrast, Bils and Kahn (2000) argue that the counter-cyclical behaviour of inventory-sales ratios casts doubt on such supply side explanations, which imply counterfactually that inventories should be relatively tight (in relation to sales) during recessions and plentiful in expansions.

The linear-quadratic model

The workhorse of applied inventory research is the linear-quadratic cost minimization model developed by Holt et al. (1960). The firm is assumed to face a stochastic demand process independent of its inventory and production decisions. Consequently, whether it is a competitive price-taker or has monopoly power, the firm can condition on its expected sales process and minimize costs, which take the form

\[
\sum_{t=1}^{\infty} \beta^{t-1} \left[ c_1 y_t + c_2 y_t^2 + c_3 \left( h_t - h^* \right)^2 \right],
\]

subject to

\[
h_t = h_{t-1} + y_t - s_t,
\]

where \( y \) denotes production, \( s \) sales, \( h \) the end-of-period inventory stock, \( h^* \) the desired or ‘target’ stock, and \( \beta \) a discount factor. Some versions of the model include additional cost terms such as a cost of changing production. The target \( h^* \) is usually assumed to be either a constant or proportional to expected sales. In addition, \( c_1 \) may be stochastic, and there may be additional additive stochastic terms (for example, materials prices).

A standard informational assumption is that production decisions at date \( t \) are based on period \( t - 1 \) information, with the implication that \( h_t \) is not controlled directly. Letting \( \theta = c_2 / c_3 \) the solution to the problem (1)–(2) is:

\[
E_{t-1} \left[ h_t \right] = \lambda h_{t-1} + \lambda E_{t-1} \left[ \sum_{t=1}^{\infty} (\beta \lambda)^{t-1} \left[ \theta^{-1} h^* + \beta \tilde{s}_{t+1} - s_t \right] \right]
\]

where \( \lambda \in (0, 1) \) is the smaller root of \( \beta \lambda^2 - (1 + \beta + \theta^{-1}) \lambda + 1 \). In the limiting case with \( \theta = c_2 = 0 \) the solution is \( E_{t-1} \left[ h_t \right] = h^* \). If \( h^* \) is a constant, then the only motive for varying inventories is to smooth production. Durlauf and Maccini (1995) decisively reject this version of the model. It is worth noting that the solution (3) bears some similarity to another widely used model, the flexible accelerator of Lovell (1961) and others.
\[ h_t - h_{t-1} = \lambda_1 (h_t^* - h_{t-1}) - \lambda_2 (s_t - E_{t-1}(s_t)) + u_t, \]

where \( u_t \) is a disturbance term, and both \( \lambda_1 \) and \( \lambda_2 \) lie between zero and 1.

Both the linear-quadratic and flexible accelerator models, however, have a history of empirical difficulties. Blinder (1986) pointed out that, for the pure production-smoothing model (with \( h^* \) a constant), the model counterfactually implies that the variance of sales exceeds that of production. West (1986) showed that a more general variance inequality implied by the model with a target proportional to expected sales is also violated in US manufacturing data. Moreover, among studies of similar data, there is disagreement in the literature on the magnitudes, and even the signs, of key parameters. For example, Ramey (1991) finds negatively sloped marginal cost, in contrast to most other studies. West (1986) finds a relatively small cost of inventory deviations from their target. West and Wilcox (1994) find that obtaining precise estimates of the linear-quadratic model may be problematic with realistic sample sizes.

Regarding the flexible accelerator, Feldstein and Auerbach (1976) estimated small values for both \( \lambda_1 \) and \( \lambda_2 \), which is paradoxical because a small \( \lambda_1 \) implies large adjustment costs, but a small \( \lambda_2 \) implies that sales surprises are largely offset by within-period production responses. Their proposed solution is a target ratio that itself adjusts slowly over time. They do not provide a strong theoretical foundation for their 'target adjustment' model, however. One theme of the alternative approaches discussed in the next section is the effort to base inventory models on more rigorous microfoundations in the hope of resolving the empirical puzzles.

**Other approaches**

Motivated by the empirical difficulties described above, researchers have examined a number of alternative approaches to modelling inventory behaviour. One, the so-called 'stockout-avoidance' model, provides a rigorous microfoundation for the target stock. Building on Karlin and Carr (1962), Kahn (1987; 1992) considers a firm that faces a non-negativity constraint on its inventories, and must commit to production and pricing decisions each period before observing potential sales, or 'demand' \( x_t \). Consequently, sales equal the minimum of \( x_t \) and the stock available \( h_{t-1} + Y_t \). If we let \( F \) denote the distribution function for \( x \), profit maximization implies

\[ p_t (1 - F(h_{t-1} + Y_t)) - c_t + \beta E_t (c_{t+1} F(h_{t-1} + Y_t) = 0, \]

where \( p \) is price and \( c \) is marginal cost. Then, if demand uncertainty is multiplicative, for example, and \( p \) and \( c \) (and hence the markup) are constant, the firm will set \( h_{t-1} + Y_t \) proportional to expected demand \( E_{t-1}(x_t) \). In addition, positive serial correlation in demand results in the variance of production exceeding the variance of sales.

Another important implication of this approach is that inventory-sales ratios depend on price-cost markups. Bils and Kahn (2000) show, in a model in which expected sales are increasing in the stock available, that the optimal inventory-sales ratio is a function of the markup and a discount rate \( \beta E_t (c_{t+1} / c_t) \). They argue that the counter-cyclical behaviour of the inventory-sales ratio implies a counter-cyclical markup, or, equivalently, pro-cyclical marginal cost.

An alternative approach builds on the work of Scarf (1960), who modelled inventory behaviour with fixed ordering costs. Scarf provided conditions under which inventories would fluctuate between a fixed upper and lower bound, which he dubbed ‘S’ and ‘s’ respectively – hence the moniker (S,s) model. (The conditions, such as i.i.d. orders, are quite restrictive, however.) Caplin (1985) showed that this model implies that the variance of orders exceeds the variance of sales, and Hornstein and Fisher (2000) extended this approach to a general equilibrium setting. Hall and Rust (2000) provide some empirical support for 'generalized' (S,s) behaviour where the two limits depend on the spot price of the good in inventory. While the existence of fixed costs at the microeconomic level is well established, their importance for aggregate inventory behaviour at business cycle frequencies remains a matter of debate.

**Inventories and the great moderation**

Recently attention has again turned to inventory behaviour as a possible explanation for the dramatic reduction in aggregate volatility, which in the United States dates from approximately 1984 (McConnell and Perez-Quiros, 2000). Kahn, McConnell M. and Perez-Quiros (2002) show that reduced volatility is most pronounced in the durable goods sector.
and for production more than for sales. At the same time, that sector has experienced large declines in inventory-sales ratios, as shown in the accompanying Figure 1, and reduced volatility of inventory investment. They also provide a model in which improved information about demand shocks results in reduced output volatility. While there is much anecdotal evidence of efforts to improve inventory control by techniques such as ‘just-in-time’ management, there remains nonetheless considerable debate over the importance of inventories in increased aggregate stability.

Abstract

Investment is capital formation – the acquisition or creation of resources to be used in production. As such, it captures the production side of intertemporal consumption/savings decisions. This entry focuses on neoclassical approaches to the study of investment. Theoretical and empirical issues are discussed.

Keywords

acceleration principle; adjustment costs; capital–output ratio; CES production function; depreciation; distributed lags; elasticity of substitution; Euler equations; full employment; human capital; investment (Keynesian); investment (neoclassical); irreversible investment; opportunity cost of capital; public capital; saving and investment; user cost of capital

Article

Investment is capital formation – the acquisition or creation of resources to be used in production. In capitalist economies much attention is focused on business investment in physical capital, such as buildings, equipment and inventories. But investment is also undertaken by governments (see public capital), nonprofit institutions and households, and it includes the acquisition of human and intangible capital as well as physical capital. In principle, investment should also include improvement of land or the development of natural resources, and the relevant measure of production should include non-market output as well as goods and services produced for sale.

Thus, acquisition of an automobile by government or households is as much investment as acquisition of an automobile by a business firm. The car is used in all cases for the production of transport services. Similarly, government construction of roads, bridges and airports is as much investment as business acquisition of trucks and planes. Expenditures for research and development are investment whether undertaken by business, government or nonprofit universities. And, most important, education and
training, wherever undertaken, are major forms of investment in human capital. There is a widespread mythology that investment is good and the more investment the better. But investment may be good or bad and there may be too much as well as too little. Classical and neoclassical economists have stressed the role of investment in providing for the future. Maintaining the current level of output requires keeping up the existing means of production. Economic growth, or the increase in the rate of output, is then seen as depending considerably on the acquisition of additional means of production, that is, investment in excess of the wearing away or depreciation of existing capital. Investment may also contribute to higher output where the new capital ‘embodies’ new and improved technology. That investment will contribute to economic growth presupposes, however, that the additional capital is useful. It must have a positive net product, which is to say that the additional capital must contribute more to future production than the value of the resources used to create it. How far one should go in allocating resources to investment depends upon our preferences for current consumption versus future consumption, or our preferences between our own consumption and that of our children and grandchildren. It also depends on the production function, that is, the terms under which additional capital can be converted into additional future output. It would hardly seem desirable to sacrifice 100 dollars of current consumption to produce 100 dollars of capital that would result in future production of only 90 dollars. The notion that this is not a relevant issue stems from the assumption that profit-seeking entrepreneurs would not freely undertake investment in which the costs are greater than the returns. It is not always perceived, however, that where governments offer subsidies or ‘tax incentives’ for businesses to undertake investment that would not otherwise seem profitable, such unproductive capital formation is exactly what may be expected.

A second major role for investment has been seen in the achievement and maintenance of full employment. This requires that aggregate investment plus aggregate consumption equal the total output that would be produced if all individuals who wish to work could find employment. Investment may then be inadequate not only in failing to provide sufficient resources for future production, it may also be inadequate if it is insufficient to bring about the full utilization of existing resources. This latter problem has received major attention as a consequence of the work and influence of John Maynard Keynes (1936).

Another way of stating the condition necessary for full employment is that aggregate investment must equal aggregate saving out of the full-employment level of income. In national income accounts, measured investment and saving are always identically equal, owing to the identity of output and income, which, apart from receipts from abroad, is earned only from production. That part of income not spent on consumption is saved. But that part of production not purchased by consumers must be acquired (or kept) by producers and hence is investment, though not necessarily intended investment. If we designate \( Y \) as income and output, \( C \) as consumption, \( S \) as saving and \( I \) as investment, we then have \( S = Y - C = I \).

While realized investment is thus identically equal to saving, investment and saving may be more or less than investment demand, that is, intended investment. If investment demand is less than saving at the current level of income, producers will find that they cannot sell all that they produce. They will accumulate undesired inventories of finished goods (unintended investment in inventories), which should lead them to reduce production. Reduced production means less income and hence less consumption and saving. A shortfall of investment demand in relation to saving therefore brings on a cumulative reduction of output and income until saving and investment are brought down to equality.
with the lesser investment demand. Insufficiency of investment demand has been identified with
depression and recessions and tendencies towards chronic unemployment. Stimuli to investment, such as
reductions in tax rates on income from capital, have thus seemed in order to bring investment demand up
to the levels of saving that would be forthcoming with full employment. Conversely, excessive levels of
investment demand can create inflationary pressures, calling for policies that would restrict investment.
These Keynesian perceptions as to the costs and benefits of investment are startlingly different from
those of the classical models – old and new – which assume, implicitly or explicitly, that the economy is
operating at full employment and full utilization of resources. In the classical models, more current
production of capital must mean less current production of consumption goods and services. And more
consumption now must mean less current investment and less output and consumption in the future.
In an economy with substantial unemployed resources, however, more investment need not and probably
will not bring less consumption. Expenditures for additional investment will rather constitute additional
incomes for their recipients, and this income will in turn largely be spent on increased consumption.
Thus the production of consumption goods and services will increase rather than decline. And more
consumption may bring about more investment, as producers see a need for additional capital to increase
the output of consumption goods and services.
Classical and Keynesian views also differ on the principal mechanism by which intended investment and
saving are equated. In the classical view, changes in the rate of interest are presumed to perform this
task. Investment demand is thought to be negatively related and very sensitive to the rate of interest,
which is the cost of borrowing funds to finance capital spending. If investment demand is smaller than
saving at the full-employment level of incomes, the classical analysis holds that the excess of funds in
the credit market will depress interest rates, thereby inducing increases in investment demand (and
possibly reductions in saving as the interest earned by savers falls) until intended investment and saving
are equal. Thus, no change in the level of economic activity (output) need occur as in the Keynesian
analysis. The Keynesian view of the equilibrating process has interest rates playing a smaller role than
changes in output, because investment demand is thought to be relatively insensitive to interest rates,
being dominated instead by producers’ expectations of future demand for their products. Even if the
investment demand were sensitive to interest rates, expectations could be so pessimistic that, even if the
rate of interest were to fall to zero, there would be insufficient investment demand.
Empirical studies have attempted to measure the influence of interest rates, taxes and expectations of
future demand on investment decisions. Producers are presumed to acquire capital to increase their
expected profits. The profitability of additional capital depends on its cost, on its expected productivity
and on expectations on the price at which additional output can be sold. On the assumption that output is
a fixed, ‘well-behaved’ function of capital and labour (strictly concave, with declining partial derivatives
of output with the respect to capital and labour and positive cross-partial derivatives), producers will
acquire capital to the point where its declining marginal product equals its cost. This will then define
both the desired, or equilibrium, capital–labour ratio and capital–output ratio. With the supply of labour
and the rate of output fixed and no change in the relative price of capital and labour, investment in
equilibrium will be equal to depreciation, or what is necessary to maintain the existing capital stock, and
net investment will be zero. Positive net investment will then stem from increases in the demand for
output or reductions in the relative price of capital. Increases in output will generate investment demand
to maintain the equilibrium capital–output ratio. A reduction in the cost of capital would generate
investment in order to increase the capital–labour and capital–output ratios. In either case, maintaining
increased amounts of capital will generate further investment to cover increased depreciation. In general, the desired capital stock may be written as:

\[ K^* = f(p, c, Y^*), \]

(1)

where \( p \) is the price of output, \( c = q[i - (\frac{q}{q}) + d] \) is the rental price or user cost of capital, \( q \) is the supply price of capital goods, \( i \) is the opportunity cost of capital, \( d \) is the rate of economic depreciation and \( Y^* \) is desired output. If firms minimize expected costs of producing an exogenously given or expected output \( Y \), then the wage rate, \( w \), would be substituted for \( p \). The rental price, or user cost of capital, \( c \), is the cost per period of holding and maintaining one unit of capital. In the absence of taxes, it is the price of capital goods multiplied by the sum of the real interest rate and the rate of economic depreciation. The former measures the opportunity cost in terms of forgone net earnings from lending or otherwise investing money, plus the capital loss (or minus the capital gain) associated with changing prices of capital goods.

Building on this neoclassical theory of the firm developed by Haavelmo (1960), and assuming a Cobb–Douglas production function with elasticity of output with respect to capital, \( b \), Jorgenson (1963; 1967) arrived at a demand function for capital with a particular form that has been employed in a large number of influential studies:

\[ K^* = b(p/c)Y^*. \]

(2)

With an implicit unitary elasticity of \( K^* \) with respect to \( c \), this formulation implies strong effects of monetary policy, via the rate of interest, and of tax policy so far as, by accelerated tax depreciation, investment subsidies or exclusion of capital gains from taxation, it affects the value of \( c \) (see below). The more general constant-elasticity-of-substitution (CES) production function may be used to generate a demand for capital having the form:

\[ K^* = n(p/c)^s(Y^*)^r, \]

(3)

where \( s \), the elasticity of substitution between labour and capital, is the critical elasticity of demand for
capital with respect to the relative price of capital, and $r$ is the elasticity of demand for capital with respect to output. The elasticity, $r$, will be greater than, equal to, or less than unity as the returns to scale are decreasing, constant or increasing.

If relative prices are constant, or if technology requires that capital and labour be used in fixed proportions (in which case the elasticity of substitution is zero), then with constant returns to scale, desired capital is proportional to the demand for output. This form of the demand for capital leads to the ‘acceleration principle’, according to which net investment demand, arising from a desire to change the stock of capital, depends not on the level of demand for output, but on the change in demand for output (Clark, 1917). To induce firms to invest (acquire more capital), demand for output must be expected to rise. Both the original formulation by Jorgenson of the demand for capital (2) and the more general formulation (3) underly a ‘flexible accelerator’, where the desired capital–output ratio is not constant but depends on prices and on the scale of output and, as seen below, investment is subject to a distributed lag process (Koyck, 1954) affected by adjustment costs and the dynamic process governing the formation of expectations of future variables (Eisner and Strotz, 1963; Helliwell and Glorieux, 1970; Lucas, 1976; Eisner, 1978).

Many early econometric studies of investment behaviour tested the accelerator in various forms, but generally they did not allow for effects of prices on the desired capital–output ratio, which is the hallmark of Jorgenson's neoclassical approach. The major competing hypothesis was that investment depends on the level of profits, on the grounds that realized profits measure expected profits, or that capital market imperfections cause firms' capital expenditures to be constrained by the flow of internal funds (Meyer and Kuh, 1957). Reviews of these earlier investigations are found in Eisner and Strotz (1963) and Jorgenson (1971). The practice in recent studies has been to capture profit expectations by including expectations of the major determinants of profits, namely, sales, prices and wages, or to approximate them by stock market valuations of firms. The flow of internal funds may play some role in investment decisions, not as a determinant of the desired capital stock but as a factor influencing the speed of adjustment of capital (Coen, 1971).

To study the effects of tax policy on demand for capital, the rental price can be generalized to incorporate parameters of the tax system. For example, the after-tax cost of holding one unit of capital would be:

$$
c = q[(1 - uv)i - (1 - uw)(q / q) + d] [1 - k - wz] / (1 - u) \tag{4}
$$

where $u$ is the rate of taxation of business income; $v$ is the proportion of the opportunity cost of capital (such as interest, dividends and forgone earnings) that is tax deductible; $w$ is the proportion of capital gains and losses effectively taxed; $k$ is the effective rate of the investment tax credit or subsidy; and $z$ is the present value of the tax depreciation expected from a dollar of investment (Hall and Jorgenson, 1967).

It can be seen, in this definition, that higher values of $v$, $k$ and $z$ (from accelerating tax depreciation)
reduce the value of \( c \), as does a higher value of \( w \), provided that capital goods prices are expected to rise. The value of \( c \) would also be lowered by decreasing the rate of interest or other measure of the opportunity cost of capital. A higher rate of inflation of capital goods prices has two opposing effects on \( c \). In so far as higher inflation reduces the real after-tax opportunity cost of capital, it reduces \( c \). However, if tax depreciation is based on the historical cost of assets rather than on replacement costs, inflation reduces the present value of tax allowances, \( z \), and thereby raises \( c \) (Feldstein, 1982). Finally, we may note that changes in the general rate of business taxation are ambiguous in their effects on \( c \). If \( v \) and \( w \) are unity, and if the opportunity cost of capital is unaffected by a change in the business tax rate, then a decrease in \( u \) will reduce, leave unchanged or increase \( c \) as the present value of tax allowances on a unit of investment (including the investment credit) is less than, equal to or greater than the present value of economic depreciation (Hall and Jorgenson, 1971). But then, going back to eq. (1), the effect of any of these parameters on \( K^* \) depends upon the elasticity of the latter with respect to \( c \).

The desired capital stock does not in itself indicate the rate of investment, which is the rate of replacement of existing capital plus the rate of net additions. Both entail a combination of financial considerations and costs of adjustment, which will in turn relate to costs of acquiring information necessary to decisions, costs of planning and the supply function for capital goods, all filtered through the expectations of agents. If adjustment costs are an increasing function of the rate of investment, it will generally prove optimal not to adjust capital to the desired level immediately, but instead to distribute changes in the capital stock over time (Eisner and Strotz, 1963).

The speed of adjustment of capital to changes in its desired or equilibrium level may depend on the causes and magnitudes of the changes. An increase in the demand for output may generate investment with all due speed as expectations become firm with regard to the permanence of the increased demand. If, however, the increased demand for capital is due to a fall in its relative price (because, let us say, of a reduction in the rate of interest), thus generating a demand for more durable and hence more substantial and expensive capital, the rate of investment may be slowed by the availability of existing capacity sufficient for current production. These considerations underlie the ‘putty-clay’ model in which the capital–labour ratio can be varied on newly installed capacity but cannot be altered on existing capacity. A demand for additional housing services will bring on investment in housing as rapidly as cost considerations permit. A lower rate of interest, causing substantial investment in more durable brick houses to replace less durable houses of wood or straw, would cause the rate of investment to increase only as existing houses of wood and straw wear out and are replaced.

Investment equations should thus in principle involve separate distributed lag responses to changes in relative prices and to changes in output. They should also admit the possibility that the lag distribution is not fixed and may vary with other economic parameters and the expectations function.

A logarithmic transformation of eq. (3) yields

\[
\ln K^* = \ln h + s \ln (\frac{\rho}{\tau}) + r \ln Y.
\]

(5)
Putting this in first difference form, we have:

\[ \Delta \ln K^* = s \Delta \ln (\frac{p}{c}) + r \Delta \ln \gamma. \]  
(6)

Since the change in the logarithm of capital is the relative change in capital, we may treat the ratio of net investment to existing capital stock as approximately equal to \( \Delta \ln K \), which may in turn be written as a distributed lag function of changes in the determinants of desired capital:

\[ \frac{I_N}{K-1} = s[q_1(L) \Delta \ln (\frac{p}{c})] + r[q_2(L) \Delta \ln \gamma], \]  
(7)

where \( q_1(L) \) and \( q_2(L) \) are lag operators that indeed should be functions of such variables as the rate of interest, and the cost and availability of capital. Then, finally, since investments equal net investment plus replacement, we may write

\[ I = I_N + R = I_N + dK_{-1}, \]  
(8)

where \( d \), the replacement rate, may vary over time.

Estimates of investment functions of this type have often neglected influences of economic variables and expectations on adjustment processes and the replacement rate. Lag distributions are assumed to be of some fixed functional form, and \( d \) is assumed to be constant (for evidence that \( d \) may not be constant, see Feldstein and Foote, 1971; Eisner, 1972; Feldstein and Rothschild, 1974; Coen, 1975).

Where production and lag parameters have not been unduly constrained by a priori specifications, estimates have generally yielded values of \( s \), the elasticity of substitution, considerably less than unity, in some cases not substantially greater than zero (see Eisner and Nadiri, 1968; Coen, 1969; Lucas, 1969; Eisner, 1978; Chirinko and Eisner, 1982). Lag distributions estimated from time series and cross-section data have usually extended over a number of years (Eisner, 1978), and they often have inverted-U shapes. Where a putty-clay formulation has been employed with separate lags on relative prices and output, the mean lags on prices are typically much longer than those on output (Bischoff, 1971).

These findings of small price elasticities of demand for capital suggest some role, but a limited one, for monetary and tax policies in directly affecting the general rate of investment through the rental cost of capital. The long lag distributions on relative prices suggest further difficulties in the use of monetary or
fiscal policy for reducing cyclical fluctuations in investment. However, policy impacts may operate not only on the desired capital stock but also on the speed of adjustment of capital. Repeated changes in tax parameters such as $k$, the rate of investment tax credit or subsidy, may be used to bring about intertemporal substitution of investment even if the effects on its long-run average are small. Thus, when investment is low, the marginal rate of subsidy, $k$, might be raised, while if investment were deemed too great, the value of $k$ could be reduced to zero or indeed made negative (an investment tax instead of subsidy). Paradoxically, a fluctuating and uncertain investment subsidy/tax may have substantial effects on investment where permanent subsidies or taxes would not. There is thus an asymmetry between effects of changes in the cost of capital and changes in the demand for output, the effects of which on investment will be proportional to the permanence with which they are perceived (Eisner, 1978).

Most investment functions, with their ad hoc, fixed lag distributions and assumptions of static expectations, fail to capture accurately the effects of economic policies on the timing of investment or to distinguish properly between the effects of temporary and permanent policy changes (Lucas, 1976). To correct these shortcomings, adjustment costs must be explicitly introduced in the firm's optimization problem, so that instead of there being a desired stock of capital towards which the firm moves in a mechanistic way, there is a desired path of capital accumulation. Along such a path, the optimal rate of investment at each point, including the present, will in general depend on expected relative prices and output over the entire planning horizon.

Obtaining solutions to the firm's dynamic optimization problem under very general specifications of technology and expectations has proven difficult. To make such an approach empirically tractable, strong assumptions are usually made, for example, that the production function is quadratic, that adjustment costs are quadratic, symmetric and separable from the rest of technology (the cost of adjusting capital, for example, does not depend on the quantities of capital and labour currently employed), and that expectations are characterized by relatively simple autoregressive processes. The critical role in current investment of unobservable adjustment costs and of uncertain, shifting (and generally not directly observable) expectations of the future, stressed by Keynes, has sparked interest in a formulation of an investment function that directly relates demand prices and supply prices of capital. Going back to Keynes's *General Theory*, we have investment undertaken to the point where the expectation of marginal profit on investment (the ‘marginal efficiency of investment’) is equal to the rate of interest or, alternatively, the present value of expected returns from the marginal investment, using the rate of interest as the discount factor, is equal to the marginal supply price of newly produced capital goods. Building on this, Brainard and Tobin (1968) and Tobin (1969), presented a ‘$q$-theory’, which sees investment as a positive function of the ratio, $q$, of the market value of capital to its replacement cost.

The former may in principle be observed in the trading prices of stock shares along with bonded indebtedness of business firms. With proper adjustment for tax considerations, when the value of $q$ is greater than unity, investment will take place because the cost of additional capital will be less than the market evaluation of the present value of returns from capital. Conversely, when $q$ is less than unity, business demand for capital may be better satisfied by acquisitions taking over existing firms and their facilities than by new investment. In general, the rate of investment should be greater the greater the value of $q$.

Empirical estimation of ‘$q$’ investment equations and predictions based on these estimates have not, however, proved very successful (von Furstenberg, 1977; Abel, 1980; Summers, 1981; Hayashi, 1982;
Abel and Blanchard, 1986). Suggested explanations of the difficulties include the fact that market values of firms may relate to much more than the tangible capital generally included in business investment, and the failure to distinguish marginal and average values of the cost of new capital versus the acquisition costs of existing firms (Chirinko, 1986).

Investment decisions are but one element of producers’ plans for hiring or acquiring factors of production. Interrelationships between investment demand and demands for other inputs have been a subject of growing interest. Since factor demands are derived from a given production function, they share common technological parameters and may be estimated as a system of demand functions (Coen and Hickman, 1970). Such an approach calls attention to effects of investment stimuli that are often overlooked. For example, at a given level of output, the direct impact of an investment tax credit is to reduce the demand for labour, since it raises the relative cost of labour. Employment may eventually be raised, but only if the expansion in aggregate output induced by the increase in investment demand is large enough to offset the adjustment to a higher capital–labour ratio.

Additional interrelationships may arise when capital is not the only factor of production subject to adjustment costs. If labour input is also costly to change, then the rate of investment may depend not only on the desired adjustment in capital stock but also on the desired adjustment in employment (Nadiri and Rosen, 1969; Brechling, 1975; Epstein and Denny, 1983). Furthermore, since a firm must operate on its production function, factor adjustments cannot be entirely independent. If output is exogenously given and there are $n$ inputs, $n - 1$ inputs can be independently adjusted, but the $n$th is determined by the production function, the level of output, and the quantities of the other inputs (Gould, 1969). It may be unreasonable to view the production function as a binding constraint, however, because it is difficult, if not impossible, to measure perfectly all inputs and their utilization rates.

With the development of dynamic optimization models of interrelated factor demands in which various types of capital and other inputs are subject to adjustment costs, and expectations are not treated as static, it is possible to estimate the magnitude of adjustment costs for capital, to see how they affect and are affected by adjustments of other inputs, and to study the impacts of changes in producers’ perceptions of the processes generating prices, output and policy parameters. As we noted above, this approach necessitates strong restrictions on functional forms to obtain explicit decision rules for accumulation of capital and employment of other inputs (Meese, 1980). Where general forms of the production, adjustment cost and expectations functions are assumed and the model cannot be solved completely, it is still possible to estimate the first-order conditions (Euler equations) that implicitly define the evolution of the optimal inputs (Pindyck and Rotemberg, 1983; Shapiro, 1986). Such estimates do not give a complete account of the dynamics of investment behaviour for any initial conditions and stochastic environment, but they do give insights about differing short- and long-run responses to, say, an unexpected increase in the price of energy starting today versus the same increase beginning five years from now but anticipated today. An important empirical development in the study of investment is the use of more disaggregated data-sets; an important example is Cummins, Hassett and Hubbard (1994), which analyses the effects of major tax reforms on investment based on firm-level panel data. The paper is important in providing much stronger evidence on the importance of the user cost of capital than appears in aggregate studies. Chirinko (1993) is still of value as a survey.

Yet, as noted in the valuable review of Caballero (1999), a general dissatisfaction with the empirical performance of the neoclassical model led to change in investment research which emphasized the role
of irreversibilities. See irreversible investment for these new developments.

Investment decision criteria

Jack Hirshleifer
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Investment is present sacrifice for future benefit. Individuals, firms, and governments all are regularly in the position of deciding whether or not to invest, and how to choose among the options available. An individual might have to decide whether to buy a bond, plant a seed, or undertake a course of training; a firm whether to purchase a machine or construct a building; a government whether or not to erect a dam. Under the heading of investment decision criteria, economists have addressed the problem of how to choose rationally in situations that involve a tradeoff between present and future.

The Economic Theory of Intertemporal Choice

The object of investment is taken to be to optimize one's pattern of consumption over time. The elements needed to determine an individual's investment decision are: (a) his endowment, in the form of a given existing income stream over time; (b) his preference function, which orders in desirability all possible time-patterns of consumption; and (c) his transformation set, which specifies the possibilities for transforming the original endowment into other time-combinations of consumption.

Figure 1 illustrates an artificially simple case of only two periods (say, this year and next) under conditions of certainty. Each point represents a combination of current consumption \( c_0 \) and future consumption \( c_1 \). The endowment combination \( Y \) has coordinates \((y_0, y_1)\). Time-preferences are portrayed by the indifference curves \( U_1, U_2, U_3, \ldots \), each such curve connecting combinations yielding equal satisfaction. The curve \( QQ' \) through the endowment position \( Y \) pictures the intertemporal productive opportunities. By sowing seed, for example, a person can sacrifice current consumption for future consumption – represented in the diagram by a movement from \( Y \) along \( QQ' \) to the northwest. (There may also be disinvestment opportunities, i.e., the individual might be able to draw upon the future so as to augment current consumption, which would be represented by a movement from \( Y \) along \( QQ' \) to the south-east.)

Figure 1
Investment and saving in a 2-period model
For a Robinson Crusoe, the optimum balance of present and future consumption—which in his isolated state must necessarily be identical to his provision for present and future production—occurs at point $X^*$ along $QQ'$. In the situation pictured he achieves this optimum by investing the quantity $y_0 - x_0$ of current consumption claims. For example, having at hand a current corn endowment of $y_0$, he retains $x_0$ for current consumption and plants the remainder as seed. Next year he will reap as return from investment the amount $x_1 - y_1$ to augment his endowed availability of future corn.

If markets for trading between present and future income claims exist, however, in contrast with the Robinson Crusoe situation the individual will be able to disconnect the amount he invests from the amount he saves. These trading opportunities are shown in Figure 1 by the family of ‘market lines’ whose general equation is:

$$c_0 + c_1 / (1 + r_1) = W_0$$

(1)

Here $r_1$ is the interest rate that discounts one-year future claims $c_1$ into their equivalent value in terms of $c_0$ claims. Along each market line the parameter $W_0$ represents the associated level of wealth. Put another way, wealth in equation (1) measures the present worth of any specified $(c_0, c_1)$ vector—the future-dated element being ‘discounted’ at the given market interest rate $r_1$. In the diagram two market lines are shown: $MM'$ through the endowment vector $Y = (y_0, y_1)$ indicates the individual’s endowed wealth $W_0^* = y_0 + y_1 / (1 + r_1)$, while $NN'$ represents the maximum attainable level of wealth $W_0^* = c_0^* + c_1^* / (1 + r_1)$.

If an individual has both productive and market opportunities, his optimizing decision in Figure 1 can be thought of as taking place in two stages. First he locates his ‘productive solution’ $Q^* = (q_0^*, q_1^*)$ by moving along $QQ'$ so as to maximize attained wealth at the tangency with market line $NN'$. Second, he then transacts in the funds market, by lending or borrowing (exchanging current for future claims or vice versa) along $NN'$ to find his ‘consumptive solution’ $C^* = (c_0^*, c_1^*)$ at the tangency of $NN'$ with indifference curve $U_2$ in the diagram. Notice that his preferences do not at all affect the productive solution, but only how he chooses to ‘finance’ the investments made. Specifically, in the diagram here the amount he invests $(y_0 - q_0^*)$ exceeds the amount he saves $(y_0 - c_0^*)$. By borrowing on the market, in effect he has been able to get others to undertake part of the saving necessary to finance his projected investments.

This disconnection between the individual’s productive and consumptive decisions in a regime of perfect markets is known as ‘Fisher’s Separation Theorem’. The essential implication is that individuals with diverging time-preferences can nevertheless come together and agree upon joint productive investments. Business firms and (to some extent) governments can be regarded as institutions designed for undertaking joint investments whose scale is too large for any single individual. The underlying principle is that those investment choices maximizing wealth value or present worth of the mutual undertaking will also maximize wealth for each and every participant therein.

The Present-Value Rule

The economic theory of intertemporal choice leads immediately to what is known as the Present-Value Rule for investment decision. This rule can be expressed in two essentially equivalent forms:

1. (i) Among the opportunities available, adopt the set of investments that maximizes wealth $W_0$.
2. (ii) Adopt any single investment project if and only if its present value $V_0$ is positive. (Taking into account, of course, any repercussions of that project upon the returns yielded by other members of the adopted investment set.)

As an obvious corollary, if two available projects are mutually exclusive, the one with the larger present value $V_0$ should be chosen.

Generalizing to the multi-period context, wealth as maximand becomes:

$$W_0 = q_0 + q_1 / (1 + r_1) + q_2 / [(1 + r_2)(1 + r_1)] + \cdots + q_T / [(1 + r_T)\cdots(1 + r_2)(1 + r_1)]$$
Here the \( q_t \) are the coordinates of points along the \( T+1 \)-dimensional productive opportunity surface

\[
\varphi(q_0, q_1, \ldots, q_T) = 0,
\]

a generalization of curve \( QQ' \) in Figure 1. \( T \) is the ‘economic horizon’, which may be infinite. And the \( r_t \) represent the successive short-term interest rates, each of which discounts prospective payments at any date into its wealth-equivalent at the next preceding date.

For a single project in the multi-date context, present value is defined as:

\[
V_0 = z_0 + z_1 / (1 + r_1) + z_2 / [(1 + r_2)(1 + r_1)] + \cdots + z_T / [(1 + r_T)(1 + r_2)(1 + r_1)]
\]

Here the \( z_t \) are the dated payments or ‘cash flows’ associated incrementally with the project considered. Normally the \( z_1 \) elements for earlier dates would include some with negative signs – or else the project could not be described as an investment – while those for later dates would have predominantly positive signs. In the special case where \( r_1 = r_2 = \cdots = r_T = r \) – that is, where interest rates are expected to remain constant at the level \( r \) over time – the Present-Value formulas reduce to the more familiar forms:

\[
W_0 = a_0 + a_1 / (1 + r) + a_2 / (1 + r)^2 + \cdots + a_T / (1 + r)^T
\]

\[
V_0 = z_0 + z_1 / (1 + r) + z_2 / (1 + r)^2 + \cdots + z_T / (1 + r)^T
\]

The Present-Value solutions can also be formally generalized to allow for continuous rather than discrete time. As an illustrative simplified example, consider a project whose scale of current input or investment sacrifice \( i_0 \) is fixed while the output date is subject to choice (e.g., when to cut a growing tree). In Figure 2, horizontal distances represent time \( t \) and vertical distances value \( V_t \) at each date. Present Value \( V_0 \) is indicated by height along the vertical axis. The curve \( GG' \) represents productive growth of the asset – in the case of a tree, market value of the standing timber at any date. The ‘discount curves’ \( D, D', D'', \ldots \) are analogous to the ‘market lines’ of Figure 1. Each such curve represents the growth of a specific sum of present dollars by continuous compounding at a constant market rate of interest \( r \), or alternatively the Present Value of any future payment continuously discounted at \( r \). The optimal investment period \( t^* \) is then the one that maximizes Present Value \( V_0 \), subject to the constraint on the available \( V_t \) described by the curve \( GG' \), in the equation:
The solution condition is then:

\[
\frac{V_t'}{V_t} = r
\]  

(5)

Geometrically, \( r^* \) is determined by the tangency of \( GG' \) with the highest discount curve (constant-wealth curve) attainable.
Other Investment Criteria

Certain investment criteria employed in business practice are definitely erroneous. One such is rapidity of ‘payout’ (the date when cash inflows first balance initial outlays), a formula that obviously fails to allow properly for time-discount. Controversy among theorists has centred upon a more interesting concept known variously as the ‘internal rate’ or the ‘rate of return’. The internal rate for a project (or set of projects) is defined as $\rho$ in the discrete discounting equation:

$$0 = z_0 + z_1 / (1 + \rho) + z_2 / (1 + \rho)^2 + \ldots + z_T / (1 + \rho)^T$$

As before the $z_t$ here are the successive terms, positive or negative, of the payments-receipts sequence associated incrementally with a particular project. In the special ‘deepening’ case illustrated in Figure 2, the corresponding concept under continuous compounding is defined implicitly in:

$$0 = -i_0 + V_t e^{-\rho t}$$

where once again the $V_t$ at any date is described by the productive opportunity curve $GG'$. Under these conditions $\rho$ represents an average compounded rate of growth. There has been some confusion between two quite different investment decision rules that both employ the internal-rate measure $\rho$: (i) choose projects so as to maximize $\rho$, versus (ii) adopt projects incrementally so long as $\rho > r$.

Maximum $\rho$ Rule
If the internal rate \( \rho \) is interpreted as the average rate of growth, it may seem plausible that the investor should maximize \( \rho \) rather than wealth \( W_0 \). (Of course, maximizing a growth rate would scarcely make sense unless the initial outlay or scale of investment were held constant, which would not in general hold true.) The solution of (7) that maximizes \( \rho \) is shown in Figure 2 as \( t=t^* \), notably earlier than the Present-Value solution \( t=t^* \).

In favour of \( B \) over \( r^* \) it has been argued that, if the growth opportunity were to be replicated in perpetuity, returns from choosing the earlier ‘rotation period’ \( B \) must ultimately dominate those associated with cutting on each cycle at \( r^* \). That is certainly true. However, if the decision problem concerns infinite rotation rather than a one-time cutting, for a valid comparison the relevant Present-Value measure would have to be a generalized one that allows for the associated infinite sequence of discounted returns. It can be shown that this generalized Present-Value does coincide with \( B \) if the growth opportunity can be reproduced on an ever-broadening scale (e.g. on new land) – but only as funds are freed by cutting the tree or trees. This turns out to be an impossible or uninteresting case, because it implies that the productive opportunity must be of infinite market value if the maximized \( \rho \) exceeds the market interest rate \( r \) (and of zero value otherwise). In contrast, if the opportunity is a unique one which cannot be reproduced after cutting, as pictured in Figure 2, the simple \( t=t^* \) solution remains correct. Another solution, \( t=F \), found by the German forester Faustmann, is appropriate when the opportunity can be reproduced over time by cutting and replanting but cannot be broadened in scale. \( F \) would be found by maximizing the Present Value \( V_0 \) of an infinite sequence of rotations, each being a constant-scale replication of the original opportunity. Like all the correct solutions, it is equivalent to maximizing the present worth of the opportunity under the stated assumptions. (\( F \) is not shown in Figure 2 but would lie between \( B \) and \( r^* \)).

**\( \rho \) vs. \( r \) Comparison Rule**

The Comparison Rule says to adopt any project whose internal rate \( \rho \) exceeds the market rate of interest \( r \). This rule remains popular in business practice, in part because it offers a convenient division of labour: calculation of the \( \rho \)'s on individual projects might be delegated to subordinates, while top decision-makers choose the cutoff rate \( r \) that corresponds to the relevant market interest rate faced by the firm. Unfortunately, however convenient such a decision of labour may be, once again this is not in general a correct method of project selection.

The difficulty with the Comparison Rule first came to be appreciated when it was discovered that a sequence of positive and negative cash flows could have more than one \( \rho \) serving as solution of equation (6) above. A project represented by the annual payments sequence \(-1, 5, -6\), for example, has two solutions: \( \rho =1 \) and \( \rho =2 \). (It can be shown that a project with \( T+1 \) dated elements may have as many as \( T \) solutions.) This of course destroys the idea that the internal rate can generally be identified with a growth rate; an outlay of one dollar cannot be said to grow at both 100% and 200%. Various answers have been offered to the puzzle of which \( \rho \) to use in such cases. But the difficulty is immediately explained and resolved if we think instead of terms of Present Value. It turns out that the sequence \(-1, 5, -6\) has positive \( V_0 \) (and is therefore worth adopting) for any constant market interest rate \( r \) between 100% and 200%, but at other values of \( r \) has negative Present Value (and should not be adopted). Perhaps even more illuminating is the project described by cash flows \(-1, 3, -2 \frac{1}{2}\). This sequence has no real solution for \( \rho \) in equation (6), the reason in Present-Value terms being that \( V_0 \) investment opportunity. After all, there is no justification for postulating (as is implicitly done by the Comparison Rule) that the anticipated sequence of market interest rates \( r_1, r_2, \ldots, r_T \) must be constant over time (always equal to a common \( r \)). It turns out that the cash-flow pattern \(-1, 3, -2 \frac{1}{2}\) has positive Present Value (i.e., the project would be worth adopting) for many possible non-constant interest-rate sequences – for example, \( r_1=100\% \) and \( r_2=200\% \).

Summing up, therefore, the Present-Value Rule for investment decision – corresponding as it does to the principle of maximizing wealth within the opportunities available – is correct itself and also serves to define the range of validity of all the other rules considered.

**Generalizations and Extensions**

The preceding analysis needs to be extended in at least two important ways, so as to allow for: (1) uncertainty, and (2) imperfect and incomplete markets.

**Uncertainty**

Investment choices, involving as they do present sacrifice for future benefit, are peculiarly sensitive to uncertainty. However, so long as we can continue to assume a regime of complete and perfect markets, the Present-Value Rule is robust enough to retain validity even in a world of uncertainty. For, the proximate goal of any individual (or group of individuals organized in a firm or other joint enterprise) will still be to undertake productive activities so as to maximize wealth. Having achieved that goal, each and every individual investor will be in a position to distribute his attained wealth as desired over all possible dated contingencies in accordance with his time-preferences, degree of risk-aversion, and
Economists use two main models for the analysis of uncertainty – state-preference and mean-versus-variability analysis. Since the latter, under certain assumptions, can be regarded as a special case of the former, for our purposes attention can be limited to the state-preference model. If markets for state-claims are complete and perfect, any pattern of varying returns over states of the world at a given date has a certainty-equivalent in value terms as of that date. In equations (3) and (3'), the $z_t$ for any project can now be interpreted as certainty-equivalents (rather than as simple cash flows) defined by:

$$z_t = P_t z_{t1} + P_t z_{t2} + \ldots + P_t z_{tS}$$

Here $z_t$ represents the cash flow at date $t$ contingent upon state of the world $s$ obtaining – there being $S$ distinguishable such states – while $P_t$ is the price at which a unit claim to income in state $s$ at date $t$ can be converted into (traded for) current certainty income.

Incomplete or imperfect markets

Markets are said to be incomplete if some objects of choice are non-tradeable. For example, futures markets for some commodities at far-distant dates do not exist, nor is it possible to trade in claims contingent upon each and every conceivable future uncertain event. Markets are said to be imperfect if there are costs of trading – for example, brokerage fees, transaction taxes, or expenses in locating exchange partners. Any real-world regime of markets will necessarily be both incomplete and imperfect, but for some purposes the assumption of complete and perfect markets may be a usable idealization. Unfortunately, once we depart from this idealization the problem of investment decision criteria becomes very difficult. The reason is that the Separation Theorem fails. Only under complete and perfect markets is the concept of wealth or Present-Value unambiguously defined, so that the choice of productive investments can be entirely disconnected from individuals’ personal time-preferences, risk-preferences, beliefs etc. Failure of the Separation Theorem particularly subverts the ability of investors to join together in undertaking large projects or groups of projects. However, two different lines of analytical approach have yielded results of interest. (i) A number of techniques have been devised for locating ‘utility-free’ or ‘efficient’ investment choices. In general such techniques cannot determine an optimal project set, but they can serve to filter out options whose payoff patterns over dates and/or states are dominated by other available projects or project combinations. (ii) While investors’ personal circumstances may diverge in innumerable ways, there should be some tendency for those similarly situated to group together. Thus, a firm whose investment opportunities yield far-future payoffs should tend to be owned by a ‘cliente’ consisting of individuals with moderate time-preferences, willing to forego current dividends in the hope of large long-term gain. It follows that unanimity as to the investment choices to be made may after all govern within the firm, for example as to the discount rate to employ in calculating Present Value, even in the absence of perfect and complete markets.

Bibliography

The modern theory of investment and intertemporal choice was set down in classic form by Irving Fisher as part of his great works on interest (1907, chapters 8–9; 1930, chapters 10–13). The seminal works on uncertainty theory include Arrow (1953) for the state-preference approach and Markowitz (1959) and Sharpe (1964) for the mean-versus-variability model. Choice over time and choice under conditions of uncertainty are integrated in the treatise by Hirshleifer (1970) that builds upon these foundations. All these topics have been followed up in an enormous literature, of which only a few illustrative instances can be cited here: on investment decision formulas, Samuelson (1976); on utility-free or dominant choices, Pye (1966), Hanoch and Levy (1969), and DeAngelo (1981). A survey of investment decision criteria used in current business practice appears in Schall, Sundem, and Geijsbeek (1978).

invisible hand

Mark Blaug
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Adam Smith employed the term ‘invisible hand’ twice in his published writings, and a considerable secondary literature has explored the multiple meanings he intended to convey by the use of this metaphor. I argue that, whatever he did mean, he certainly did not mean that competition or the market mechanism promoted efficiency: instead it promoted the growth of income, even for the poor.

Article

The ‘invisible hand’ was a metaphor used by Adam Smith to describe ‘the principle by which a beneficent social order emerged as the unintended consequence of individual human action’. This is Vaughn's succinct summary of Smith's intentions in employing the metaphor (1987, p. 997). More recently, Grampp (2000) has reviewed nine different interpretations of the famous metaphor, concluding that the three references to the invisible hand in Smith's works are not expressions of the same concept, an opinion share by many other commentators.

Smith referred to the ‘invisible hand’ twice in his published writings (there is a third reference in his unpublished ‘Essay on Philosophical Subjects’), and he did so at greatest length in Book IV, Chapter 2, of the Wealth of Nations. It is easier to say what he did not mean by the invocation to the ‘invisible hand’ than to spell out precisely what he did mean. What he definitely did not mean is the so-called first fundamental theorem of modern textbook welfare economics, although that reading has been frequently
ascribed to him (for example, Arrow and Hahn, 1971, p. 1; Mas-Colell, Whinston and Green, 1995, pp. 308, 327, 524, 545, 549). The first fundamental theorem states that, subject to certain exceptions such as externalities, economies of scale, public goods and imperfect information, every competitive equilibrium is Pareto-optimally efficient. It is indeed possible to find statements in Chapter 2 of the Wealth of Nations on mercantilism that appear to endorse something like the first fundamental theorem. Capitalists have a preference for domestic over foreign investment for reasons of security, Smith asserts, but the result of the free movement of capital is nevertheless of benefit to society as a whole:

As every individual, therefore, endeavours as much as he can both to employ his capital in support of domestic industry, and so to direct that industry that its produce may be of the greatest value; every individual necessarily labours to render the annual revenue of the society as great as he can. He generally, indeed neither intends to promote the public interest, nor knows how much he is promoting it. By preferring the support of domestic to that of foreign industry, he intends only his own security; and by directing that industry in such a manner as its produce may be of the greatest value, he intends only his own gain, and he is in this as in many other cases, led by an invisible hand to promote an end which was no part of his intention. (Smith, 1776, pp. 455–6).

The natural interpretation of this passage is, at least for domestic industry, that total product is maximized by free competition. This is almost the first fundamental theorem – but not quite. First, a presumption of maximization is not a mathematical theorem and, secondly and more significantly, free competition or free unrestricted entry into industries is a far cry from perfect competition without which the notion of the price-taking behaviour of numerous, small competitors, adjusting only the quantities they buy or sell, falls to the ground. Cournot invented the concept of perfect competition de novo in 1838 and, since the proof of the first fundamental theorem absolutely requires the concept of perfect competition, the idea that Adam Smith somehow stated a primitive version of the first theorem must be wrong; it is in fact a historical travesty.

Adam Smith clearly believed in competition, or rather ‘the simple system of natural liberty’, but his idea of competition was a behavioural one, not defined by the number of firms in the market as in Cournot. Competition, for Smith as for all the classical economists, implied rivalry by price and non-price means, rivalry among consumers bidding for a limited supply and rivalry among producers to dispose of that supply on the most advantageous terms. In other words, he had what I have called a ‘process conception of competition’, nowadays associated with Austrian economics, in contrast to the orthodox conception of economics, in which all the emphasis is directed to the nature of the final equilibrium, regardless of how that final equilibrium is attained (Blaug, 1997, p. 678; see also Coase, 1997, p. 318; Kirzner, 2000). Although the first theorem cannot be found in the Wealth of Nations, what can be found is the notion that competition has desirable properties, namely, that it promotes the rate of growth of national income or what he labelled ‘the wealth of nations’, which results in the material improvement of the standard of living even of the poorest members of society. This idea is not only the mainspring of the famous opening chapter of the book on ‘The Division of Labour’ in the pin factory, but it accounts for the emphasis on capital accumulation and the crucial distinction for Smith's theory of economic growth between ‘productive and unproductive’ labour in Book II, not to mention the content of the whole of
Book III with its revealing title ‘The Different Progress of Opulence in Different Nations’, which translated into modern jargon reads ‘On Differences in the Growth Rate of Different Countries’. Much of Book III is devoted to persuading the reader that there had been material progress since Elizabeth I, a thesis which surprisingly was frequently denied at the time. In short, what was good about what he called ‘the commercial society’ was that it grew rapidly, not that it was efficient, a term and indeed a concept that never appears in the *Wealth of Nations*.

Smith’s references to an ‘invisible hand’ in the *Wealth of Nations* have attracted an enormous secondary literature (for example, Hayek, 1973, ch. 2; Vaughn, 1987; Persky, 1989; Grampp, 2000; Rothschild, 2001, pp. 116 ff; Streissler, 2003, Minowitz, 2004; Vivenza, 2005), no doubt because they express three closely connected but separable ideas: (a) the private actions of individuals can have unforeseen and unintended social consequences; (b) these private self-interested actions and unintended social consequences may be harmonious in mutually promoting the interests of all members of society; and (c) there is an order in these harmonious outcomes as if private self-interested actions were centrally coordinated to produce a coherent overall pattern. This is a profound assembly of ideas that captures the doctrine of ‘spontaneous order’ employed by many thinkers of the Scottish Enlightenment to explain the emergence of such social institutions as language, the law, private property, the monetary system and even the market mechanism itself, not by central design or collective regulation but by individual action undertaken for quite different reasons. It arises most clearly in Adam Ferguson’s *Essay on the History of Civil Society* (1767), published a decade before the *Wealth of Nations*, and even earlier in Hume’s *Treatise of Human Nature* (1740). But important as the idea of a ‘spontaneous order’ may have been to Ferguson and Hume, as well as to Mandeville, Turgot and Dugald Stewart, it was not actually in the forefront of Adam Smith’s thinking and, in any case, he never characterized the price system or even free competition as an ‘invisible hand’. This is a modern reading of Smith under the influence of Walras and Pareto as translated by Arrow and Debreu.

It was only in the last quarter of the 19th century (as a result of German critics of Smith) that the phrase ‘invisible hand’, which after all occurs only once in the *Wealth of Nations*, was elevated to a proposition of profound significance. Rothschild deals expertly with the subject and concludes that ‘the image of the invisible hand is best interpreted as a mild ironic joke’ (2001, p. 116). This may be going a little too far in the opposite direction to the now prevailing interpretation, but there is no doubt that Smith himself did not attach great importance to the idea of an invisible agency channelling the behaviour of self-interested individuals and instead regarded the metaphor of the invisible hand as a sardonic, if not ironic, comment on the self-deception of all of us, including moral philosophers.

Support for this view of his intentions is found in the one reference to the ‘invisible hand’ in *The Theory of Moral Sentiments*, a reference that is frequently ignored in the exegetical literature on Smith. In that passage in the *Theory of Moral Sentiments* (1759, 184–5) Smith argues that mankind has progressed in the face of pronounced and persistent inequalities and that the rich, despite their natural selfishness, end up unintentionally sharing their wealth with the poor, who for their part end up no worse than the rich themselves. Both Grampp and Minowitz, alone among all the Smithian commentators, object to this conclusion as too Panglossian. Be that as it may, this passage soon dispels the belief that Smith meant one thing and one thing only by the metaphor of ‘the invisible hand’.

The notion of a spontaneous order in the sense of a self-regulating system accounting for the existence of economic institution went underground after the Scottish Enlightenment, and references to an ‘invisible hand’ are rarely encountered in any of the classical economists, although the idea that
economics studies an underlying invisible reality beneath the surface appearance of a free market economy continued to dominate the thinking of Ricardo, J.S. Mill and particularly Karl Marx.

involuntary unemployment

John B. Taylor
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
aggregate demand; efficiency wages; frictional unemployment; incentive wages; involuntary unemployment; labour supply; marginal rate of substitution; matching; minimum wages; natural rate of unemployment; nominal wages; non-accelerating inflation rate of unemployment (NAIRU); optimal contracts; real business cycles; real wages; search theory; staggered wage setting; sticky wages; unemployment; unemployment measurement; wage differentials; wage rigidity

Article
The most common and analytically useful definition of involuntary unemployment is based on the labour supply curve: if workers are off the labour supply curve – so that there is an excess supply of labour at the current real wage – then, by definition, there is involuntary unemployment. The amount of involuntary unemployment is equal to the amount of excess labour supply. If workers are on the labour supply curve, then, by definition, there is no involuntary unemployment. One could analogously define involuntary overemployment as a situation of insufficient supply of labour at the prevailing real wage (as may occur during wartime with wage and price controls), but the term is seldom used.

In a static, deterministic, utility maximization framework, the labour supply curve is simply the set of real wage and employment pairs for which the marginal rate of substitution of income for leisure is equal to the current real wage. Hence, involuntary unemployment can be equivalently defined using the utility function: if the real wage is greater than the marginal rate of substitution of income for leisure, then, by definition, there is involuntary unemployment. If the marginal rate of substitution of income for leisure is equal to the real wage, then there is no involuntary unemployment.

Historical examples of usage
This definition of involuntary unemployment is very close to that used by Keynes (1936). In Chapter 2 of the General Theory, Keynes writes ‘… the equality of the real wage to the marginal disutility of
involuntary unemployment: The New Palgrave Dictionary of Economics

employment … corresponds to the absence of “involuntary” unemployment’ (p. 15). (Keynes makes the simplification that the marginal utility of income is constant, so that the marginal disutility of employment is the same as the marginal rate of substitution of income for leisure.) Keynes excluded frictional unemployment from involuntary unemployment. However, it is important to note the Keynes also excluded unemployment ‘due to the refusal or inability of a unit of labour, as a result of legislation or social practices or of a combination for collective bargaining or of a slow response to change or of mere human obstinacy, to accept a reward corresponding to the value of the product attributable to its marginal productivity’ (Keynes, 1936, p. 6). Thus, Keynes chose to exclude union wage differentials as well as minimum wage legislation as sources of involuntary unemployment. Clearly, Keynes wanted to focus on a particular type of involuntary unemployment.

Patinkin (1965, ch. 13) also used the static labour supply definition in his well-known analysis of involuntary unemployment:

The norm of reference to be used in defining involuntary unemployment is the supply curve for labor … as long as workers are ‘on their labor supply curve’ – that is, as long as they succeed in selling all the labor they want to at the prevailing real wage rate – a state of full employment will be said to exist in the economy. (pp. 314–15)

Although Keynes developed and emphasized the idea of involuntary unemployment much more than economists had done before, the above definition based on the labour supply curve predates Keynes writings. In fact it was used by the ‘classical’ economists. For example, in 1914 Pigou proposed measuring involuntary unemployment of a group of persons by the number of hours’ work by which employment ‘… falls short of the number of hours’ work that these persons would have been willing to provide at the current rate of wages under current conditions of employment’ (see Casson, 1983, p. 39).

According to Keynes, however, classical theories (such as Pigou's) did not admit the possibility of involuntary unemployment. Unemployment of a particular group caused by union wage differentials or minimum wage legislation was admitted by the classical theory, but as mentioned above Keynes chose to classify this as voluntary.

Criticisms of the definition of involuntary unemployment

Despite the analytical simplicity of the above definition based on labour supply, the term involuntary unemployment has resulted in many critiques and controversies. One of the criticisms stems from simple conflicts between the above technical definition and everyday non-technical usage of the term involuntary. For example, Fellner (1976) wrote, ‘… distinguishing elements of voluntariness from elements of involuntariness in the unemployment problem is a hopeless endeavour …’ (p. 134) and that ‘Keynes’ definition is unhelpful and so are all variants inspired by that definition’ (p. 53). Fellner and others have been concerned that one can never determine the intentions of a given unemployed person so that the broad classification of unemployment into involuntary and voluntary is meaningless.

Although the many connotations of the term involuntary may cause semantic difficulties (as may other concepts in economics such as ‘rational’ or ‘marginal’), focusing on the technical definition given above would seem to avoid these difficulties.
A second criticism arises in the practical use of the concept of involuntary unemployment for public policy. From the above definition, one criterion of good macroeconomic performance would be zero, or very small, involuntary unemployment. (Strictly speaking, this is true only if the measured real wage is equal to the marginal productivity of labour, an equality that might not hold if optimal contracts of the type described below are important in the economy.) Since government unemployment statistics are commonly taken as an indicator of economic performance, one might hope that measured unemployment could be related to the concept of involuntary unemployment. However, this is very difficult and any attempt is bound to be criticized. Government unemployment statistics typically attempt to measure the number of unemployed who are looking for work, but who have not yet found work. However, aside from the problem of determining whether someone is looking for work, or how intensively, unemployment statistics obviously include frictional unemployment and other types of unemployment that would not be included as involuntary according to the above definition. Even in a condition of relatively full employment, there exists some ‘normal’ unemployment, which government statistics need to be corrected for. Milton Friedman (1968) used the term ‘natural’ unemployment for the amount of unemployment that would exist, without excess supply, in equilibrium after wages and prices have adjusted. Another concept of normal unemployment is the non-accelerating inflation rate of unemployment (NAIRU), defined as the amount of unemployment that would exist when there is no tendency for wage or price inflation to rise or fall. Measuring the ‘natural’ rate or NAIRU in practice entails looking for an unemployment rate for which inflationary pressures are small and adjusting this rate for known changes in the demographic characteristics of the labour force. The natural rate of unemployment is not a constant, however, and these measurements have considerable error. Nevertheless, a practical alternative to involuntary unemployment as a measure of economic performance is the difference between the actual unemployment rate and the natural unemployment rate. For policy purposes, this may serve as a reasonably close approximation to involuntary unemployment, but clearly it is a different concept. In particular, note that this measure can be negative, as when the unemployment rate falls below the natural rate in boom times. Fellner (1976) suggested focusing on this measure and hence on inflation stability, rather than on involuntary unemployment, and he argued that demand management (monetary and fiscal policy) should promote the maximum amount of employment that can be achieved without inflation instability. This measure is also the criterion used in stabilization studies that characterize a macroeconomic trade-off in terms of the fluctuations of unemployment about the natural rate versus the fluctuations in inflation (see Taylor, 1980).

A third reason for criticism of the term involuntary unemployment is that the standard definition is essentially static and deterministic. In fact, the static, deterministic labour supply and demand model does not admit an explicit theory of frictional or natural unemployment. Without such a model it is difficult even to discuss whether a given level of unemployment is voluntary or optimal or not. Research on the microfoundations of unemployment (see for example Phelps et al., 1970), had as a major goal the development of a model of equilibrium unemployment – using search and matching theory. Some search models generated unemployment that was Pareto optimal (see Lucas and Prescott, 1974, for example), but others included trading externalities and generated unemployment which could be non-optimal (see Diamond, 1982, for example). While not yet definitive, at least this research shows that for many public policy questions it is necessary to go beyond the simplest model of labour supply, and thereby beyond the simple definition of involuntary unemployment.
In the *General Theory* Keynes presented a more convoluted definition of involuntary unemployment, and this has been a fourth source of controversy. According to Keynes (1936, p. 15),

> Men are involuntarily unemployed if, in the event of a small rise in the price of wage-goods relatively to the money-wage, both the aggregate supply of labour willing to work for the current money-wage and the aggregate demand for it at that wage would be greater than the existing volume of employment.

One can clearly envisage a point off the labour supply curve from this definition. However, there is much more. Embedded in the definition of involuntary unemployment are some of Keynes's other ideas that were part of his *theory* of involuntary unemployment, but logically distinct from the *definition* of involuntary unemployment. Within the definition it is noted that workers would be willing and able to have a reduction in their real wage (and still increase their work) if it occurred through an increase in the price level, but not if it occurred through a decline in the nominal wage. This ‘stickiness’ of nominal wages, which is generated as part of the market mechanism, is of course crucial to Keynes's theory. Also embedded in the definition is the assumption that firms are in their labour demand curve, so that a lower real wage would stimulate unemployment, an idea that is much less crucial for Keynes's ideas, as Leijonhufvud (1968) has emphasized. Why did Keynes emphasize this convoluted definition of involuntary unemployment? It seems clear that he wanted to highlight the crucial difference between his theory of unemployment and what he called classical theory. This difference centred on the inability, given the way labour markets and the whole economy interact, of individual workers to reduce unemployment simply by reducing nominal wages. As indicated above, Pigou based the definition of involuntary unemployment on the labour supply curve in much the same way that Keynes did, but the classical reason for its existence – simply that real wages were too high – was much different from the theory of deficient aggregate demand put forth by Keynes. In retrospect Keynes would have added clarity to his discussion by unbundling his theory and his definition of involuntary unemployment.

### Implications of recent technical research for the concept of involuntary unemployment

Five research developments since the 1960s have had great relevance for the concept of involuntary unemployment: equilibrium macroeconomics, optimal contract theory, disequilibrium macroeconomics, efficiency or incentive wage theory, and staggered-wage setting theory. However, this relevance must be inferred from the research, because the term involuntary unemployment is seldom used explicitly, and perhaps avoided by many recent researchers.

#### Equilibrium macroeconomics

One strand of research macroeconomics has established a strategy of trying to explain the observed fluctuations in unemployment by equilibrium models in which workers are always on their labour supply curves. Wages and prices are perfectly flexible, and all markets clear in these models. Lucas and Rapping (1969) and Kydland and Prescott (1982) represent some of the seminal work in this strand of research. Clearly if these models turn out to be successful and to dominate other models, then the idea of
involuntary unemployment would become useless for macroeconomics. Shifts of the labour supply curve—caused by intertemporal substitution of labour supply in response to temporary actual or perceived fluctuations in the real wage—are the main source of employment variability in these models. Research in this area is continuing and branching out into ‘real business cycle’ theory which ignores monetary factors in the cycle altogether. It appears, however, that a very high labour supply elasticity—by the standards of recent microeconomic empirical research (see MaCurdy, 1981)—is required for these models to be able to explain the observed fluctuations in employment.

Optimal contract theory

Studies by Azariadis (1975), Baily (1974) and others attempted to explain why involuntary unemployment would arise when there exist optimal contracts between firms and workers stipulating for fixed wage payments. However, when firms and workers have equal access to information, these studies have shown that, in the relevant sense, involuntary unemployment does not exist despite the fixed wage bill. In these optimal contract models the marginal rate of substitution of income for leisure is equal to the marginal productivity of labour—the condition for the optimality—in all possible states. Although workers are off their labour supply curve ex post (since the real wage is not necessarily equal to the marginal rate of substitution), this discrepancy has no welfare significance. Models in which firms have more information than workers about the nature of the shock can lead to a breakdown in the marginal conditions for optimality, but unless firms are more risk averse than workers the result is involuntary over-employment: the marginal productivity of labour is less than the marginal rate of substitution of income for leisure (see Green and Kahn, 1983, and Grossman and Hart, 1983). Viewed as an attempt to explain involuntary unemployment this research, therefore, has been unsuccessful. Taken literally, it shows that much of the unemployment that may have appeared as involuntary is, in fact, voluntary or at least efficient!

Disequilibrium theory

Malinvaud’s (1977) careful examination of fixprice multimarket equilibria, following the tradition of Clower (1965) and Barro and Grossman (1971), has greatly helped to clarify the conceptual difference between Keynes’s explanation of involuntary unemployment due to insufficient aggregate demand (where firms are constrained in product markets), and the classical unemployment associated with the real wage being too high (where firms are not constrained in product markets). This research also has had considerable policy relevance in the early 1980s because the high rates of unemployment in western Europe were diagnosed as classical rather than Keynesian by many economists.

Efficiency or Incentive Wages

Calvo (1979) and others have argued that involuntary unemployment can occur because high wages must be paid to give workers the incentive to work hard, to be productive, and not to shirk. As firms attempt to bid up their wages relative to other firms, an equilibrium is reached with all firms paying more than the wage in the absence of incentive effects and with involuntary unemployment: an excess
supply of labour with unemployed workers willing to work at the going wage. This type of unemployment is not of the deficient demand type emphasized by Keynes, and given Keynes's willingness to lump other minimum wage unemployment in with frictional unemployment, it is likely that Keynes would have classified this type of unemployment as voluntary. Incentive wages would increase the normal unemployment (natural or NAIRU) rate, but there is little empirical evidence of how quantitatively important the effect is.

**Staggered-wage setting theory**

In these models (see Taylor, 1980, for example), wages are set with an aim to maintain relative wages unless there is a reason for relative wages to adjust. This relative wage setting leads average nominal wages to adjust with a lag described by a predictable dynamics to changes in demand. In these models prices are set as a markup over wages, and for this reason aggregate prices are almost as sticky as nominal wages. Combined with an elementary model of aggregate demand and an aggregate demand policy that does not fully accommodate inflation, these models are designed to be compared directly with the data and in fact lead to fluctuations in unemployment which have features similar to the real world. The unemployment in these models comes close to the usual definition of involuntary unemployment, but since explaining empirical regularities is a primary objective, unemployment enters the model directly as the deviation of unemployment from the natural rate – a more readily measurable quantity than involuntary unemployment. These models show that wage rigidities need not be very long to generate the type of fluctuations in unemployment that characterize the business cycle. Like the equilibrium models discussed above, and unlike the other three research developments described above, these models are dynamic and can therefore be directly tested against time series data.

Although there has been a tendency for much recent research to avoid the term involuntary unemployment, and instead to define unemployment as appropriate to the theoretical or empirical objectives of the research itself, the term involuntary unemployment will probably continue to be used. Despite the criticism and controversy discussed above there is little harm in this usage, as long as the technical definition is emphasized. Its usage may encourage researchers to point out the connection of new results to past achievements.

Ireland, economics in

Tom Boylan and Renee Prendergast

Abstract

This contribution provides an overview of Irish economic thought from the 17th to the late 20th century. Broadly speaking, the pioneering contributions of the 17th and 18th centuries were concerned with the issue of improvement or economic development. The 19th century saw the formal institutionalization of political economy in Ireland and seminal contributions to value, distribution, and international trade theory in addition to work on public finance and methodology. The achievement of independence in the 20th century led to new concerns with development and policy experiments aimed at promoting lasting growth.

The 17th and 18th centuries

William Petty and Richard Cantillon are commonly regarded as the founders of classical political economy. Both had connections with Ireland. Petty, English by birth, came to Ireland with the Cromwellian army in 1652 and became interested in ‘political anatomy’ in the course of surveying the country in preparation for the confiscation of Irish lands. Cantillon was born in Ireland but spent his adult life in as a banker in Paris, where he wrote what many regard as the first systematic treatise on economics. Despite his nationality and his importance, Cantillon's work is not considered here. It was not written in Ireland; it was neither inspired by Irish conditions nor known to contemporaries living in Ireland.

*Political Anatomy of Ireland,* written in 1671–2, was Petty's first attempt to uncover the symmetry, fabric and proportion of the body politic by means of political arithmetic. Like all of Petty's writings, it contains pregnant theoretical suggestions, but our interest here is in its systematic approach to economic development. Petty sought to identify Ireland's development potential by considering the distribution and value of land and by estimating the number of ‘spare hands’ who could potentially add to local or universal (tradable) wealth. Petty identified the main causes of Irish underdevelopment as constraints on Ireland's trade with England and the plantations, insufficient coin, underdeveloped consumption patterns, perceived illegitimacy of rulers, rent-seeking and low population density. Petty's proposed remedies as set out in a *Report of the Council of Trade in Ireland,* 25 March 1676, included regularization of money, restoration of trade with the plantations and (particularly the cattle trade) with England, a bank based on landed property as security, reformation of the housing of the poor, legislative union with England and later the transportation of large numbers from Ireland to England. Despite a reference to discountenancing the use of certain foreign commodities in the report, Petty seems not to have favoured protection, arguing in *Political Anatomy* that the proceeds of exports would be more than sufficient to pay for imported products.

Partly as a result of prohibitions on the export of live cattle to England, farmers turned their attention to sheep, with the result that towards the end of the 17th century Irish wool and woollen yarn were among its most important exports. This promising development was nipped in the bud by restrictions introduced under the Wool Acts of 1698–9. This added to the fragility of an already weak economy, resulting in widespread poverty and unemployment in the early decades of the 18th century. Despite their confused and somewhat contradictory Irishness, the new generation of planter stock, including the likes of Prior, Dobbs, Browne, Molesworth, Hutcheson, Swift and Berkeley, responded with a steady stream of pamphlets advancing various proposals for improvement. These included increased agricultural investment, drainage and reclamation of bogs, improvement of inland waterways, encouragement of sea fisheries, mining and manufacturing, the setting up of a mint, consumption of locally produced goods, taxation of absentee rents, removal of restrictions on foreign trade and deportation of the undeserving poor (Kelly, 1991). The main differences were between those such as Browne and Berkeley, who were relatively positive about Ireland's development prospects, and those such as Swift, who believed that plausible sources of improvement had little realistic chance of being implemented by those with the power to do so. Swift's position was vigorously expressed in *A Modest Proposal* (1729), a powerful
satire on the pamphlet literature of his own time and one of the most telling critiques of positive
economics ever to have been written anywhere.
While most authors emphasized the need to remove the constraints on trade, Berkeley argued that it
would be more prudent to concentrate on those branches which were permitted, including Ireland's
domestic trade (Berkeley, 1752). Development would be possible even if the country were surrounded
by a wall of brass. This, however, would require the substitution of domestically produced goods for the
imported luxuries consumed by the elite as well as an expansion of the wants of the poorer classes in
order to make them industrious. An argument for the reform of consumption patterns had already been
made in 1726 by Francis Hutcheson in his ‘Remarks upon the Fable of the Bees’ in the course of
controverting Mandeville's claim that luxury and vice were inseparable from economic development.
Berkeley, who was also an implacable adversary of Mandeville, was even more emphatic than
Hutcheson in his opposition to luxury, and he showed himself willing to contemplate sumptuary laws to
achieve this objective. While Berkeley's proposals for development on the basis of the domestic market
were innovative at the time, his most radical proposals related to the adoption of paper money and the
setting up of a national bank. Real wealth, Berkeley argued, consisted not in gold or silver but in the
plenty of the necessaries and comforts of life and the power to command the industry of others. Money
was simply a ticket or a counter for conveying or recording such power. As such, paper money and bank
deposits were perfectly adequate and had some advantages over coin. The ruinous effects of the
Mississippi and South Sea schemes were not due to paper money as such but to its use for speculative
purposes rather than as a catalyst of industry. Private banks being subject to frauds and hazards,
Berkeley proposed the setting up of a public bank, which he assumed would not suffer from these
disabilities. The radicalism of Berkeley's position can be appreciated if we bear in mind that support for
a fiduciary credit system as opposed to metallic money was in his time very much a minority view and
remained so until recently (Murphy, 2000).
The recovery of the Irish economy which took place in the second half of the 18th century was partly
due to the success of the linen industry, which had been encouraged as a replacement for wool, and
partly to the gradual weakening of commercial restrictions as Britain's population grew and Ireland
became an important source of food and agricultural raw materials. During a brief period of legislative
independence from 1782 to 1800, the Irish Parliament took steps to encourage domestic industry with
various protective measures. It also introduced a corn law to encourage corn production for the British
market.

The 19th century
Following the Act of Union in 1801, Ireland was assimilated into the administrative and political
jurisdiction of the United Kingdom. Many of its newly established industries went into gradual decline
and corn production became a major source of employment. Population increased and with it poverty
culminating in the Great Famine of 1845–50. These conditions influenced developments in political
economy in Ireland and elsewhere. The need to counter the argument that high rents were a major cause
of Irish poverty was a catalyst for the development of Malthus's rent theory (Prendergast, 1987). The
attention devoted by John Stuart Mill to the incentive effects of different forms of land tenure was partly
a response to Irish land conditions. The scale of the human tragedy of the Irish famine influenced the
perception and standing of laissez-faire political economy in Ireland and elsewhere. Irish economists
became pioneers of the Historical School, which emphasized the specificity of time and place. The formal institutionalization of political economy in Ireland began with the establishment of the Whately Chair in Trinity College in 1832. The chair was funded by Richard Whately, the Protestant Archbishop of Dublin, who came to Ireland from Oxford in 1831. The chair was part of a larger crusade by Whately to promote the dissemination of political economy with a view to encouraging more economically responsible behaviour. The Whately chair was to be filled by a number of outstanding occupants, which included Mountifort Longfield, John Elliot Cairnes and Charles Bastable. Chairs in jurisprudence and political economy were also established in the new Queen's colleges set up in at Belfast, Cork and Galway in 1845 (Boylan and Foley, 1993). Outside of the universities, the principal institutional development was the founding in 1847 of the Dublin Statistical Society, later the Statistical and Social Inquiry Society of Ireland, which had Whately as its first president (Daly, 1997). The society aimed at ‘promoting the study of Statistical and Economical Science’ and its participants included the academic, administrative and professional elite of Irish society. By the mid-19th century an extensive institutional infrastructure for the teaching and dissemination of political economy was in place (Boylan and Foley, 1992).

Irish political economists in the 19th century made original contributions to a number of theoretical areas within the discipline. In value theory, the seminal contribution of Longfield, the first holder of the Whately Chair, has received considerable attention and is recognized as providing one of the earliest attempts at formulating a subjective theory of value (Moss, 1976). A number of Longfield's immediate successors, including Isaac Butt, James Anthony Lawson and William Neilson Hancock, also subscribed, albeit in a limited way, to a subjective theory of value, which led R.D.C. Black (1945) to suggest that the early Whately professors constituted a ‘Dublin school’ of subjective value theorists who anticipated by 30 years the marginal revolution of the 1870s. Longfield's contribution contained in his Lectures on Political Economy (1834) is by far the most original offering reflecting his disagreement with the dominant Ricardian framework of analysis in value and distribution theory.

Longfield approached value and distribution as pricing problems. The theory of value, in which commodity prices were determined in markets by supply and demand, was at the centre of his analysis. Longfield did not neglect the influence of cost on market price through changes in supply, but his main emphasis was on demand. The concept of a demand schedule was introduced, in which market demand was conceived as a ranking of individual demands according to their intensity, where ‘the market price is measured by that demand, which being of the least intensity, yet leads to actual purchases’. Longfield invoked the concept of the individual's demand schedule as being composed of ‘several demands of different degrees of intensity’ (Longfield, 1834, pp. 113, 114). This is now interpreted as a seminal statement, foreshadowing the principle of marginal utility that was to find its more formal articulation in the marginalist writers of the 1870s.

Though not a member of the Dublin ‘school’, William Edward Hearn's Plutology: Or the Theory of the Efforts to Satisfy Human Wants (1863) was a significant contribution to the debate on the subjective theory of value. Hearn was appointed the first Professor of the Greek Language in Queen's College Galway in 1849. He left Galway in 1854 and became Australia's first professor of economics (Boylan and Foley, 1984b). Plutology contained an extended and sophisticated taxonomy of the different kinds and degrees of human wants. Hearn went on to examine how demand could influence the impact of changes in the cost of production for different kinds of commodities; he distinguished between the
demand for essential commodities or ‘necessities’ and non-essential or ‘superfluities’. In this analysis Hearn provided a valuable extension to Longfield's earlier contribution, which was well regarded by contemporaries and later writers including Jevons and Marshall.

If Longfield and the Dublin ‘school’ represented an anti-Ricardian position in value and distribution, the Ricardian tradition was powerfully represented by Cairnes, the sixth holder of the Whately Chair at Trinity from 1856 to 1861 and Professor of Jurisprudence and Political Economy at Queen's College Galway from 1859 to 1870. Cairnes was arguably the most distinguished of the 19th-century Irish academic economists, and contributed to a number of areas of economic theory and contemporary policy issues. Cairnes was a close personal friend of J. S. Mill and was strongly influenced by Mill's analysis, but he produced a more complicated version of the theory of value than Mill. In *Some Leading Principles of Political Economy Newly Expounded* (1874), Cairnes provided a cost-of-production theory of value. But it is clear not only that Cairnes's ‘normal value’ is to be identified as cost of production, but that cost should be interpreted as real cost or sacrifice. In the course of his analysis he made the innovative move of applying Mill's proposition of the determination of international values by reciprocal demand in the case of factor immobility between countries to the internal economy of a country. In the latter situation, the existence of internal factor immobility gave rise to what is arguably Cairnes's most original application of the concept of non-competing groups. Cairnes's tenure in the Whately Chair broke the intellectual continuity of the Dublin ‘school’ by virtue of his commitment to the Ricardo–Mill approach.

In the domain of distribution theory one of the most interesting contributions was made by William Thompson (1775–1833), an Owenite and supporter of the French Revolution. Thompson pursued the aim of formulating an alternative economic system based on the rights of the primary producer. He emerged as the most analytical and original thinker of the Owenite movement, which later became identified with the Ricardian socialists. Thompson was a personal friend of Bentham and it has been argued that Thompson's originality as a thinker consisted in his appropriation of the greatest happiness principle as a basis for fundamental social reform (Duddy, 2002). While radical utilitarianism provided him with a critical component of his rationale for social reform, it was the adoption of Owen's system of mutual cooperation by Thompson, as a model of social organization, that would deliver to individual primary producers the fruits of their labour, which was fundamental to the Ricardian Socialists’ doctrine. In contrast to the Irish contributions to the Ricardian tradition of distribution theory, Longfield was forging a rather different approach in his *Lectures on Political Economy* of 1834. As Moss (1976) has argued, if the classical economists found the unifying principle for their theories of distribution in the concept of cost of production on the supply side, then Longfield could be said to have discovered his unifying principle of factor pricing in his supply and demand analysis. His identification of the role of marginal demand in the commodity market and marginal productivity in the factor market, justifies Longfield's claim as one of the leading progenitors of the neo-classical marginal theory of commodity and factor pricing.

In the area of international trade, the originality of Irish economists matched their contribution to value and distribution theory. In his *Three Lectures on Commerce and One on Absenteeism* (1835), Longfield extended the theory of comparative cost in significant directions, including the addition of both the multi-commodity and multi-factor case. He also addressed the issue of the incidence of tariffs and traced their effects on the relative price ratios between trading countries. Isaac Butt, Longfield's successor in the Whately Chair, considered the case for protection in his *Protection to Home Industry: Some Cases of Its
Advantages Considered (1846). This work, which was influenced by conditions in Ireland, was both methodologically engaging and analytically perceptive in its assessment of the benefits and weaknesses of protection in the context of particular circumstances.

Cairnes's reputation in the area of international trade rests on his systematic integration of the concept of non-competing groups into his analysis. This allowed him to distinguish between the role played by costs of production in determining international prices where effective competition existed; but where competition was absent, as in the case of non-competing groups, the fundamental determinant of international prices was not costs of production but reciprocal demand between non-competing groups. He also provided an account of the factors determining the movements and range of a country's prices and money incomes arising from international trade, along with an original analysis of the process of international borrowing and the effects of loans on the equilibrium of international trade. This contribution that has been described as ‘perhaps of greater permanent merit than any of his doctrines’ in this area (Angell, 1926, p. 94).

If the early and middle parts of the 19th century are associated respectively with the writings of Longfield and Cairnes, the latter part of the century must be identified with the work of Charles Bastable, who occupied the Whately Chair for 50 years, from 1882 to 1932. Bastable's Public Finance, first published in 1892, was a pioneering treatise that integrated, for the first time since McCulloch's Taxation and the Funding System (1845) what had become a rapidly expanding field of enquiry. Reviewing Public Finance in the Economic Journal, L.L. Price (1892) suggested it was the most comprehensive treatment of the topic since Adam Smith's Wealth of Nations. Bastable also made important contributions to international trade. In The Theory of International Trade (1887), he introduced varying elasticities of demand, increasing and decreasing returns and an extended analysis of obstacles to competition. In The Commerce of Nations (1892), he provided a stringent critique of protection, while his name is associated with the celebrated ‘Mill–Bastable’ condition, which became an important part of the extended analysis of protection (Chipman, 1965).

A distinguishing characteristic of many Irish economists in the 19th century was their commitment to an inductive method of approach. This was certainly true of the early Whately Professors. Isaac Butt maintained a robust scepticism with respect to the generality of economic principles, while Lawson was highly critical of Senior's efforts to reduce political economy to an axiomatic basis. It was not that the Irish writers called into question the validity of the deductive method in political economy. Rather, their position was that empirically observed facts should provide the basis for deductive reasoning. The methodological bias towards the inductive approach has been linked to the fact that the majority of the Irish professors were lawyers by training and profession and this allied to the preoccupation with the land question influenced their concentration on detailed studies of applied issues (Black, 1947). Two of the most important representatives of the inductive approach were Thomas Edward Cliffe Leslie and John Kells Ingram. Both were major figures in the English-speaking world as pioneers of the Historical School of political economy. They were critics of the classical method of deduction and stressed the absolute necessity of an inductive approach to the study of economic issues, which in their view could never be separated from the larger social matrix of relations. The exception among the Irish contributions to economic methodology in the 19th century and to the inductivist position in particular was Cairnes who, in The Character and Logical Method of Political Economy, provided the most rigorous exposition of the deductive method that was produced in the course of the century.
At the beginning of the 20th century, Belfast was Ireland's leading industrial centre, with strengths in linen, shipbuilding, rope making and engineering. Elsewhere agriculture predominated, and manufacturing was limited mainly to the food and drink industries. Against this background, the nascent independence movement regarded the development of industry as a matter of strategic importance. Drawing on the German economist Friedrich List, Arthur Griffith, the founder of Sinn Fein, proposed a programme for balanced economic development using protection on a broad scale. Protection was not to be permanent and was to be removed when the protected industries were strong enough to meet international competition (Griffith, 2003). Industrial Development Associations throughout the country urged people to purchase Irish-made goods. Although the validity of the infant industry argument was widely acknowledged, in the main professional economists were not advocates of protection. Professor Oldham of University College Dublin argued that the relative openness and small size of the Irish economy meant that the protection of the home market could not provide a basis for development. Oldham was also concerned about the hidden costs of protection and suggested that bounties should be preferred to tariffs on grounds of their greater transparency and controllability (Oldham, 1908; 1917). During the 1921 Treaty negotiations with Britain, which were led by Arthur Griffith, professional economists including Riordan, O'Brien and Smiddy played a valuable role in securing the right of the Irish Free State to determine its future tariff regime (Girvin, 1989). However, despite this and the fact that partition, which accompanied independence in 1922, involved the loss of Ireland's leading manufacturing centre, the new Free State government was cautious in its approach to economic policy and favoured free trade, fiscal prudence and the maintenance of the link with sterling. Bastable of Trinity and George O'Brien of University College Dublin were members of a committee set up in 1923 to consider the case for greater protection. The committee came out strongly against tariff protection for industry. Among the grounds given were that protection would raise costs for exporting industries, including the all-important agricultural sector, whose increasing efficiency and exports were seen as the main motor for growth. The Great Depression of the late 1920s and the widespread protectionism to which it gave rise made a re-evaluation of the free-trade position necessary. In any event, a new government with a different electoral base placed strong emphasis on self-sufficiency in both agriculture and industry. A bitter Anglo–Irish dispute over land annuities added further momentum to the protectionist drive. This led the Trinity College economist Joseph Johnston to argue in his polemical Nemesis of Nationalism (1934) that the Anglo–Irish dispute had been provoked by Eamon de Valera, the prime minister, in order to expedite his drive towards self-sufficiency. To judge from the contents of the Statistical and Social Inquiry Society journal during the period, the most prominent academic economists were also opposed to the policy of self-sufficiency. One of the few economists to comment favourably on the policy was J. M. Keynes, who also cautioned that only a modest degree of self-sufficiency could be achieved in such a small economy without a drastic impact on the standard of living (Whitaker, 1983, p. 59). The protectionist policies were successful in increasing industrial output and employment, but, as predicted by Keynes and as understood by Sean Lemass, the industry and commerce minister, and his top civil servant, the real challenge was to nurture industry to international competitiveness and to maintain the impetus for development once the initial easy phase of import substitution was over.
event, the onset of the Second World War in 1939 and the growing scarcity of imported manufactures forced a further intensification of the policy of self-sufficiency. As elsewhere, the exigencies of the war economy led to greater government involvement in the allocation of resources and entrepreneurial activity generally. This continued after the war and, as late as 1959, Professor Charles Carter, formerly of Queen's University Belfast, commended the southern government for its willingness to engage in state enterprise if private enterprise failed to work, and contrasted this with the view taken in Northern Ireland that the function of government was to create the conditions for development and offer appropriate inducements but no more than that (Carter, 1969).

In preparation for the aftermath of the war, policy debate on appropriate strategies for agriculture and employment took place in the early 1940s. A committee on agricultural policy chaired by T. A. Smiddy, De Valera's economic advisor, emphasized the importance of agricultural efficiency and the restoration of exports as a means of earning the foreign exchange that was necessary for the purchase of raw materials for industrial development. The other major policy debate of the period was occasioned by the publication in the UK of the Beveridge Report and the *White Paper on Employment*. The spectrum of Irish attitudes towards Keynesianism was reflected in a discussion of the problem of full employment held by the Statistical and Social Inquiry Society on 27 April 1945 (Lynch et al., 1945, 438–59).

Opening the debate, Patrick Lynch, an economist in the Department of Finance and later Professor at University College Dublin, argued that the time had come to accept the Keynesian analysis of the economic system (Lynch et al., 438–41). The problems of the Irish economy were acute and required increasing state intervention. Government had to concern itself with the economy as a whole and not just its own expenditure as in the past. Lynch argued that government proposals for rural electrification and building were appropriate forms of intervention by means of which employment and further development could be stimulated. On the other hand, T. K. Whittaker, then number two at the Department of Finance, argued that Ireland was less exposed to cyclical fluctuations than Britain and America (Lynch et al., 446–9). Its unemployment problem was not primarily of a cyclical nature but the result of the insufficient investment in industry and agriculture. The problem was one of underinvestment rather than fluctuations in investment. Whitaker implied that increased investment in industry or agriculture would yield bigger returns at lower cost than the social investments mentioned by Lynch. Summarizing the debate, George O'Brien felt that there was general agreement that the Beveridge analysis did not apply to Irish circumstances (Lynch et al., 456–9). He noted that the main way in which Ireland had solved its unemployment problem during the last one hundred years was through the export of its people. Dr Beddy's recent paper comparing Irish and Danish agriculture (Beddy, 1943–4) had shown that a more efficient agriculture was likely to employ fewer rather than more people. While the comparison with Denmark showed the possibilities offered by secondary industries, O'Brien himself felt that tertiary industries such as tourism had considerable potential.

While there were some attempts at policy and institutional innovation in the late 1940s and early 1950s, these involved attempts to make existing policy more effective rather than any major policy shifts. The performance of the economy was sluggish with low or sometimes negative rates of growth, and high levels of emigration. The publication of *Economic Development* (Department of Finance, 1958) prepared by the Secretary of the Department, T. K. Whitaker, is commonly regarded as a major turning point in policy. The report demonstrates a remarkable consistency of position with the positions expressed by Whitaker in the 1945 debate on the *Beveridge Report*. The emphasis was on the need for productive investment. Whitaker argued that investment for which part if not all of the cost of servicing
must be paid by the taxpayer was redistributive rather than productive, and should be replaced by productive investment. Despite the emphasis on the importance of investment, Whitaker cited A. K. Cairncross to the effect that entrepreneurial capacity was an even more important factor (1958, pp. 6–7), and in the body of the report he argued that the problem was not so much one of obtaining capital as securing ‘know-what’ as well as ‘know-how’ (1958, p. 154). These, it was suggested might have to come from external sources including foreign direct investment. The report also argued that, since the home market had been largely catered for, further development would have to depend on exports.

The 1958 Programme for Economic Expansion based on *Economic Development* involved a shift of emphasis from the promotion of domestically owned import-substituting industry to foreign-owned export-oriented industry. The implementation of the shift in policy over the following decade involved the easing of restrictions on foreign ownership and the implementation of incentives in the form of grants and tax exemptions on export generated profits. It also involved a shift from state-led enterprise to private enterprise, although Whitaker himself recognized that, since private investment was limited, productive investment would have to be engaged in by the public sector for some time to come. Another feature of the programme was its argument against existing policies of decentralization and in favour of the concentration of industries in large population centres with good internal and external communications and pools of skilled labour. A similar position on the concentration of new enterprises and infrastructure was later put forward in the Buchanan Report on regional development, which was published in 1968 and led to considerable debate (Buchanan and Partners, 1968).

The introduction to the Programme for Economic Expansion emphasized that it was not a plan and argued that the setting of detailed targets was inappropriate in a private enterprise economy exposed to fluctuations in external trade (Chubb and Lynch, 1969). A few years later, there was much greater optimism about the value of planning. A second programme, which was developed in cooperation with the newly created Economic Research Institute (currently Economic and Social Research Institute, ESRI) and with input from Professor Louden Ryan of Trinity College, was much more specific in its targets. However, the actual performance of the economy in the period covered by the programme deviated from the planned targets, which were then abandoned. Drawing on this experience, the third programme emphasized the conditional nature of targets (Chubb and Lynch, 1969). Despite this, the policies which were evolved in the programmes for economic expansion are widely regarded as providing the underpinning for the subsequent expansion of the economy. Governments also engaged in mildly expansionary fiscal policy, which helped to avoid the deflationary impact of Whittaker's own proposals. During the 1970s an attempt was made to counter the effects of oil price shocks by means of deficit spending. As the expected recovery failed to materialize, Ireland's debt burden grew and by the 1980s had reached unsustainable levels. During this period, Irish economists were vocal in their criticisms of fiscal policy and earned something of a reputation as hard-nosed monetarists. The world recession of the early 1980s resulted in the closure of some foreign plants and made it difficult to attract new investment, so that there were net job losses in the foreign-owned sector. Irish economists criticized the Industrial Development Authority for subsidizing capital as a means of job creation. The Telesis review of industrial policy proposed a more selective approach to foreign direct investment, a shift of emphasis towards building strong indigenous national champions, the substitution of employment grants for capital grants and the setting up of a national linkage programme (NESC, 1982). The emergence of the economy from the 1980s recession, sometimes characterized as expansionary fiscal contraction, was achieved through a partnership agreement involving trade unions, employers and government.
Partnership agreements have remained in place and are now regarded by economists in Ireland and elsewhere as an important industrial relations and development innovation (Teague and Donaghey, 2004). In the decades since the 1960s, other policy issues with which economists engaged were the Anglo–Irish Free Trade Agreement, entry into European Economic Community, the Common Agricultural Policy and European Monetary Union. More recently, there has also been increasing emphasis on the factors governing the productivity and competitiveness of the economy as a whole. When Ireland achieved independence in 1922, its cadre of professional economists was small, and the Statistical and Social Inquiry Society and its journal provided the main discussion forum for academic economists and government officials. Although some academics, including O'Brien, were literary in their approach, others such as George Duncan of Trinity College and John Busteed of University College Cork used a variety of statistical and empirical techniques. Duncan produced estimates of Irish national income to supplement T.J. Kiernan's pioneering efforts. Given that Duncan could be not regarded as anti-statistical, it is perhaps surprising that he was one of the main protagonists in a protracted debate between economists and Roy Geary. Geary was Ireland's foremost statistician but he also made important technical contributions to economics, including the Stone–Geary utility function as well as methods for updating input–output tables, for making international comparisons of real income, and for calculating the change in real income arising from changes in the terms of trade (Neary, 1997, Spencer, 1997). Geary argued that economics could become a science only through measurement and that economists’ failure to appreciate the value of statistical work was due to their lack of awareness of the power of modern statistics. Geary also felt that economic theory was of very little value in the solution of practical problems and that academic economists were not sufficiently active in researching the social problems of the day. Duncan countered that the collection and manipulation of data could not by themselves advance knowledge of economic behaviour (Fanning, 1984, pp. 151–5). He also pointed out that the Irish universities were seriously underfunded and had very little resources with which to carry out research. Part of the problem was a difference in attitude. Duncan, who had Austrian sympathies, disapproved of government intervention in general and of the protectionist policies of the day in particular. Geary, on the other hand, viewed policy issues as problems that could be solved with the correct technical means.

The present generation of Irish economists are more numerous and better trained than their predecessors in the early years of the 20th century. Many are the products of graduate schools in United States and in Britain. A recent examination of the journal output of Irish economists over the period 1970 to 2001 identified a total of 659 individual authors and 1,610 contributions, of which 218 were in the 1970s, 406 in the 1980s and 1,013 in the 1990s (Barrett and Lucey, 2003). Of the total over the full period, half were in the main Irish journals: the Economic and Social Review, the Journal of the Statistical and Social Inquiry Society of Ireland and the Irish Banking Review. Other popular outlets for Irish economists were Regional Studies Applied Economics and the Economic Journal. A relatively small number of Irish economists contributed to the top international journals during the period surveyed by Barett and Lucey. Of these, Peter Neary made important contributions to the theory of international trade as well as consumer theory, industrial organization and macroeconomics. In international trade, he is best known for work on Dutch Disease and the implications for trade of imperfect competition and technology policy.

In his seminal work on 20th century Ireland, the historian Joseph Lee (1989) argued that Irish
economists have been impressive in the analysis of short-term movements but have contributed little to understanding the long-term development of the economy and have failed to contribute to development economics more widely. Whatever its truth in the past, this statement is no longer an accurate reflection of the state of affairs. Since the early 1990s, the Irish economy has experienced rapid growth so that its GDP per capita is now among the highest in Europe. This has led to considerable interest in understanding the nature and timing of the forces at work in Ireland's catch-up (Honohan and Walsh, 2002). Meanwhile, however, Ireland's own development challenges have changed from those of catch-up to those of innovation and growth on the frontier. Meeting these challenges will require not only the strengthening of R&D capabilities but also addressing the special challenges of innovating in a small open economy.

The ‘iron (or brazen) law of wages’ is a term invented by Ferdinand Lassalle (1862) to describe the inexorable tendency of real wages under capitalism to adhere to a level just sufficient to afford the bare necessities of life. This law, he claimed, was not just a socialist indictment of capitalism but was authorized by leading ‘bourgeois’ economists such as Malthus and Ricardo. He failed to point out, however, that in Malthus and Ricardo the so-called ‘subsistence’ theory of wages was predicated on a theory of population growth according to which the supply of labour responds automatically to any gap between the going ‘market price’ and ‘natural price’ of labour, the latter being defined as a real wage sufficient to reproduce a working population of given size and composition. Lassalle, however, being a socialist, followed Marx in rejecting the Malthusian theory of population; what ensured the ‘iron law of wages’ for Lassalle, as for Marx, was the tendency for any rise in real wages to generate unemployment, thus setting in motion forces that reversed the rise. This threw the entire weight of argument for equilibrium adjustments in the labour market on the side of employers’ demand; it provided no explanation of the supply of labour and thus failed to furnish a determinate theory of wages in long-run equilibrium. Ironically, therefore, there may be an ‘iron law of wages’ in Malthus and Ricardo, but there is certainly no such iron law in socialist economics. The question whether Malthus and particularly Ricardo can be said to have held the iron law or subsistence theory of wages was a favourite debating question in the latter half of the 19th century (see, for example, Marshall, 1890, pp. 508–9). There is no doubt that they held the view that real wages tend to fluctuate around a natural point of ‘gravity’, namely, the minimum level of food and other necessities required for existence. But, in the first place, these fluctuations, depending as they did upon decisions to marry and to have children, involved a lag of at least 15–18 years, a point which Malthus (but not Ricardo) conceded explicitly. In the second place, the minimum-of-existence level of ‘natural wages’ was admitted to be a matter of custom and habit and
The iron law of wages is subject to a secular upward drift. It was therefore perfectly possible to argue for the existence of something like a normal long-run supply price of labour – a constant real wage, everything else being the same – while at the same time granting that the ‘market price’ of labour fluctuated around an ever-rising trend. In short, rising living standards under capitalism do not violate the iron law of wages, understood as a theory about the long-run equilibrium price of labour. But that is only to say that the iron law or subsistence theory of wages amounts for all practical purposes to accepting customary wages as an institutional datum (Schumpeter, 1954, p. 665).

There has been a revisiting of the old debate about whether Ricardo held the iron law of wages, but in an entirely new form: did Ricardo hold real wages to be constant at the subsistence level in stationary equilibrium or did he allow for an initial stage of increasing real wages followed by a final stage of declining wages alongside a secular fall in the rate of profit (Hollander, 1983)? It is doubtful whether this question yields one simple, neat answer, since it is clear that Ricardo operated with a number of different models regarding the determination of the ‘natural price’ of labour. In the very opening paragraph of the chapter on wages in Ricardo's *Principles of Political Economy of Taxation*, the ‘natural price’ of labour is defined as ‘that price which is necessary to enable the labourers, one with another, to subsist and to perpetuate their race, without either increase or diminution’. This defines the natural price of labour to be the commodity wage that ensures a zero rate of population growth. But a page or two later, the natural price of labour is said to be that commodity wage which ensures a rate of growth of population equal to the rate of growth of the capital stock, so that market wages only rise above natural wages when capital accumulates faster than the growth of population. It is possible to make sense of this in terms of modern growth theory, and many have done so (see Casarosa, 1978), but it is questionable whether Ricardo himself was aware of what he was doing, the more so as he frequently resorts to the constant-subsistence-wage assumption in the later tax chapters of the *Principles*.

irreversible investment

Janice C. Eberly
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The cost of an irreversible investment cannot be recovered once it is installed. This restriction not only truncates negative investments, but also raises the threshold for positive investment. The threshold return that justifies an irreversible investment increases with uncertainty, or more precisely, with the probability mass in the lower tail of outcomes. Irreversibility constrains the ability to redeploy capital in ‘bad’ states, so the agent is particularly sensitive to these states when investing ex ante. This finding is analogous to valuation and exercise of financial options, and irreversible investments are valued and understood by using option pricing techniques.

Keywords

adjustment costs; irreversible investment; option pricing theory; option valuation; put–call parity; uncertainty

Article

Irreversible investment acknowledges that the value of capital may not be fully recoverable when resold. This simple generalization has rich implications for investment. Beyond truncating disinvestment, irreversibility changes the dynamics of investment by creating a threshold level of returns for positive investments. Below this threshold, investment is zero – which immediately implies intermittent rather than continuous investment activity. Moreover, the threshold return that justifies investment exceeds the required return on a reversible investment.

Investment and options

Marschak (1949) raised the potential role of irreversibility in factor accumulation by emphasizing the convertibility or liquidity of capital. Work by Arrow (1968) and Henry (1974) considered when irreversible actions in environmental applications were justified and emphasized the idea of an option value. This idea was extended by Bernanke (1983) to the role of uncertainty in delaying investment decisions. McDonald and Siegel's (1986) article ‘The Value of Waiting to Invest’ provides the first explicit valuation of investment allowing for irreversibility, incorporating option valuation (real options) into investment theory. McDonald and Siegel analyse a project of fixed size, so the timing of the project is the only choice to be made. They show that the value of the project includes an ‘option value of waiting’, that can be valued and interpreted using option pricing theory. The additional value of being able to choose when to invest, rather than a ‘now or never’ investment decision, can be quantitatively large, and has interesting implications for the investment decision. First, the presence of this option implies that it is optimal to delay the investment, rather than undertaking it immediately, even when immediate execution has positive value. Instead, value can be increased by waiting for additional information. Second, like most options, the value of the option to wait is increasing in uncertainty. This feature implies an effect of uncertainty on the value and timing of investments that is absent in most conventional models.

Later work by Pindyck (1988) and Bertola (1988), allows for incremental investment, so that the firm chooses both the timing and the size of its investments. They show that there is a threshold for investing with irreversibility that exceeds the return that would justify a positive reversible investment. Instead of a single investment decision, as in McDonald and
Siegel, there is an infinite sequence of investment decisions, where each satisfies the threshold condition.

**An illustrative model**

Most irreversible investment models work in continuous time, so that optimal investment timing can be calculated exactly. An introduction to these techniques, as well as a broader overview, is found in Dixit and Pindyck's (1994) *Irreversible Investment*. The intuition can be understood in a discrete time framework, adapted from Abel, Dixit, Eberly and Pindyck (1996), specialized to the case of irreversible investment.

Consider the decision of a single firm to undertake a capital investment at time 1. In the first period, the return to installing capital $K_1$ is $r(K_1)$. The total return $r(K_1)$ is strictly increasing and concave in $K$ and satisfies the Inada conditions. The firm pays a price $b$ per unit of capital to purchase capital. In the second period, the return to capital is uncertain and equal to $R(K, \varepsilon)$, where $\varepsilon$ is stochastic. The derivative of $R(K, \varepsilon)$ with respect to $K$, $R_K(K, \varepsilon)$, is continuous and strictly decreasing in $K$, continuous and strictly increasing in $\varepsilon$, and $R(K, \varepsilon)$ also satisfies the Inada conditions. Define a threshold value of $\varepsilon$ by

$$R_K(K_1, \overline{\varepsilon}) = b,$$

as illustrated in Figure 1.

**Figure 1**

The second period marginal return to capital
Assume that the resale price of capital is zero, or complete irreversibility. In the second period, the capital stock is optimally chosen at a level equal to $K_2(\epsilon)$, subject to the irreversibility constraint. When $\epsilon > \tilde{\epsilon}$, the optimal capital stock rises to satisfy the first-order condition $R_K(K_2(\epsilon), \epsilon) = b$. However, when $\epsilon < \tilde{\epsilon}$, the marginal return to capital is less than its purchase price. If the firm could resell capital at its acquisition price $b$ (costless reversibility) it would do so. However, the available resale price is zero, so the firm prefers to keep its capital stock, which has positive marginal return; in this case $K_2(\epsilon) = K_1$. The optimal second-period marginal return to capital is graphed in Figure 1 as the lower envelope of $R_K(K_1, \epsilon)$ and $b$.

Conditional on the optimal second-period capital stock, the firm chooses its capital stock at time 1 to maximize $V(K_1) - bK_1$, where $V(K_1)$ is the first period value of the firm equal to $r(K_1) + \gamma E[R(K_2, \epsilon)]$ and $0 < \gamma < 1$ is the discount factor. The first-order condition for the optimal capital choice is

$$V'(K_1) \equiv r'(K_1) + \gamma \int_{-\infty}^{\tilde{\epsilon}} R_K(K_1, \epsilon) dF(\epsilon) + \gamma b[1 - F(\tilde{\epsilon})] = b,$$

(2)

where $F(\epsilon)$ is the cumulative distributive function (CDF) of $\epsilon$.

Notice that the term $V'(K_1)$ is the marginal value of an additional unit of capital, or marginal $q$. The standard investment first-order condition equating marginal $q$ to the marginal cost of capital still holds with irreversibility. The effects of irreversibility are incorporated into the value of marginal $q$, so when investment is non-zero the standard $q$-theory first-order condition equating the marginal value and the marginal cost of investment still holds.
Embedded options

Now rewrite this first-order condition to highlight the investment options and their implications for the investment decision. Rewrite eq. (2) as

\[ q(K_1) = V'(K_1) = n(K_1) - \gamma c(K_1) \]  

(3)

where

\[ n(K_1) = r'(K_1) + \gamma \int_{\varepsilon}^{\infty} R_K(K_1, \varepsilon) dF(\varepsilon) > 0 \]  

(4)

and

\[ c(K_1) = \int_{\varepsilon}^{\infty} [R_K(K_1, \varepsilon) - b] dF(\varepsilon) > 0. \]  

(5)

The marginal value of an additional unit of capital is decomposed into two terms. The first term, \( n(K_1) \), is equal to the present value of marginal returns to capital, evaluated at its current level, \( K_1 \). The second term subtracts the discounted value of a call option, \( c(K_1) \), to add more capital, as illustrated in Figure 1, where the returns to the call option are represented by the area under \( R_K(K_1, \varepsilon) \) and above the line \( b \). The call option reduces the marginal value of capital because additional capital irrevocably reduces the marginal return to capital owing to the concavity of the revenue function. If one combines these two terms, the marginal value of capital is the discounted sum of marginal revenues on the assumption that the capital stock is fixed, less the marginal value of the option to increase the capital stock. Note that the concavity of the revenue function is crucial to this mechanism. Hence, models such as Abel and Eberly, (1997) which assume constant returns to scale, do not generate these option values.

The effects of uncertainty are not transparent in the above formulation, since both terms in eq. (3) depend on the distribution, \( F(\varepsilon) \). To better discern the effect of uncertainty, rewrite eq. (2) instead as

\[ q(K_1) = V'(K_1) = j(K_1) - \gamma p(K_1) \]  

(6)

where
irreversible investment: The New Palgrave Dictionary of Economics

\[ j(K_1) \equiv \alpha' + \gamma b > 0 \]

(7)

and

\[ p(K_1) \equiv \int_{-\infty}^{\infty} \left[ b - R_K(K_1, \epsilon) \right] dF(\epsilon) > 0. \]

(8)

The marginal value of an additional unit of capital is again decomposed into two terms. The first term, \( j(K_1) \), is the discounted marginal return to costlessly reversible capital: the firm earns the marginal revenue in period one and can sell the capital for the same price \( b \) in period two. This is the Jorgensonian marginal return (Jorgenson, 1963); notice that it is independent of \( \epsilon \) and risk free. The second component of \( q \) is the put option to sell capital at price \( b \). When investment is irreversible, the put option is not available to the firm, since it cannot sell capital at any positive price. The value of the put option must be subtracted from the Jorgensonian valuation (where resale at price \( b \) would be permitted) to obtain the marginal value of irreversible capital. Marginal \( q \) can thus be written as a frictionless value less the value of the put option that is eliminated by the irreversibility constraint. This is illustrated in Figure 1 by subtracting the returns to the put option (the area under the line \( b \) and above the function \( R_K(K_1, \epsilon) \)) from the frictionless return \( b \).

Effects of uncertainty and put–call parity

To calculate the effect of uncertainty on marginal \( q \) from eq. (6), one need only calculate the effect of uncertainty on \( p(K_1) \), since \( j(K_1) \) is risk free. The effect of uncertainty on \( p(K_1) \) is clear: \( p(K_1) \) is an option value, and an increase in uncertainty increases the value of an option. In this case specifically, a second-order stochastic dominant shift in the distribution of \( \epsilon \) shifts the CDF up for every value of \( \epsilon \). Since \( R_K(K_1, \epsilon) \) is increasing in \( \epsilon \), the term \( [b - R_K(K_1, \epsilon)] \) is decreasing in \( \epsilon \). Hence, greater uncertainty in \( \epsilon \) shifts more weight of the CDF towards the large option payoffs in the left tail and unambiguously increases the value of the option, \( p(K_1) \). Greater uncertainty unambiguously lowers the value of \( q(K_1) \).

Since \( q(K_1) \) is decreasing in \( K_1 \), a downward shift in \( q(K_1) \) reduces the optimal value of \( K_1 \) for a given value of \( b \), as illustrated in Figure 2. This decrease is the incremental investment counterpart to McDonald and Siegel's finding that greater uncertainty increases the option value of waiting, lowering the value of investing immediately.

Figure 2
Marginal \( q \) and the optimal capital stock under low and high uncertainty
This formulation of $q(K_1)$ also demonstrates Bernanke's (1983) 'bad news principle' of irreversible investment. The distribution of $\varepsilon$ only appears in the expression for $q$ in eq. (6) via the put option $p(K_1)$. The put option only depends on the lower tail of the distribution of $\varepsilon$, below the threshold $\bar{\varepsilon}$. That is, the only part of the distribution of shocks that affects the value of $q(K_1)$ is the lower tail -- or the 'bad news'. The upper tail is irrelevant, since in that region, the firm invests until the marginal product of capital equals its price. The exact realization of the shock in this region is irrelevant to the marginal return. In the lower tail, on the other hand, the firm neither invests nor disinvests, and the realization of the shock determines the marginal return to capital.
irreversible investment: The New Palgrave Dictionary of Economics

Figure 1 illustrates these arguments. The second period return to capital is the lower envelope of the price of capital, \( b \), and the second-period marginal return, \( R_K(K_1, \varepsilon) \) evaluated at \( K_1 \). The value of these returns depends on \( \varepsilon \) only in the lower tail of the distribution of \( \varepsilon \) (the bad news principle). The lower envelope can be expressed as either the function \( R_K(K_1, \varepsilon) \) less the area labelled call returns in Figure 1; adding this difference to first-period marginal returns \( r'(K_1) \), we obtain the expression for \( q \) in eq. (3). Equivalently, the second-period marginal return can be expressed the line \( b \) less the area labelled put returns in Figure 1. Adding the first-period marginal return \( r(0) \), we obtain the expression for marginal \( q \) in eq. (6). The fact that the second-period return can be written in two equivalent ways using options follows from put–call parity, a fundamental property of options prices. In fact, in this setting put–call parity is found simply by setting the two expressions for \( q \) in eqs (3) and (6) equal to each other. Equating these two expressions for \( q \) and simplifying, we find

\[
\gamma p(K_1) + n(K_1) = \gamma c(K_1) + j(K_1).
\]  

This expression equates the value of a portfolio containing a put option and the underlying security, \( n(K_1) \), to the value of a portfolio containing a call option and a risk-free asset. For a financial security such as a stock with price \( S \), put–call parity analogously states that \( P(S, \tau) + S = C(S, \tau) + X / (1 + r)^\tau \), where \( X \) is the strike price of the options and \( \tau \) is the time to maturity. The terms \( P(S, \tau) \) and \( C(S, \tau) \) are the value of the put and call, respectively, on the underlying stock, \( S \). \( X / (1 + r)^\tau \) is the present value of a risk-free payoff (a zero coupon bond) of \( X \) in \( \tau \) periods.

Extensions and applications

The above analysis assumes complete irreversibility. However, less stringent forms of the constraint deliver similar implications. Abel and Eberly (1996) examine costly reversibility, where capital can be disinvested and resold at a price less than the purchase price of capital. In this case, the gap between the investment and disinvestment thresholds opens quickly, even for small differences between the purchase and sale prices of capital. Moreover, this formulation has assumed kinked, linear adjustment costs, so that the degree of irreversibility is summarized by the ratio of the purchase and sale prices of capital. However, with more general cost formulations, such as Abel and Eberly (1994), capital may have a positive resale price and still be effectively irreversible when other costs of reselling capital exceed any potential benefits. In addition to a resale market discount, convex adjustment costs and fixed costs, for example, may induce irreversibility.

Research on irreversibility has branched out both empirically and theoretically. Initial applications included energy and natural resource markets (Brennan and Schwartz, 1985), with extensions to virtually all types of quasi-fixed capital, including durable goods, real estate and equipment investment. Modelling has been extended to include multiple types of quasi-fixed capital goods (Eberly and van Mieghem, 1997). Aggregating models with infrequent adjustment to incorporate equilibrium effects is challenging, and the results remain controversial. Except in very special cases (Caplin and Spulber, 1987) aggregating requires tracking a distribution of agents. However, it is precisely this feature that can match the observation that much of the volatility in empirical investment arises from the extensive margin (the number of agents adjusting) rather than the intensive margin (the average size of the adjustment). Much progress has been made in this direction (for example, Caballero and Engel, 1999), though the quantitative implications vary with modelling strategy (Veracierto, 2002).

**Islamic economic institutions**

Timur Kuran

Edited by Steven N. Durlauf and Lawrence E. Blume

**Abstract**

The economic institutions of the classical Islamic world include Islamic contract law and the waqf, a form of trust. Until modern times, these two institutions were generally beneficial to economic performance. However, each had limitations that eventually blocked modern economic growth. Islamic contract law discouraged the formation of large and long-lived partnerships, thus obviating the need for business techniques and organizational forms associated with economic modernization. The waqf, designed as a rigid organization, locked capital into inefficient uses. Not until modern times has the corporation, a more flexible organizational form, entered the legal systems of the Islamic world.

**Keywords**

charitable contributions; choice of law; contract law; corporation; double-entry bookkeeping; industrial revolution; inheritance; interest; Islamic economic institutions; limited liability; partnerships; tax farming; waqf; zakat

**Article**

Prior to the 18th century, the Islamic world did not appear economically underdeveloped to outside observers. Comparative studies by economic historians confirm that it became ‘poor’ in relation to Europe during the Industrial Revolution. Until that point, economic institutions grounded in Islamic law had afforded a respectable level of wealth by standards of the day. They had also facilitated the spread of Islam across Asia, southern Europe, and the coasts of Africa.

**Law of contracts**

The first few centuries of Islam – c. 622–1000 ad – witnessed the gradual development of an elaborate law of contracts. It enabled the pooling of labour and capital through several forms of partnership,
including ones providing limited liability to passive investors. Profit shares, negotiated in advance, could be unequal or contingent. Islamic partnership contracts were enforced, with minor variations, wherever Muslims ruled. As merchants and producers moved, they carried Islamic law with them, helping to spread Islam. Huge numbers of people converted in order to gain acceptance into lucrative commercial networks managed according to Islamic law.

Islamic law limited neither the size of a partnership nor its duration. However, in practice the typical Islamic partnership consisted of two people, who pooled resources for a single economic venture expected to last just a few months (Çizakça, 1996). Lacking a life of its own, it was not what we call a firm. If a partner died during the contract period, the partnership became null and void, and the decedent's share of the assets fell to his heirs. There could be numerous claimants, for the Islamic inheritance system, by medieval standards remarkably egalitarian, assigns mandatory shares to a possibly long list of extended relatives. Accordingly, reconstituting a dissolved partnership could be very costly. Merchants and investors minimized the risk of dissolution by keeping their partnerships small and ephemeral (Kuran, 2003b).

A long-term consequence is that Islamic partnerships remained structurally simple, which obviated pressures to develop the sorts of organizational forms and business techniques that, in western Europe, gradually led to the modern economy. For instance, double-entry book-keeping did not develop, and no markets arose for trading enterprise shares. This institutional inertia made it impossible to borrow new organizational forms, except as part of a comprehensive legal reform. Advanced organizational forms, such as the joint-stock company and the corporation, reached the Islamic world in the 19th century through the imposition of secular commercial law. By that time the financing and organization of the region's external trade was largely under Western control; and, as a result of the Industrial Revolution, productivity was much higher in the West than elsewhere. The very commercial institutions that had served Muslims well through the Middle Ages were now hindering the exploitation of modern technologies.

Role of minorities

The religious minorities of the Islamic world might have escaped the limitations of Islamic commercial institutions, because they enjoyed ‘choice of law’ – the privilege to do business under legal systems of their own. Yet as individuals non-Muslims could opt unilaterally to take anyone to an Islamic court, whose decision would trump that of a non-Muslim judge or arbitrator. To achieve predictability in their economic relations, non-Muslims thus tended to base their financial and commercial contracts on Islamic law; their claims induced their own court systems to emulate Islamic legal practices. Consequently, until the 18th century the economic performance of non-Muslim peoples of the Islamic world did not diverge significantly from that of Muslims. Most non-Muslim communities started pulling ahead, however, as western Europe developed the legal infrastructure of modern capitalism. Vast numbers of Christians, Jews and other non-Muslims gained an economic advantage over Muslims by doing business under western or western-inspired laws (Kuran, 2004b; Issawi, 1982).

The waqf
Another contributor to the Islamic world's economic successes and also to its subsequent economic retardation is the waqf, Islam's distinct form of trust. From the eighth century to modern times, Muslim-governed states provided few public goods directly, beyond law and order. They left the supply of public goods largely to waqfs established in a decentralized manner. Vast resources flowed into waqfs; by the early 18th century they owned between a quarter and half of all real estate, depending on the country. The services financed through waqfs included mosques, schools, hospitals, water fountains, roads, parks, inns, bathhouses, orphanages and soup kitchens.

A waqf is an unincorporated trust established under Islamic law by an individual owner of immovable property for the perpetual provision of a service. It emerged in the early Islamic period, a time of weak property rights, partly to enable landowning high officials to shelter wealth. Converting property into waqf yielded considerable immunity against confiscation, because waqf-owned assets were considered sacred, and this made legitimacy-seeking rulers reluctant to expropriate them. In addition to social status and religious satisfaction, the founder usually obtained pecuniary benefits. He could make himself the waqf's mutawalli (trustee and manager), set his own salary, appoint relatives to paid positions, and designate his successor. This last prerogative enabled circumvention of the Islamic inheritance system. In founding a waqf, then, an individual did not simply engage in charity. In return for shouldering social responsibilities, he obtained the privilege of sheltering wealth for personal use. Local norms determined the share of a waqf's income that its mutawalli could reserve for himself and his family.

For a millennium this system for supplying public goods remained a distinguishing feature of the Islamic world. It owed this remarkable longevity to identifiable benefits that it yielded to huge groups. Property owners achieved a measure of material security. Rulers unburdened themselves of the responsibility to provide public goods. And the average person received diverse forms of philanthropy. Nevertheless, the waqf system had a flaw that became increasingly serious over time. Although some opportunities existed to reallocate resources to new uses, the waqf was designed to serve its founder's wishes for ever. As such, it could not adapt quickly to changing social needs, and it locked capital into inefficient uses. By the 19th century, a time of massive technological change, the waqf system had become conspicuously dysfunctional, and reformers took to dismantling it (Çizakça, 2000; Kuran, 2001).

Up to that time, services to the Middle East's great cities were supplied mostly by waqfs. The 19th century saw the establishment of the region's first municipalities, under secular laws. These municipalities, which attained corporate powers, could reallocate resources relatively quickly. Within a few decades, they assumed most of the functions previously relegated to the waqf sector.

Absence of the corporation

Islamic law, which borrowed from various pre-existing legal systems, had spurned the Roman concept of the corporation. Limiting legal standing to natural persons supported Islam's political mission, which was to turn Arabia's feuding tribes into an undivided religious community. Corporations might have undermined that goal by enabling tribes to form autonomous organizations. During the formative period of Islam – from the seventh through the tenth centuries – the Middle East thus experienced no incorporation wave analogous to that observed in contemporaneous western Europe. One reason is that the waqf, by providing the means for delivering perpetual services with large sunk costs, alleviated the need for corporations. Another is that the waqf system spawned constituencies with a stake in preserving its key features; yet another that merchants and producers who stood to benefit from corporate powers...
Islamic economic institutions: The New Palgrave Dictionary of Economics
could not muster the collective action necessary to reform the legal system. Not until the modern era did
the concept of the corporation enter legal systems of the Islamic world.
In the late 20th century, certain predominantly Muslim countries started to revive their waqf sectors,
though in modernized and secularized form. Unlike the traditional waqf, a modern waqf enjoys legal
personhood, and its founder may be a group. It is managed by a mutawalli board rather than a single
caretaker appointed for life. Most critical, as a self-governing organization it can remake itself.
Secularists, civil rights groups and economic liberalizers are the key constituencies of coalitions formed
to promote waqf founding. These groups see their mission as a vehicle for shrinking the state,
strengthening local governance, and promoting democratization (Çizakça, 2000). Thus, having played an
enormous role in Islamic economic history, the waqf is now turning into an agent of political and
economic modernization.
Because the Qur'an does not mention the waqf, many Islamists are indifferent to ongoing efforts to
reinvigorate the waqf sector. Their overriding goal is to purge interest from financial transactions,
largely in the belief that the Qur'an bans interest categorically (Saleh, 1986; Lewis and Algaoud, 2001;
Kuran, 2004a). In fact, Islam's prescriptions concerning interest have always been a matter of
interpretation, and throughout Islamic history interest-based transactions have been common (Rodinson,
1966). Nevertheless, Islamists treat Islamic banking, intended to be free of interest, as the sine qua non
of a properly Islamic economy. Yet Islamic banking is a modern creation. Pre-modern economies based
on Islamic law had moneylenders but no banks (Udovitch, 1979). The first banks of the Islamic world,
all foreign-owned and -managed corporations, date from the mid-19th century (Kuran, 2005).

Property rights

Until modern times economies of the Islamic world suffered from a lack of institutions to tie the hands
governments. This meant that private property rights remained weak. Although material insecurity
varied across time and space, taxation was often arbitrary, and states resorted to compulsory labour.
Private property rights did not achieve credibility even in the eyes of state officials – one reason why
endowing waqfs was so popular. A scribe could be plucked out of obscurity to become a prosperous
statesman, and then, all of a sudden, fall into disgrace and lose everything. The expropriation of large
estates was especially common, all the more so in times of financial crisis. Because this practice violated
the Islamic law of inheritance, typically it was based on the ground that the deceased was not the rightful
owner of his estate (Findley, 1989).
In the seventh century, the first Islamic state in Arabia had instituted a tax-and-subsidy system that
might have strengthened property rights. Known as zakat, it required the payment of taxes to the state in
specific forms of income and wealth at predetermined rates. In providing the state the resources to fund
various activities, including charity, it also capped taxation (Rahman, 1974). However, precisely because
of the inflexibility of its rate structure, within a couple of generations revenue-hungry rulers abandoned
it for taxes that gave them greater latitude. Thereafter zakat metamorphosed into a narrow religious duty,
incumbent on people of means, to assist the poor on an annual basis (Kuran, 2003a). Modern Islamists
have tried to turn zakat into a state-run social welfare system to which the wealthy make obligatory
contributions. But throughout the Islamic world taxation remains an essentially secular matter. It has
also become more predictable. The wealthy classes of the present have far better defences than those of
the past against government predation. Taxation can be arbitrary without being devoid of logic. In pursuing opportunities to raise revenue, rulers sought to limit transaction costs, in particular to minimize the costs of measuring income, identifying assets, and collecting taxes. To that end they tended to collect fixed taxes directly, leaving the collection of variable taxes to local officials (Co•gel and Miceli, 2005). They also made extensive use of tax farming, which assigns collection rights to people knowledgeable about tax units.

Islamic finance

Mahmoud El-Gamal

From The New Palgrave Dictionary of Economics Online, , 2009
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Islamic laws on financial matters date back to medieval times. They were reinterpreted in the 20th century to provide guidelines for the burgeoning Islamic financial sector. Compliance with religious law is a driving force in this sector, and a variety of financial instruments have been developed that are adjudged to be acceptable for use by Muslims. These continue to evolve, and the rules could be considered to merit reinterpretation to better enable Islamic financial institutions to deal with risk factors and obey the spirit, rather than merely the letter, of medieval Islamic jurisprudence, which was regulatory in nature.

Keywords

Islamic finance; Shari’a law; mudaraba

Article

The notion of ‘Islamic finance’ was born during the tumultuous identity-politics years of the mid-20th century. Indian, Pakistani and Arab thinkers contemplated independence from Britain, and the independence of Pakistan from India, within a context of ‘Islamic society’. Islam was assumed to inspire political, economic and financial systems that are distinctive and independent of the Western (capitalist) and Eastern (socialist) models of the epoch. The term ‘Islamic economics’ was coined by Abu al-A‘la Al-Mawdudi, whose students and followers worked to develop an ostensible Islamic social science (Kuran, 2004). Mawdudi’s influence on Arab Islamists began with the writings of Sayid Qutb, the father of modern Arab political Islam, whose quasi-exegesis Under the Qur’anic Shade referred exclusively to Mawdudi’s writings on economic matters. Mawdudi’s migration from majority-Hindu Indian society to majority-Muslim Pakistan thus became a prototype for Islamist migration away from secular political and economic systems.
Islamic finance: The New Palgrave Dictionary of Economics Online

From Islamic economics to Islamic banks

In the first few decades of its existence, Islamic economics focused on comparative economic systems (a fashionable field at the time) as well as neoclassical and Keynesian modelling with a highly stylized *homo islamicus* (a moral and ethical individual who shuns excessive greed and consumerism) in place of mainstream economics’ *homo economicus* (a selfish utility and profit maximizer) (Haneef, 1995). As a byproduct, Islamic banking emerged in the Islamic economists’ literature as a financial system based exclusively on profit-and-loss sharing, which was argued to be more equitable and stable (Chapra, 1996; Siddiqi, 1983). In the process, Islamic economists focused on the Islamic prohibition of *riba* or usury, which they interpreted as a prohibition of all interest-based lending, in accordance with earlier interpretations of the Judeo-Christian canon.

Classical Islamic jurisprudence had interpreted interest-based lending, the cornerstone of fractional-reserve depositary banking, as riskless – and therefore illegitimate and inequitable – return for idle capitalists. Indeed, the importance of credit and counterparty risk for any financial analysis remains conspicuously absent from the writings of the Islamic-economics faithful. The preferred financial model, they postulated, would be based on the ancient silent-partnership model known in Islamic writings as *mudaraba*, corresponding to the Jewish *heter iska* and the Christian-European *commenda* (Udovitch, 1970).

An ‘Islamic bank’ was envisioned as a two-tier silent partnership. Thus, deposits seeking a return (as opposed to fiduciary deposits, for which 100 per cent reserves are required) would not be guaranteed loans to the bank, but rather silent-partnership investments in the bank’s portfolio. In turn, the bank’s investments of those funds would not consist of loans and acquisition of debt instruments, but rather profit-and-loss sharing investments in other silent partnerships. Thus, the Islamic bank would serve its financial intermediation function (pooling of return-seeking savings and diversification of investments) through profit-and-loss sharing. This idea continues to serve as the cornerstone of Islamic banking today, despite being thoroughly debunked by prominent jurists (Tantawi, 2001; El-Gamal, 2003).

Potential loss of return-seeking deposits was assumed by Islamic-banking proponents such as the Islamic Financial Services Board (IFSB) to encourage depositor-monitoring and risk-mitigating market-based discipline. Thus, the grossly inadequate depositor-protection measures supported by the industry have focused on transparency of operations and profit-distribution mechanisms (IFSB, 2006).

The practice of Islamic banking

This risk-sharing model has continued to shape the liabilities side of Islamic banks’ balance sheets, with a few exceptions in Europe and the United States, where regulators have required Islamic financial providers that function as banks to guarantee deposits. The assets side of Islamic banks and financial providers, on the other hand, has utilized multiple structured-financial models to replicate loans and fixed-return securities that limit the banks’ exposure to credit risk. The transformation from the idealistic profit-and-loss sharing model of Islamic economics – which continues to be hailed as the ‘Islamic ideal’ by industry practitioners and commentators – to replication of modern financial products and markets in ‘Islamic’ garb coincided with the increased importance of classical methods of Islamic jurisprudence and a limited rhetorical role for Islamic economics.
Early models in the subcontinent during the 1950s and in Egypt during the 1960s notwithstanding, the true beginnings of Islamic banking and finance occurred in the mid-1970s. Islamic jurists including the Shiite scholar Baqir al-Sadr and many Sunni scholars in Egypt, Saudi Arabia and elsewhere collaborated with Islamist bankers to replicate loans using ancient contract forms. Baqir al-Sadr, in his classical work *The Non-Usurious Bank in Islam* (long out of print), had attempted to use similar structured products to replicate guaranteed bank deposits on the liabilities side. However, since risk-sharing depositors were clearly beneficial to the shareholders of Islamic banks, and because the latter drove innovation in Islamic banking through the retention of lawyers and religious scholars, most of the ‘innovations’ were restricted to the assets side of the balance sheet.

**Murabaha (cost-plus sale) financing**

The workhorse of Islamic banking has been the *murabaha* (cost-plus sale) contract. The logical evolution of this form of finance is indicative of the general methodology of Islamic finance to this day. In the early 1980s, Islamic banks in the Gulf were flush with petrodollars, and Western corporations were eager to borrow from them as Western-bank credit dried up following the petrodollar-driven Latin American debt crisis. Islamic banks resorted to the easiest ancient trick: introducing a property to separate lent principal from repaid principal plus interest. In the simplest ruse, the bank could have sold some commodity to its potential borrower on credit (for principal plus interest payable later), and then bought it back for cash (principal paid immediately), thus effectively replicating the cashflows of the loan, with the commodity making a round trip from bank to customer and back. However, this ancient ruse was forbidden by name as same-item sale resale (*bay` al-`ina*). In practice, one credit sale and one spot sale of liquid commodities were still used to accomplish the desired goal by conducting the second spot sale with a third party. Interestingly, Al-Rajhi Investment Company in Saudi Arabia, which has one of the strictest religious-scholar boards, received a question on the legitimacy of the credit sale of gold, and ruled that such sales were disallowed because gold is a monetary commodity. Promptly thereafter, the same board was asked if platinum can be sold on credit, and issued a *fatwa* that this was permitted. Thus, Islamic banks could simply trade precious metals, acquiring an amount of platinum (or other metal excluding gold and silver) equal in value to the desired loan principal. The metal was then sold on credit to the Western borrower under a *murabaha* contract, with a credit price equal to the desired principal plus interest. The customer was then able to sell the metal quickly to receive the desired borrowed principal, perhaps less a small transaction cost.

This was the juristic solution first popularized by the late banker Sami Humud in his book *Evolving Banking Transactions in Accordance with Islamic Law* (1976). The prohibition of *riba* (usury) in the Islamic canon and subsequent juristic analysis left room for such ruses. The Qur’an merely mentioned *riba* in the abstract without specifying precisely which transactions were thus forbidden. The Prophetic tradition merely listed six commodities: gold, silver, dates, wheat, barley and salt, all of which were used at some point as commodity monies in the ancient world, stipulating that those may be traded only hand-to-hand and in equal amounts measured by weight or volume. One school of jurisprudence (*Hanafi*) expanded the prohibition to all commodities measured by weight or volume, but still did not treat them as money. Therefore, while trading platinum now for platinum later, or trading gold now for silver later, would both be deemed impermissible based on the *Hanafi* interpretation, trading platinum now for
dollars later was considered permissible. Interestingly, the Halacha, developed by Jewish scholars prior and in parallel to the development of Islamic Fiqh, forbade such embedded-interest credit sales (Reisman, 1995, p. 112). In contrast, all major schools of Islamic jurisprudence (four Sunni and four Shiite) have allowed credit sales at prices possibly exceeding the spot price. Initially, this was only a method for seller financing. Thus, the financier needed first to acquire the property before selling it on credit. In addition, to give the contract an Islamic flavour, the industry adopted the name of an ancient cost-plus sale – murabaha, a contract devised to protect buyers who were unfamiliar with market prices, allowing them to negotiate prices by negotiating markup over revealed cost.

The contract that emerged in the 1970s was formally known as ‘cost-plus sale to the customer who ordered the initial purchase’ (murabaha lil-‘amir bil-shira’). It was initially subject to scholarly controversy, especially as bankers added provisions to eliminate all forms of risk other than customer credit. In order to eliminate property-related risks, which were ironically the basis on which jurists allowed earning a return on the transaction, they allowed banks to stipulate that the eventual buyer must guarantee to buy the property on credit once the bank acquires it. Eventually, wide consensus emerged and the contract became the workhorse of Islamic banking practices, from large multi-million-dollar loans to Western corporations to retail-bank secured lending.

### Tawarruq (monetization) financing

In order to reduce transaction costs, especially for retail customers who wished to borrow cash, Islamic banks in Gulf Cooperation Council (GCC) countries revived another ancient financial trick: monetization. This transaction is very similar to the cost-plus commodity-sale finance model, with the added complication that the Islamic bank executes all three legs of the transaction: (i) buying the principal's worth of metals at the spot price, (ii) selling said metals to the customer on credit for principal plus interest, and (iii) selling the metals back to the dealer, as the customer's agent, for the spot price less a small fee. All three transactions can be concluded within minutes via fax. This transaction avoids the forbidden two-party sale–resale trick by adding not only one commodity as a degree of separation between lent principal and repaid principal plus interest, but also a third-trading-party degree of separation (the metals dealer) so that every two parties formally trade the commodity only once. The commodity still completes a round-trip (dealer→bank→customer→dealer), spot cash in the amount of desired principal completes one trip (bank→dealer→customer), and the credit-sale-price payment of principal plus interest occurs in the future (customer→bank). This three-party variation on same-item sale resale was also known in ancient and medieval practice, and deemed forbidden or reprehensible by most schools of law. Some medieval scholars within the Hanbali school of jurisprudence, which is dominant in the GCC, had permitted this practice. Despite the fact that the most respected 14th-century scholars ibn Qayim and ibn Taymiya forbade the transaction (as merely an expensive and potentially more hazardous type of usury/riba), contemporary Hanbali jurists who dominate one juristic council in Saudi Arabia permitted the practice in 1998. The same council later forbade the organized practice of Islamic banks using this contract in 2003, but the practice continued to thrive.

Ijara (lease) financing, securitization and sukuk (Islamic bonds)

Despite juristic approval of credit-sale-based financing methods, the practice remained suspect in scholarly as well as general Islamist circles. In addition to objections that the practice merely replicated interest-based financing with interest characterized as profit or markup, there were problems with securitization and trading of receivables from *murabaha* and *tawarruq* facilities. Those problems arose from the fact that most jurists, with the notable exception of those in Malaysia, forbade trading of debts, except under very strict transfers at face values and resale to the debtor. This prevented the development of secondary markets that would allow banks to diversify their portfolios and sources of funds. Lease financing provided a partial solution to both problems: it was ostensibly based on real assets that continued to play a role throughout the life of the financial facility, and it was possible to trade lease receivables on secondary markets as ostensible shares in the leased assets.

Jurists were adamant that Islamic lease or *ijara* financing must be truly asset-based, and therefore must be structured as operating rather than financial leases. However, recent advances in structured finance – which helped corporations such as Enron to move debts and interest payments off balance sheets through sale-leaseback structures – had blurred the line between operating and financial leases. As a result, a prestigious juristic council declared in 2008 that more than 80 per cent of lease-based bond (*sukuk*) structures were un-Islamic, since material ownership of the underlying assets was not real. Developed initially as another mode of secured lending, lease financing proceeded by acquiring durable assets and leasing them with an option to buy – principal plus interest passing to the lessor as rent plus potential final payment. For banks in countries that forbid them from owning real estate, special purpose vehicles (SPVs) received credit that were used to acquire the assets and lease them till maturity. Shares in those SPVs were treated as shares in the leased properties, thus allowing them to trade on secondary markets. In the United States, such structures were used to originate mortgage loans that were then securitized through Fannie Mae and Freddie Mac, and marketed both domestically and in the cash-rich GCC, especially after the second wave of petrodollar flows began in 2001.

Bond structures were easily adapted from these financial forms. An entity that wished to issue a bond would create an SPV, which sold shares for the amount of financing desired. The proceeds of that sale were used to buy some asset from the originator, which asset was promptly leased back. The originator would thus collect the proceeds of the sale of its asset as principal, and pay principal plus interest in the form of rent and/or a final repurchase price, which payments were passed through to the *sukuk* or bond holders. An added advantage of this structure is that the payments were made ostensibly on shares in ownership of the real asset, thus the contract could be advertised as a form of partnership, which appealed to the earlier political-Islam inspired literature on Islamic economics.

Jurists further facilitated securitization of debts by allowing a portfolio of asset-based and purely debt-based receivables (that is, lease-based and credit-sale-based, respectively) to be traded as long as the asset-based component exceeded 51 per cent of the total face value (Usmani, 1998). This strange provision clearly imposed no significant constraints on securitization, since successive portions of pure-debt receivables could be bundled iteratively with the same asset-based ones, which could be bought back repeatedly for the purpose of bundling with pure-debt tranches. Thus, Islamic finance became an equal partner in the credit bubble the ensued in the first decade of the 21st century. In fact, the volume of *sukuk* remained sufficiently small (relative to demand by Islamic banks) to merit abnormally high prices and low yields relative to conventional debts issued by the same entities.
Islamic mutual funds

A widely publicized area of Islamic finance was the development of ‘screening’ methods to identify ‘Shari’a compliant’ stocks. These screens excluded stocks of companies with significant forbidden activities (such as breweries), and also of firms with excessive debt or interest income. The debt screen chosen by the industry was particularly perplexing, as it excluded firms with debt to market capitalization ratios exceeding one-third. This rule clearly forced fund managers to buy high and sell low in highly volatile markets. Moreover, the rule diverted funds away from Muslim-owned companies, which were not allowed any degree of unsecured-loan leverage, in favour of western firms with moderate levels of leverage. The financial screens themselves had no foundation in Islamic law or reasonable economic analysis, starting as they did at 5 per cent debt to assets and evolving during the tech-stock bubble of the late 1990s into 33 per cent of debt to assets and then 33 per cent of debt to market capitalization. It is not clear whether and when these rules can be replaced with sensible ones.

Takaful (Islamic insurance) and derivatives

One of the fast-growing sectors in Islamic finance is an Islamic alternative to commercial insurance known as takaful (mutual support). The rhetoric of this sector is based on the idea of mutual protection against losses, but most takaful companies to date have not been structured as mutual insurance companies (in which policyholders and shareholders are the same individuals). Instead, takaful companies are generally shareholder-owned and act through silent partnership or agency to invest the policyholders’ premiums and pay legitimate claims in the form of ‘voluntary contributions’ – thus avoiding the Islamic prohibition of gharar, which includes trading known amounts (policy premia) for uncertain future amounts (on potential valid insurance claims). The prohibition of gharar was also invoked to forbid derivative securities, but forwards and options were easily synthesized from the ancient contracts of salam (prepaid forward sale) and ‘urbun (downpayment call option), respectively.

Substance and form

El-Gamal (2006, 2008) has argued that the essence of the ancient religious law was regulatory. It is well known in financial economics that financial innovators eventually find means to circumvent outdated regulation, thus increasing systemic risk. Financial crises later propel political and economic authorities to impose further regulations for innovators to circumvent. In this regard, the ancient religious regulations enshrined in medieval Islamic jurisprudence, especially if interpreted naively as prohibitions of certain contracts and permissions of others, are woefully out of date, and therefore ceased to perform their regulatory function centuries ago. Indeed, that is precisely why majority-Muslim societies had abandoned those outdated contract-based frameworks before the Islamist revisionism of the mid-20th century. The ancient law, which is not uniquely Islamic, does contain many lessons for today’s societies – Muslim and otherwise. However, rent-seeking behaviour by bankers, lawyers and religious scholars on the one hand, and incoherent pietism and adherence to fictional Utopian history on the other, have prevented societies from adapting this centuries-old accumulated human wisdom for any purpose.
beyond short-term self-enrichment and identity-political appeasement, both of which increase rather than ameliorate systemic risks.

IS–LM in modern macro

Edward Nelson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The IS–LM framework is associated with traditional macroeconomics, but versions of IS and LM functions can be justified using dynamic general equilibrium models that assume optimizing behaviour on the part of the private sector. The baseline version of these optimizing IS–LM relationships is discussed. Relative to the traditional IS–LM specification, the IS relationship in the optimizing IS–LM framework involves an extra term, which reflects the dependence of real aggregate demand on the expected level of spending next period. This extra term is implied by the intertemporal behaviour of households.

Keywords
aggregate demand; dynamic stochastic general equilibrium (DSGE) models; infinite horizons; IS–LM in modern macro; IS–LM model; monetarism

Article

Background: traditional IS–LM

Some discussions use the term ‘IS–LM’ as a catch-all label for the approach of traditional Keynesian economics. The treatment here, however, will follow Sargent (1987, p. 53) in interpreting ‘IS–LM’ narrowly (and literally) as a pair of structural equations describing real aggregate spending as a function of the real interest rate, and real money demand as a function of scale and opportunity cost variables. From that perspective, it is not strictly accurate to talk of an ‘IS–LM model’ (since IS–LM is only a portion of a macroeconomic model) or to refer to the ‘sticky-price assumption’ of IS–LM (properly specified IS and LM equations are structural and should be independent of what is assumed about price behaviour, whose specification belongs to the supply side of a model; and IS–LM analysis in conjunction with price flexibility was considered even in Hicks, 1937). Nor should models that have
separate equations describing consumption and investment behaviour be considered models containing
IS–LM equations, since deriving an IS equation necessarily involves eliminating the components of
aggregate demand in favour of an expression for total demand.
It follows that, to find descendants of traditional IS–LM in modern macroeconomics, one should focus
on cases where general equilibrium models produce a pair of equations clearly recognizable as
corresponding to IS (real aggregate spending) and LM (real money demand)-type relationships.

IS–LM in modern macro: early literature

Early attempts to link IS–LM with dynamic optimizing macroeconomics include Aiyagari and Gertler
(1985) and Fane (1985). These attempts, however, did not use infinite-horizon agents (the standard
assumption in modern macroeconomics) and usually left more endogenous variables than output and the
real interest rate in the equation for total spending, so this equation was not clearly recognizable as an IS
relationship.
This early literature did show that it was possible to derive a conventional money demand equation from
an optimizing model. This was also shown by McCallum and Goodfriend (1987) using an infinite-
horizon model. A semilogarithmic version of McCallum and Goodfriend's money demand equation is:

\[ rm_t = c_1 c_t + c_2 R_t \]

(1)

where \( c_1 > 0 \), \( c_2 < 0 \), and \( rm_t \) and \( c_t \) denote log-deviations of real money balances and real household
consumption from their respective steady-state levels, with \( R_t \) being the short-term net nominal interest
rate minus its steady-state value.
In light of the feasibility of deriving an LM relationship from an optimizing general equilibrium model,
most discussions concentrated on whether IS-type relationships, and therefore IS–LM as a whole, are
compatible with optimizing behaviour. A symposium on the subject of IS–LM and modern
macroeconomics (Young and Zilberfarb, 2000), which largely predated the recent literature, was
generally negative about the prospects of linking up modern macroeconomics with IS–LM.

IS–LM in modern macro: later literature

In discussing the recent literature, it is worthwhile first stepping back to Hall (1978, p. 974), who
showed that an infinite-horizon dynamic general equilibrium model implied an equation for aggregate
household consumption (\( C \)) of the form

\[ C_t^{-(1/\sigma)} = \beta (1 + r_t) E_t C_{t+1}^{-(1/\sigma)} \]
where $r_t$ is the short-term net real interest rate, $\beta$ is the household's discount factor and $\sigma > 0$ is a utility function parameter (with a large $\sigma$ value implying high intertemporal substitution in consumption). A log-linearized version of this equation is:

$$c_t = -\sigma(r_t - E(r)) + E_t c_{t+1}$$

where $E(r)$ denotes the steady-state value of $r_t$. Consumption equations such as (3) continue to be present in the dynamic stochastic general equilibrium models prevalent today. What is different in the recent literature is a change in emphasis in interpreting the equation. Hall (1978) treats the real interest rate as fixed and focuses on the implied univariate behaviour of consumption. The recent literature does not treat the real interest rate as fixed, and instead builds up from the consumption condition (3) to an economy-wide description of aggregate real spending behaviour. If consumption is the only component of aggregate demand (implying the relation $c_t = y_t$), then eq. (3) implies an aggregate relationship – the optimizing IS equation – of the form:

$$y_t = b_1(R_t - E_t \pi_{t+1}) + E_t y_{t+1}$$

where $b_1 = -\sigma < 0$, $\pi_t$ is inflation minus its steady-state value, and the Fisher condition $(r_t - E(r)) = R_t - E_t \pi_{t+1}$, has also been substituted in. Under the same approximation that output equals consumption, log output becomes the scale variable in the money demand function, so that eq. (1) implies an LM relationship:

$$rm_t = c_1 y_t + c_2 R_t$$

Alternative assumptions to that of strict equality between consumption and output will deliver much the same IS relationship as eq. (4). For example, one could assume constant but non-zero investment, or
random-walk exogenous investment behaviour (as in McCallum and Nelson, 1999), or proportionality between consumption and investment, and in each case derive an IS equation isomorphic to eq. (4). Whatever the precise derivation, the common element in the recent literature that starts from the Euler consumption condition is that, instead of making restrictions, as Hall did, that lead to conclusions about the unforecastability of consumption growth, it sees the condition as underpinning a structural relationship describing the level of total real spending. In this relationship total spending is a function of the real interest rate, expected future spending levels, and exogenous shocks. The negative coefficient on the real interest rate allows a parallel with the traditional interest-elastic IS relationship $Y = f(r)$. That parallel has been highlighted by the later IS–LM literature, including Koenig (1989; 1993), McCallum (1989, p. 105), Woodford (1995; 2003), Kerr and King (1996), Rotemberg and Woodford (1997), and McCallum and Nelson (1999).

**Shocks**

It is straightforward to justify the addition of exogenous shock terms to the optimizing IS and LM equations. Preference shocks in the household’s utility function can deliver this result: for the IS equation the shock is to the marginal utility of consumption; the LM shock, on the other hand, is a combination of the shocks to the marginal utility of consumption and to the marginal utility of services generated by real money balances. In addition, the portion of government spending that is not well approximated by a (log) random walk will produce a further rationale for an IS shock.

**Treatment of capital**

As noted above, a restrictive assumption about investment (that is, that it is constant or random-walk exogenous) is needed to derive the optimizing IS eq. (4). Dupor (2001) criticizes such approximations on the grounds that investment is a sizable portion of aggregate demand and a major contributor, in arithmetic decompositions, to real GDP fluctuations. These facts can be accommodated, however, without making investment endogenous. One can simply assume that investment has a random-walk and a stationary component, both exogenous. The exogenous stationary component becomes a further IS shock and can be assumed to be highly variable.

**General equilibrium status**

Early discussions of dynamic general equilibrium models stressed the interdependence of aggregate demand and supply relationships, and, that being so, the infeasibility of labelling a subset of equations specifically ‘aggregate demand’ equations (see, for example, Sargent, 1982). By contrast, the approach that derives IS and LM relationships from a general equilibrium analysis emphasizes that a subset of equations may be labelled ‘aggregate demand’ relationships; and that other conditions describing private sector behaviour (such as firms’ pricing and hiring decisions and households’ labour supply condition) constitute the aggregate supply block. Common separability assumptions regarding the private sector’s preference and cost functions justify this division of equations. The central assumption is that the terms
involving consumption, leisure, and real balances are additively separable in the private households’ utility functions.

Is it an IS equation?

The optimizing IS function has been criticized as not descriptive of the original ‘investment–saving’ acronym, as its baseline version comes from a model with no investment fluctuation and with saving zero or constant in equilibrium. But ‘IS’ was always a description of how aggregate spending fluctuations related to interest-rate variations – an ‘income sensitivity’ or ‘interest sensitivity’ equation rather than really an ‘investment–saving’ relationship. Detailed discussion of saving issues typically would not use the assumptions (for example, those regarding infinite horizons for agents) underpinning baseline optimizing macroeconomic models. Alternatively, the old ‘investment–saving’ label could be justified on the grounds that the IS equation forms part of a model describing the process by which investment and saving are equated. That description remains true of the optimizing IS equation; it happens that in the baseline model underlying this equation, the equilibrium occurs with saving and investment at constant or zero values.

Other interest rates

It is tempting to suggest that the optimizing IS eq. (4) is subject to the monetarist critique of traditional IS–LM because it excludes money from the IS equation. But in fact monetarists did not argue that money belonged in the structural IS equation. Instead, they argued that many yields mattered for aggregate demand and that these yields could not be summarized by a single interest rate (see, for example, Brunner and Meltzer, 1973). Variations in money acquired significance because this spectrum of yields also appeared in the money demand function. The monetarist critique amounts to the suggestion, first, that different financial assets are not perfect substitutes, and second, that the discrepancies between the yields might be related to the behaviour of money. Baseline IS–LM, both old and new, presumes perfect substitutability between assets, in which case the short-term real interest rate is tightly related to other real returns prevailing in the economy. McCallum and Nelson (1999) defend the perfect-substitution assumption as the appropriate benchmark for many purposes. Nevertheless, as Bernanke and Reinhart (2004) argue, for some policy issues this assumption is not appropriate and so it would be desirable to break the link between different returns on assets, and investigate the effect of monetary policy actions on various yields. Such a generalization of IS–LM would tend to put extra real yields into the IS equation and extra nominal yields into the LM function.

The IS–LM model is a short-run macroeconomic analytical construct for studying an economy with idle productive resources. The diagram has been especially influential because its constituent curves are loci on which the goods market (IS curve) and the money market (LM curve) are respectively in equilibrium, making it possible to infer changes in fiscal policy and monetary policy, both separate and simultaneous. The model is prominent in elementary and intermediate macroeconomic textbooks, yet it fails to accommodate the main features of modern macroeconomic theory, although modern dynamic models are sometimes interpreted as having IS–LM type features.

Article

The IS–LM model is a short-run macroeconomic analytical construct for studying an economy with idle productive resources. In the form exposed by Hansen (1949), it is a two-dimensional diagram with the abscissa measuring real income and the ordinate the real interest rate. It has been widely and successfully employed in interpreting macroeconomic policy and is prominent in elementary and
intermediate macroeconomic textbooks. A close antecedent, the SI–LL diagram, first appeared in print in an influential article by J.R. Hicks (1937) that proposed an interpretation of Keynes's *General Theory* (1936) and effectively made Keynes's contribution accessible to large numbers of students ever since. Hicks's diagram had nominal income measured on the abscissa and was unclear about whether the interest rate was real or nominal. If prices are fixed or ‘sticky’ these differences are immaterial, but assumptions about prices and their measurement loomed large in subsequent controversies and applications of the diagram. Lange (1938) appears first to have required that variables were real magnitudes. Reflecting the times of its origin, the model describes a closed economy. The diagram has been especially influential because its constituent curves are loci on which the goods market (IS curve) and the money market (LM curve) are respectively in equilibrium. The intersection of the two curves is a point where both markets (and, through Walras's Law, the bond market) are in equilibrium. The labour market is not required to be in equilibrium. Because fiscal policy affects the goods market through tax, transfer and expenditure changes, the effects of fiscal policy can be inferred from the change in the intersection of the IS curve with a stationary LM curve. Similarly, because changes in the money stock affect only the LM curve, the effects of monetary policy can be inferred from the change in the intersection of the LM curve with a stationary IS curve. Finally, the effects of simultaneous changes in both fiscal and monetary policies can be predicted from the change in the intersection when both curves are moved.

By way of background, the *General Theory* contains no formal mathematical model and has only one diagram. “Keynes believed economics was over-addicted to “specious precision” – making perfectly precise what was in reality vague and complex. It is significant that he refused to present the “model” of the *General Theory* in mathematical form, even though he assembled its (verbal) elements in chapter 18’ (Skidelsky, 1994, p. 540). ‘The mathematicisation of the *General Theory* started immediately it (sic) was published but it was left to Hicks to map the mathematics on to a two-curve diagram which became the accepted form of the *General Theory’ (Skidelsky, 1994, p. 611).

Hicks's article emerged from the September 1936 European meetings of the Econometric Society at Oxford where a symposium on ‘Mr. Keynes’ System’ was held. Other important papers from the symposium interpreting Keynes were by R.F. Harrod (1937) and J. Meade (1937); both were published slightly earlier than Hicks's paper, but contained no trail-blazing graphical apparatus. Young (1987, p. 29) claims that all three papers had the same underlying equation system, which differed from that of the *General Theory* but may have appeared in Keynes's lectures at Cambridge as early as 1934. All three papers analysed the relation between their interpretation of what underlay the *General Theory* and the pre-existing theoretical framework. Keynes apparently did not object to the specifications of Hicks, Harrod and Meade, but stressed the importance of expectations and uncertainty in his subsequent discussions (1937) of the general theory; expectations do not appear formally in the three authors’ equation systems. If one accepts Keynes's (1936, ch. 12) discussion of how long-term expectations are formed, it may indeed be specious to describe commodity market equilibrium as if it were lying on a stationary curve, but that in no way reduces the usefulness of the model for designing and interpreting policy. The effects of monetary and fiscal policy actions are unaffected by random shocks to the two curves. However, the effects might be affected if the curves are moved by expectations about present or future policy moves, as has been suggested by Lucas (1976). Subsequently, J. Robinson (1975) and R. Kahn (1984), two of Keynes's contemporaries when the *General Theory* was being drafted, objected
strenuously to the IS–LM formulation and Hicks himself (1982) indicated dissatisfaction with it.

**Basic theoretical structure**

In the standard formulation of the IS–LM model, the endogenous variables to be determined are the level of aggregate output \( Y \) and the real interest rate \( r \). Aggregate demand in the goods market is modeled via the output identity:

\[
Y = C + I + G + NX
\]

where \( C \) denotes consumption, \( I \) investment, \( G \) government spending and \( NX \) net exports. The identity is given substance by replacing \( C \) with a consumption function and \( I \) with an investment function. Typically, IS–LM analysis assumes that consumption depends positively on disposable income, which equals output \( Y \) minus taxes \( T(Y) \) (income taxes induce dependence of the level of taxes that are collected on income) whereas investment depends on the real interest rate; one could also endogenize government spending and net exports. This leads to the IS equation:

\[
IS: Y = C(Y - T(Y)) + I(r) + G + NX.
\]

Money market equilibrium is defined by equating money demand and money supply. Real money demand, denoted by \( L \) to capture the idea that the demand for money is the demand for liquidity, is assumed to depend negatively on the nominal interest rate, which by definition equals the real interest rate plus the expected inflation rate, \( \pi \). Throughout, expected inflation will be treated as exogenous; as noted below a defect of the IS–LM framework is that it does not embody expectations in an interesting way. The real money supply, \( \frac{M}{P} \), is treated as exogenous, as are the price level and inflation rate. The LM equation is:

\[
LM: \frac{M}{P} = L(r + \pi, Y).
\]

If the demand for money does not depend on the nominal interest rate, then the LM curve uniquely determines the level of output. This special case is of historical importance in understanding the monetarist perspective on macroeconomics. In contrast, if the demand for money is infinitely elastic at some exogenous nominal interest rate, the LM curve uniquely determines the real interest rate. This case
The IS–LM model has a number of well-known implications with respect to the effects of changes in government policy. Increases in government spending $G$ increase the equilibrium levels of $r$ and $Y$ and decrease the equilibrium level of $I$. The reduction in investment induced by an increase in government spending is known as crowding out. When money demand does not depend on the nominal interest rate, there is complete crowding out in the sense that the increase in $G$ is completely offset by a decrease in $I$, so that aggregate demand is unaffected; the independence of money demand from the nominal interest rate has often been treated as a hallmark of monetarism, since in this case changes in fiscal policy have no real effects. Similar results occur when one considers tax changes; a reduction in either lump sum taxes or the income tax rate increases both $Y$ and $r$. With respect to monetary policy, an increase in $M$ leads to an increase in $Y$, a decrease in $r$ and an increase in $I$. Hence, unlike expansionary fiscal policy, expansionary monetary policy increases investment, and so causes crowding in. The exception to this result is a liquidity trap in which changes in the supply of money are accepted by the public at the initial nominal interest rate.

Beyond the evaluation of exogenous changes in government policies on aggregate outcomes, the IS–LM model has also been used to evaluate alternative government policies. Poole (1970) is particularly notable in this regard. Poole compares the stabilization properties of a monetary policy that fixes the nominal money supply with one that fixes the real interest rate. He shows that, if macroeconomic volatility derives from shocks to the IS schedule, then a fixed money stock policy stabilizes an economy more than a fixed interest rate policy; in contrast, when aggregate fluctuations are generated solely by shocks to the LM schedule, a fixed interest rate completely eliminates aggregate fluctuations. The idea that the effects of a monetary policy rule depend on the type of shocks an economy experiences has proven to be of importance in contexts far beyond the IS–LM model; one sees echoes of Poole's reasoning in discussions of the Taylor rule for interest-rate setting.

The IS–LM model has also been used to study the effects of changes in other exogenous (from the perspective of the model) variables on the macroeconomic equilibrium. An especially important issue concerns changes in the price level, because one wants to know whether price adjustments can move aggregate output towards a level consistent with full employment. In the specification so far described, a decrease in the price level raises $Y$ and lowers $r$ because a lower price level increases the real money supply, thereby shifting the LM schedule. This property was considered important in early expositions of IS–LM such as Modigliani (1944) that considered the possibility of a liquidity trap. However, as argued by Pigou (1943; 1947), there is another channel through which lower prices can raise demand. Pigou argued that the level of consumption depends on the level of wealth as well as on disposable income. Since a component of wealth is nominal money, price reductions can increase demand through increases in the real value of money and, hence, wealth. This is called the Pigou (or real
balance) effect. Work on the real balance effect, in turn, affected the study of monetary policy in the IS–LM framework. The seminal paper in this regard is Metzler (1951), who argued that the real balance effect implied an important difference between the effects of a helicopter dropping of money, that is, an increase in the money supply in which additional money are simply added to individual portfolios, and an open market operation, in which an increase in the money supply is generated by the trading of money for bonds, so that one nominal asset is swapped for another, thereby keeping the aggregate nominal supply of assets constant.

Another well-known property of the model concerns the equilibrium effects of an increase in the (exogenously given) inflation rate. In the IS–LM model, an increase in $\pi$ increases $Y$ and lowers $r$. Intuitively, an increase in inflation reduces money demand, requiring an adjustment of the real interest rate and output to compensate. The fact that increases in inflation lead to less than one-to-one increases in the nominal interest is known as the Mundell–Tobin effect (Mundell, 1963a; Tobin, 1965). As before, this property depends on the dependence of money demand on the nominal interest rate.

From the perspective of modern macroeconomic theory, the IS–LM model has very serious deficiencies. One problem is that the model lacks well-defined microeconomic foundations. The price level is treated as exogenous; while prices may be sticky, the complete rigidity found in the IS–LM model is unappealing. Further, the consumption and investment functions are typically specified in an ad hoc fashion, rather than as the outcome of solving explicit decision problems.

Also, the IS–LM model fails to embody aggregate dynamics. The model constructs a snapshot of the macroeconomy without accounting for the fact that the snapshot is really one frame of a motion picture. While expectations variables can be introduced into the model, its static nature precludes one from considering many implications of the intertemporal government budget constraint for the real effects of changes in fiscal policy or the effects of expectations about monetary policy on the sequence of equilibrium price levels over time. This lack of dynamics was recognized early on as a defect of the model; heuristic analyses include Patinkin (1956) who tried to link IS–LM with tâtonnement adjustment of prices à la Walras. Indeed, Patinkin's book was the high point of efforts to link IS–LM with the conceptual structure of general equilibrium models. But this type of work disappeared rather quickly. Later on, efforts were made by Blinder and Solow (1973) and Tobin and Buiter (1976) to account for changes in the stocks of various assets on the IS–LM equilibrium, with particular attention paid to understanding how permanent changes in fiscal policy affect output in the presence of the requirement that the government budget balance with respect to the present discounted value of debt and taxes. These analyses found that accounting for such effects could imply that the long-run effect of a change in government spending exceeds the short-run change. One reason for this is the increased holdings of government debt induced by a fiscal expansion will increase consumption. This type of work also failed to have much effect on the use of the IS–LM framework.

To be fair, a number of recent authors have attempted to provide more rigorous microeconomic foundations to the IS–LM model; McCallum and Nelson (1999) is the most important example. See King (2000) for evaluation of such models. While progress has been made in producing better microeconomics for the IS–LM model, it seems fair to say that much of its use, especially in pedagogical and policy contexts, relies on the model we have described.

Mundell–Fleming model
A variant of the IS–LM model that has proven important in international economics is due to Mundell (1963b) and Fleming (1962); its value derives from the consideration of how the effects of monetary and fiscal policy are altered when one considers the role of the exchange rate. In this framework, a small country is assumed so that the income of the rest of the world, $\gamma^{ROW}$, is unaffected by events in the country. However, actions of the country may affect the exchange rate $e$, defined as the number of units of foreign currency one unit of the country's currency can purchase. Net exports for the country are assumed to obey

$$NX = NX(\gamma, \gamma^{ROW}, e).$$

Higher exchange rates are assumed to lead to a lower level of net exports; this is known as the Marshall–Lerner condition.

The effects of changes in monetary and fiscal policy will critically depend on the effects of a policy on the exchange rate. This, in turn, depends on the degree of integration of international capital markets. Following the classic Mundell–Fleming analysis, suppose that international capital markets are fully integrated. In this case, the real return on investments cannot differ across countries and so $r$ is fixed since the economy under study is small. An increase in government spending by a small economy, in this case, will have no real effects. An increase in $G$ will be entirely offset by exchange rate appreciation, that is, an increase in $e$, so that there is no net fiscal stimulus as the increase in government spending is fully offset by a reduction in net exports. In contrast, an increase in the money supply will induce an increase in output via exchange rate depreciation. These outcomes, of course, presume that the exchange rate is allowed to float.

In contrast, suppose that the central bank authority is committed to maintaining a given exchange rate, $\overline{e}$. In this case, the effects of monetary and fiscal policy are quite different. Maintenance of the exchange rate eliminates any independent role for the central bank in the sense that any action it takes to raise output will have to be undone in order to preserve the exchange rate. In contrast, a fiscal stimulus will induce a subsequent increase in the money supply in order to overcome the associated exchange rate appreciation, which reinforces the effects of the stimulus that are found in the closed economy model.

While current thinking on the interactions of the exchange rate regime with policy effects has moved far beyond the details of the Mundell–Fleming model, the ideas in the model not only proved of direct value for much subsequent research (for example, Tobin and Braga de Macedo, 1980) but has also, via its limitations, defined the agendas of alternative research directions (Obstfeld, 2001).

**IS–LM in the light of macroeconomic history**

Despite its theoretical limitations, the IS–LM model is illuminating in interpreting macroeconomic policy and events in the post-war period, especially in the United States, which could reasonably be viewed as a closed economy in the early years. Between the end of the Second World War and 1951, the
Federal Reserve was committed to a policy of restricting upward shifts in the yield curve in order to reduce the cost of financing the US government's large war debt. During this period, the Federal Reserve effectively 'pegged' the short-term nominal interest rate, so that monetary policy was expansionary whenever the real rate was negative and especially so when inflation was increasing. In the inflationary period between 1945 and 1948, the real short-term interest rate was substantially negative. Although deflation accompanied the recession of 1949, when the real rate turned briefly positive this unsustainable pegging policy together with the onset of the Korean War in 1950 led to the ‘Accord’ of 4 March 1951, which permitted the Federal Reserve to undertake discretionary monetary policy. This early inflationary monetary policy bias may not have been inappropriate, because demobilization after the Second World War led to a massive leftward shift of the IS curve due to falling government spending and essentially stagnant real net foreign and gross domestic investment until 1950. Inflation occurred with the suspension of price controls in 1946, but did not begin to accelerate until the war started in June 1950. The Korean War led to a 75 per cent increase in real government spending and a sizable increase in the real government deficit between 1950 and 1954. An expansion of accelerated depreciation allowances in 1954 was associated with a ten per cent increase in real investment in producers’ durable equipment in the subsequent three years. Both events caused a rightward shift in the IS curve. However, the shifts were rather insidiously being offset by ‘fiscal drag’ that resulted from increases in the marginal income tax rate that existed when the economy was at full employment. The tax rate rose because progressive tax schedules applied to nominal income, not income adjusted for inflation. Following the Accord, the Federal Reserve used open-market operations to fight inflation by raising nominal interest rates on several occasions with unsatisfactory results. Unemployment rates rose as interest rates rose, as might have been predicted from the resulting leftward shift in the LM curve. However, it was not widely understood that the IS curve was also shifting leftward because of the cumulative effects of fiscal drag. Seemingly, restrictive monetary policy induced three recessions in this decade with unemployment rates at troughs successively higher in each recession. Inflation temporarily abated during or shortly after each recession, but then returned, in part, because real short-term interest rates were infrequently positive until 1959.

The 1960 elections resulted in John F. Kennedy becoming president and, of greater significance for this discussion, a generation of economic advisors who understood and were intent upon applying the IS–LM model. The US Council of Economic Advisors’ Economic Report of the President explicitly focused on the importance of the full-employment budget surplus (1962, pp. 78–81) and, thus, fiscal drag. The Council of Economic Advisors also worried about the fact that real gross private domestic investment had been below its 1955 peak for the subsequent six years, a possible consequence of high interest rates. The administration negotiated an arrangement with the Federal Reserve whereby it would attempt to twist the yield curve through open-market operations by increasing short-term interest rates to protect the US gold stock from foreign withdrawals and lowering long-term interest rates to stimulate investment. The Treasury assisted in this effort with its debt management policies (1962, pp. 86–91). The administration increased federal government spending significantly beginning in the 1962 fiscal year and would subsequently stimulate the economy with tax cuts. The federal government deficit rose over the four years after 1960 and the IS curve shifted rightward. Because twisting of the yield curve involved two interest rates, it cannot be interpreted directly with the LM curve; however, between 1961 and 1964 the interest rate on three-month treasury bills rose 50 per cent, the rate on three–five year issues rose 6.4 per cent, and between December 1960 and December 1964 the level of Federal Reserve
credit outstanding rose by 37 per cent. In part because of continuing gold outflows, the last was the largest rate of growth of Federal Reserve credit until that date over any four-year span since the Accord. Net of gold flows Federal Reserve credit expanded by 28 per cent in this period of relatively low inflation. It is hard to argue that the LM curve didn't also shift rightward.

Tax cuts were phased in 1962 in the form of an investment tax credit that effectively reduced the required rate of return that profitable firms needed to undertake an investment project and in 1964 and 1965 in the form of 10 per cent reductions in corporate and personal income tax rates. The investment tax credit and accommodating monetary policy was associated with a 50 per cent increase in real gross private domestic investment between 1961 and 1966; the tax credit implies a rightward shift in the IS curve. The large tax rate cuts in 1964 and 1965 did not lead to an increase in the federal government deficit, partly because GDP rose considerably in response to rising investment. The unemployment rate fell from 6.7 per cent in 1961 to 3.8 per cent in 1966 and the average annual rate of inflation from the end of 1960 to the end of 1966 was less than two per cent, although it began to rise in the fourth quarter of 1965.

Because of rising inflation, a policy change occurred at the end of 1965 when the Federal Reserve signalled with an increase in its discount rate that it would begin to restrict credit. All interest rates (real and nominal) rose sharply in 1966 and the real money supply fell for four successive quarters; the LM curve was shifting leftward. The Federal Reserve was briefly successful in reducing the rate of increase in prices at the end of 1966, but then inflation rose sharply in 1967 and 1968 as large deficits resulted from the Vietnam War. One reason inflation rose was that the Federal Reserve was focusing on nominal rather than real short-term interest rates; the latter were negative on average in the last three quarters of 1967 and so monetary policy was actually expansionary. The IS curve was shifting rightward until a temporary ten per cent income tax surcharge was imposed in January 1968 on corporate income taxes and in April 1968 on personal income taxes. The federal budget deficit in the national income accounts turned into a surplus in the third quarter of 1968. Beginning in early 1968, the Federal Reserve began to raise real interest rates dramatically. With both the IS and LM curves shifting leftward, the economy began to slow and the unemployment rate began to rise in 1969, as the model predicts.

During the 1960s it was becoming less tenable to view the United States as a closed economy. Although the percentage of US exports to GNP had risen from six per cent in 1946 only to seven per cent in 1969, international events were beginning to impair the usefulness of the original Hicksian model. The quasi-fixed exchange rate system that had been established in the 1944 Bretton Woods Conference began to collapse in 1968 when the US gold stock reached a critically low level. In light of the aforementioned important contributions by Mundell and Fleming, which argued that monetary policy is ineffective and fiscal policy is powerful in a fixed-exchange regime with perfect capital markets, it is necessary to digress to explain how the model applied before the actual collapse in 1971–3 and afterwards.

At the end of the Second World War many countries restricted currency and capital flows, which allowed both fiscal and monetary policy to be effective, as in the world Hicks envisioned. These restrictions were gradually relaxed during the subsequent years. As they disappeared, the efficacy of monetary policy weakened, although imperfect capital markets allowed it to have some residual potency. Monetary policy was weakened because countries were obliged to maintain quasi-fixed exchange rates by not allowing real interest rates to vary across countries. In contrast, fiscal policy was strengthened because central banks were obliged to take actions that offset the effects of fiscal actions on real interest rates, essentially causing the LM curve to shift in the same direction that the IS curve shifted.
By 1973 the world was in a ‘dirty’ floating exchange rate system where various countries attempted to maintain some fixed bilateral exchange rates with their major trading partners. Mundell and Fleming had argued that in a pure floating exchange rate system with perfect capital mobility fiscal policy would be ineffective and monetary policy would be very strong, because any action to change a country's real interest rate relative to other countries would be reinforced by a change in its trade balance. In other words, a shift in its LM curve would be reinforced by a shift in its IS curve in the same direction because its trade balance was negatively related to its exchange rate, which was positively related to the value of its real interest rate relative to those of its trading partners. Because countries were unwilling to have their exchange rates be completely flexible, fiscal policy was considerably weakened relative to the fixed exchange rate period but still continued to have some power. Monetary policy was strengthened.

This open economy extension of the IS–LM model has proven to be illuminating about monetary and fiscal policy in the post-1971 period, again particularly in the United States. With the change in the exchange-rate regime, the trade-weighted value of the dollar fell about 20 per cent between 1971 and 1973, which, together with a recession in 1974, was sufficient to allow the United States to have a trade surplus on average through 1976. Between 1973 and 1979 the Federal Reserve allowed the real short-term (federal funds) rate to be negative on average, which led to substantial inflation and a bubble in the housing market. However, the international trade-weighted value of the dollar was essentially unchanged between the middle of 1973 and the middle of 1978, because average nominal short-term interest rates and inflation in major trading partners of the United States moved in tandem. Beginning in 1977 the US trade deficit began to increase and after mid-1978 the value of the US dollar fell unevenly until July 1980.

In July 1980 the Federal Reserve began to reduce the real money stock and, with accompanying large tax cuts in 1981–3, real and nominal interest rates rose to record levels, actions that were not offset by matching policies in foreign countries. As a result, the trade-weighted dollar appreciated from 84.65 (March 1973=100) in July 1980 to 158.43 in February 1985 and the trade deficit soared. The IS curve shifted to the right because the increase in the federal deficit was larger than the increase in the trade deficit during these years; the LM curve shifted to the left. As the IS–LM model predicts, the expansionary effects of the 1981–3 tax cuts, as measured by changes in real GDP and the unemployment rate, were much smaller than those of the similarly sized 1964–5 tax cuts, because of both the non-accommodating monetary policy and the dollar’s appreciation.

In September 1985 a meeting of representatives of five major nations in New York resulted in a successful coordinated effort to reduce the trade-weighted value of the dollar, which fell 30 per cent in the succeeding two years and was followed by a sharp reduction in the US trade deficit. US short-term real interest rates fell until the middle of 1988 and the unemployment rate reached a low of 5.2 per cent in 1989. As the extended IS–LM model predicts, monetary policy was quite effective. Monetary policy effectiveness would be repeatedly evident in the following years. For example, the Federal Reserve raised real short-term interest rates between July 1988 and December 1990 to combat inflation, which resulted in a short recession in 1991. It successfully responded to rising unemployment by cutting its real overnight federal funds interest rate to near zero in 1993, which dramatically lowered the unemployment rate in 1995. By sharply raising this interest rate in 1994, the Federal Reserve managed to continue to lower the unemployment rate with negligible inflation until a stock-market bubble burst in 2001. Both fiscal and monetary policies were strongly expansionary between 2001 and 2005. The real federal funds rate had on average been negative since the end of 2001. As might have been predicted from the
Mundell–Fleming model, the trade deficit expanded enormously; its increase was roughly equal to the increase in the federal government deficit. Finally, a troubling problem with prolonged periods of negative short-term interest rates is that they have tended to manifest themselves in rapid rates of inflation in prices of houses – both in the 1970s and in the 2000s. As Keynes and his followers warned, expectations are at the heart of the General Theory and they are not prominent in the textbook expositions of the IS–LM model. Many macroeconometric models can be interpreted as extensions of the textbook IS–LM model, and as time has passed many of them have increasingly attempted to incorporate expectations formation. Expectations are prominent in the Federal Reserve's recent model (Brayton et al., 1997), but their formation may not yet be accurately represented.

Conclusions

The IS–LM model occupies an awkward position in modern macroeconomics. It is still a workhorse of undergraduate teaching and still widely used by economists in developing intuition about short-run macroeconomic phenomena, including policy counterfactuals; see Colander (2004) for discussion of these roles. However, the model fails to accommodate the main features of modern macroeconomic theory, although modern dynamic models are sometimes interpreted as having IS–LM type features. We expect this dichotomy and this anomalous use to continue.

Article  

French engineer and economist, Isnard was born at Paris on 25 February 1749; he died at Lyons on 25 February 1803. There are no details of his family history except that he had a devoted brother, J.L. Isnard, who was a lawyer and a judge, and who often interceded on his behalf. At the age of 17, Isnard entered the Ecole des Ponts et Chaussées which, even at this early date, inspired interest in political economy and exposed its students to heavy doses of mathematics and statistics. On successfully completing his studies, Isnard began his career as an apprentice engineer in the district of Besançon. While engaged in various works of construction in these environs, he took the time to write his remarkable two-volume work, *Traité des richesses*, which was published in 1781. Isnard's *Traité* is a highly original work, despite the fact that its theoretic core is embedded in otherwise unexceptional arguments against Physiocratic doctrines. By this fact, we may infer that Isnard knew the Physiocratic literature, but we can only speculate on his acquaintance with other writers. Given his background and training, the authors he would have most likely known are Boisguilbert and Vauban (Boisguilbert's ideas were represented in 19th-century course outlines at the Ecole des Ponts et Chaussées, and Vauban's views on the professionalization of engineers were largely responsible for the establishment of the Ecole). Boisguilbert certainly had a vision of an interconnected economy and of a kind of general equilibrium, although he failed to render his conception concrete by erecting any kind of formal, theoretic structure of a mathematical nature. Isnard, on the other hand, was the first writer to attempt a mathematical definition and a mathematical proof of an economic equilibrium. Furthermore, he gave specific form to the general equilibrium concept by constructing a set of simultaneous equations which, in general form and content, anticipated the major elements of the Walrasian system, including the general interdependence of markets and
quantities, the technical specifications of the exchange ratios, and the mathematical determination of the *numéraire*. It remained for Walras to add the engine of utility maximization and to adapt Isnard's model to his own purposes, something which, according to Jaffé (1969), he did with persistence, if not with ease. Isnard's pioneer efforts do not in any way denigrate Walras's monumental achievement, but they do lend force to the conviction that the development of economics was, and remains, a cumulative process. Isnard's *Traité* is now extremely rare. However, the mathematics of his equilibrium analysis of exchange are partially accessible in Robertson (1949), Baumol and Goldfeld (1968), Jaffé (1969) and Theocharis (1983). The significance of Isnard's performance is that he discovered early on the truth that value is not an intrinsic thing but rather is a magnitude which necessarily varies in relation to other goods, whose worth is also interdependent. Specifically, Isnard anticipated the two-good world of Walras in which, for example, the demand for eggs is the supply of wheat and the demand for wheat is the supply of eggs. This elaboration of commodity interdependencies in real terms consumes approximately the first half of Walras's *Eléments*. Mathematically, Isnard treated value as an exchange ratio, moreover, and he worked out the equilibrium process of exchange both with and without money.

It is noteworthy that Isnard extended the subjects under his analytical purview to include, besides the theory of exchange, the theories of production, capital, interest and foreign exchange. Jaffé (1969) has demonstrated that Walras's economic theory bears the imprint of Isnard in each of these areas. Underscoring merely the most striking example of the calibre of Isnard's analysis, Jaffé (1969, p. 40) emphasized his theory of capital and interest, which correctly laid down the rule for optimum resource allocation in the following terms:

> Capitals are distributed among different employments in agriculture, industry, and commerce in such a way that the ratios of their values to receipts from the sale of their products less the costs of upkeep, repair, and replacement – that is, the ratios of [invested] funds to [net] returns – are everywhere the same in all enterprises. This uniformity is achieved and equilibrium established because funds flow to and abound in places where the yield [*intérêt*] is highest and because like things have one and the same value. When things have a higher price in one place than in another, they rush there and equilibrium is re-established. Let F be the value of the funds employed in agriculture and F′ that of the funds employed in industry; let B be the payments for the value of the products of agriculture less the cost of upkeep, repairs and replacement and B′ the payments for the products of industry less the same costs, then the ratio of F to F′ must be equal to the ratio of B to B′ for the ratio of F to B to be equal to the ratio of F′ to B′ or for the rate of interest [in the sense of rate of capitalization] to be everywhere the same. This uniformity [in the rate of capitalization] is realized not only between agriculture and industry in general, but also among individual enterprises.

It is, of course, necessary that perfect knowledge obtain for this conclusion to hold, but even without always making his assumptions explicit, Isnard anticipated much of modern microeconomic theory. The scope and sweep of his analysis unquestionably entitle Isnard to a position of prominence in the history of economic thought. Yet appropriate recognition took a long time. Despite the filiation of ideas between Isnard and Walras, the ‘father’ of general equilibrium analysis mentioned Isnard's name in only
one place, and that an obscure bibliographic article (a French reprint of Jevons's famous bibliography of mathematico-economic works) published in the *Journal des Economistes* in 1878. Add to this the ambiguity, idiosyncrasy and prolixity of Isnard's treatise. His definition and use of mathematical symbols is inconsistent and the essence of his arguments difficult to extract, nested as they are in a morass of other material that is neither very original nor very interesting. Such deficiencies were bound to handicap the recognition and acceptance of Isnard's contribution. In the final analysis, however, Isnard was simply a brilliant pioneer who wrote ahead of his time, and like so many other semi-tragic heroes of economic analysis (for example, Cournot and Gossen), he failed to receive his due until long after departing the scene.

Isnard suffered in his personal life even as his ideas suffered (by neglect) in economics. Hot-tempered, yet not given to the intrigues apparently required to advance in the engineering ranks of a quasi-military public service, Isnard spent most of his career in a subordinate capacity. After he finally received a post worthy of his talents, his wife died, leaving him to raise three motherless children. At that point Isnard left government service and struggled in penury for some time. Recalled by Napoleon for the Egyptian campaign in 1798, he was inexplicably left behind. Adding insult to injury, he was forced to take an oath of allegiance to the Republic even though he was an avowed royalist. He later became a member of the Tribunate under Napoleon and took an active part in the formation of public finance and conscription policies. But upon completing his term he resumed his engineer's career at Lyons, where he died soon after, 54 years to the day from his birth. Given his apparent influence on Walras, Theocharis (1983, p. 62) probably did not exaggerate much when he labelled Isnard's *Traité* ‘one of the most important contributions in the history of the development of mathematical economics’.

How to cite this article

The history of economics in Italy reflects an interaction between scientific–educational institutions and political power, which led economists to combine a theoretical approach and political commitment. During the Enlightenment a network of circles and public academies spawned the contributions of Beccaria, Genovesi, Galiani, Ortes and Verri. The institutionalization of economics in the 19th century prepared the success of the marginalist generation led by Pantaleoni, Pareto and Barone. In the interwar period, academic economists formed a bulwark against Fascism. The post-war political climate favoured the internationalization of economics, with the importation of Keynesianism and, later, other currents of thought.

Keywords

This article examines the evolution of Italian economic thought from its origins to the post-Second World War years, when the professionalization and internationalization of economics reached maturity, sowing the seeds of the present vigorous state of economic studies. It offers an institutional history of political economy, distinguishing four epochs. The first epoch runs from the 16th to the 18th century. In this period, the alliances between enlightened sovereigns and groups of intellectuals produced a wealth of original contributions to economics. The second epoch corresponds to the Napoleonic age and the Restoration. This was a period in which, despite political repression in Italy, Smithian political economy penetrated many circles and was debated in journals and academies. The third epoch runs from the unification of Italy in 1860 to the rise of the Fascist regime in 1922, and is referred to as the ‘liberal age’. This period was crucial for the institutionalization of economics and for the prominent public role that was attributed to economists. Such a favourable environment was responsible for the high standard of scientific debate, which culminated in the generation of Pantaleoni and Pareto, when Italian economics, as Schumpeter wrote (1954, p. 855), ‘was second to none’. Finally, the fourth epoch regroups the Fascist era and the post-war years. During the decades of Fascism, the regime's attempts to control economic debate produced a reaction of self-defence and isolation among neoclassical economists. After the war, the new climate of liberty encouraged economists to get back to their public role. The political debate on economic planning was responsible for the acceptance of Keynesianism in the 1950s. The success of Neo-Ricardianism in the 1960s and, later, of American-based mainstream economics marked the internationalization of Italian economics.

Public happiness and geometrical method: from the origins to the Enlightenment

Although in the Middle Ages theological debate over the ‘just price’ and the legitimacy of usury flourished in many parts of Italy, and Italian authors came to be respected throughout Europe, the beginnings of modern economic science in this country date from the 16th and early 17th centuries, when the formation of regional states generated a need to regulate public finances, trade and the circulation of money. Some traces of economic analysis can be found in the treatises on politics published by the humanist Niccolò Machiavelli (1469–1527) (Discorsi sopra la prima deca di Tito Livio, 1513–21) and the Jesuit Giovanni Botero (1544–1617) (Della Ragion di Stato, 1589). But the most original analyses were contained in some short treatises of a systematic and highly formalized character, based on a hedonistic framework, a coherent theory of value and an extensive use of mathematics. The theoretical framework they provided could be employed to interpret the monetary and commercial problems of the time. Of this kind are the Discorso sulle monete (1582) by the aristocrat Gaspare Scaruffi, the Lezione delle monete (1588) by the merchant and historian Bernardo Davanzati (1529–1606), the Breve trattato delle cause che possono far abbondare li regni d'oro e d'argento, dove non sono miniere (1613) by Antonio Serra, whose life is shrouded in mystery, and the Trattato mercantile della moneta (1683) by Geminiano Montanari (1633–87), a professor of mathematics and astronomy. These works were connected to the diffusion of the Catholic currents inspired by Platonism and hostile to Aristotelian scholasticism that were at the root of the Galilean revolution. The abstract nature of these texts can be explained by the fact that they were a product of the scientific academies.
created in this period under the aegis of the Italian princes – especially those in Florence – with a view to encouraging knowledge which could be useful in strengthening state power and countering the civil decay of the country, for which they blamed the political influence of the Church. The authors of these economic treatises were natural philosophers who acted as temporary consultants to government or were members of the state bureaucracy.

The long wave of Galilean and Platonic doctrines continued through the 18th century and had a recognizable impact on the theoretical structure of the economic discourse in the two circles that were at the centre of the Italian Enlightenment, combining in different ways with new ideas coming from France and Scotland and with ideas from other indigenous traditions. The first of these circles was the Accademia dei Pugni of Milan, which was run by Pietro Verri (1728–97), author of the *Meditazioni sull’economia politica* (1771) and Cesare Beccaria (1738–94), known not only for his main work, *Dei delitti e delle pene* (1764), but also for a series of theoretical articles on political economy published in the journal of the academy, *Il Caffè* (1764–6). The second group was that in Naples headed by Bartolomeo Intieri, whose discussions sparked both *Della moneta* (1751) by Ferdinando Galiani (1728–87) and *Lezioni di economia civile* (1766–7) by Antonio Genovesi (1713–69). These groups became involved in the economic reforms their monarchs were trying to bring about, as revealed by the public offices obtained by Verri, Beccaria and others. Also in other parts of the country, the academies were called upon to produce a science whose utility was measured in terms of greater dominion over nature and of the greater ability of governments to increase ‘public happiness’. But it was the 1753 foundation of the Accademia Economico-Agraria dei Georgofili in Florence that sanctioned the scientific status of economics and its political role in the strategy of reform. Right up to the end of the 18th century, this academy was to be one of the main vehicles for the spread of Physiocratic and Smithian doctrines in Italy. Its journal was an example of the many agricultural periodicals that hosted economic debates, often of a practical kind, albeit open to the new science of political economy.

Collaboration between philosophers and princes ushered in the creation of the first teaching of political economy as part of a reform of university studies whose purpose was to bring them under the umbrella of the state, combating the control that religious orders and professional bodies had traditionally exerted over them. A chair of Commercio e meccanica was founded in Naples in 1754 on the initiative (and funding) of Intieri, and conferred on Genovesi. Another professorship of political economy, established at the Scuole Palatine, Milan, in 1768, was assigned to Cesare Beccaria. Similar chairs were created in Modena, Catania and Palermo. The aim of these chairs was twofold: they should instruct government bureaucrats in the art of governing economic and financial affairs, and stimulate the application of new agricultural techniques and agrarian laws.

From a theoretical point of view, the contribution of these authors – to whom one should add at least Giammaria Ortes (1713–90) and Gianbattista Vasco (1733–96) – is quite homogeneous. Their core approach is based on a natural law framework which turns around a static rather than dynamic notion of equilibrium, and suggests that there are forces in society that tend to restore equilibrium when natural disasters, changes in tastes, or political errors create unbalances. Another basic assumption is the sensationalist view that human beings are constantly under the guidance of pleasure and pain. The underlying methodology is still abstract and ‘geometrical’, as in the works of their predecessors. The focus of analysis is on problems of exchange rather than of production (although Beccaria gave the clearest definition of the division of labour before Adam Smith). Their main contributions concern the analysis of value, based on utility and scarcity: Ortes, Beccaria and Verri attempted a mathematical
formulation of the law of demand and supply as a guide to the analysis of price adjustments. Another theme of inquiry is the theory of money, where Galiani, adopting metallist assumptions, expounded a clear distinction between short-run variations in the value of money and long-term effects, and between real and monetary effects. Finally, these authors shared a view of the sovereign as a reformer and supreme moral authority, who takes into account the feelings and needs of individuals and constructs a social order according to the dictates of reason and natural law. This order consists of an equilibrium of interests that generates ‘public happiness’ (felicità pubblica).

The spread of classical economics in the age of Risorgimento (1815–60)

Although the Napoleonic age is considered, in Europe as a whole, a period in which political economy was regarded with suspicion, in Italy the establishment of the Empire's satellite kingdoms favoured the discipline's development and its institutionalization. However, the content of teaching was radically modified: theoretical economics was reduced in order to make room for legal and statistical notions, which were considered more urgent for the training of public officials. Moreover, Napoleonic administrations concentrated on the collection of detailed statistical information about the condition of their départements, in order not only to promote anti-feudal reforms but also to protect French interests. A new generation of government officials was assigned to this task: among them there was the most important economist of this period, Melchiorre Gioja (1767–1829), who published his main work, the Nuovo prospetto delle scienze economiche, between 1815 and 1817. Gioja examined Smith's and Say's theories with a critical eye, and his original analysis of cooperation, division of labour and machinery was acknowledged by Charles Babbage as an anticipation of his own theories. Regarding economic policy, Gioja was favourable towards state intervention in order to foster the development of agriculture and manufactures.

Another Napoleonic official was Pietro Custodi (1771–1842), who from 1803 to 1805 edited the 50 volumes of a collection titled Scrittori classici italiani d'economia politica, which reproduced most of the Italian texts on political economy from previous centuries. Custodi aimed at stimulating the patriotic spirit of his fellow citizens by encouraging them to improve their economic and statistical knowledge. This collection produced in the next generation of intellectuals of the Risorgimento era an exaggerated feeling of national pride, which nevertheless encouraged the study of economics. Economics experienced its worst period after the Restoration in 1815. The reactionary governments of the Italian regional states considered the teaching of economics to be a vehicle for liberal and democratic ideas. As a consequence, all chairs of political economy were suppressed, except in Naples and Sicily, where they were put under strict political control. Only in the 1840s, in Piedmont and Tuscany, with the establishment of constitutional governments, was the teaching of political economy restored. Antonio Scialoja (1817–77), first, and then Francesco Ferrara (1810–1900) were appointed professors at the University of Turin, while other chairs of economics were created in Pisa and Siena. In these conditions, discourse on political economy went on largely outside universities. This does not mean that it was clandestine, since it was developed in academies and associations which enjoyed an official status. But the political control over these institutions implied that public debate on controversial issues was sometimes tolerated and sometimes heavily repressed. Already in the Napoleonic age newly founded institutions, such as the Accademia Pontaniana of Naples or the Istituto Nazionale, established in Bologna and transferred to Milan in 1810, had included departments of moral and political sciences.
where political economy was discussed. Furthermore, the experiences of 18th-century agrarian academies had prompted the establishment of a network of provincial associations termed ‘agrarian’ or ‘economic societies’, which aimed at promoting the development of local economies. These associations continued their activities even during the decades following the Restoration, expanding from Piedmont to Sicily. Despite their eminently practical goals, economic societies gave an important impetus towards the spread of British and French political economy and laissez-faire ideals. 

Another means by which political economy spread through the Italian learned classes was the periodical press, despite the existence of censorship. In the early decades of the 19th century the heading ‘political economy’ appeared on a growing number of articles published in new journals of ‘sciences, letters and arts’, such as the *Biblioteca italiana*, founded in Milan in 1816, the *Antologia*, created in Florence in 1821, and *Il progresso delle scienze, delle lettere e delle arti*, first published in Naples in 1832, where it acted as the main point of convergence of liberal culture. Lively exchange of ideas was also found in journals of agriculture, especially the *Giornale agrario toscano*, founded in 1827, which together with the Accademia dei Georgofili promoted an original debate on sharecropping echoing Sismondi’s remarks in *Tableau de l'agriculture toscane*.

The first signs of a trend towards specialization in economic disciplines came with the birth of several journals mainly devoted to statistical and economic themes, such as the *Annali universali di statistica* and the *Giornale di statistica*. The former was first published in Milan in 1822 and had among its contributors Gioja and Giandomenico Romagnosi (1761–1835). The latter was founded in Palermo in 1836 as the organ of the Central Statistical Office. Edited by Ferrara, it achieved immediate recognition as the premier forum for debate among Sicilian laissez-faire economists. Another interesting experiment was *Il Politecnico*, launched by Carlo Cattaneo (1801–69) in 1839. The majority of the essays were composed by Cattaneo himself, and dealt with various practical issues. However, in two remarkable articles Cattaneo focused on doctrinal questions, criticizing the protectionist theories of Friedrich List, and arguing that knowledge and motivation are the most important factors of economic development. But one should also mention a number of journals created in Naples in the 1840s, which arose against the backdrop of private law schools, established as an alternative to the more conservative form of instruction offered by the universities. These journals and institutions soon became a focal point for the new school of liberal economists, of which Scialoja was the main representative.

As this description makes clear, the political economy debated in these forums was that of Smith and Say. In northern Italy a key figure was Romagnosi, a legal philosopher who – taking inspiration from Giambattista Vico's philosophy of history – formulated a peculiar version of Smithian political economy, in which the notion of ‘natural progress of opulence’ was employed to argue that economic development depended on a framework of formal and informal institutions (so-called *incivilimento*), and that government-induced industrialization would result in social disaster. Romagnosi’s ‘institutionalist’ approach influenced a whole generation of economists, stimulating interesting contributions on the relationships between law and economics. In the south of Italy, the penetration of classical economics was mediated by the influence of the French idéologues, which caused Say's work to be received enthusiastically. The most brilliant product of this environment was Scialoja's *I principj della economia sociale esposti in ordine ideologico* (1840), translated into French in 1844, which adopted Say's subjectivist approach to value and developed the analysis of the entrepreneur in a pre-Schumpeterian sense.

But the most acute and original economist of this age was Ferrara, who in his lecture notes of 1856–8
in the prefaces to the *Biblioteca dell’economista* – a ‘library’ containing the Italian translation of a vast number of foreign works on economics, of which he was the editor – proposed a generalization of the cost of reproduction theory of value formulated by Henry Carey and John Rae. Ferrara’s version of this theory took into consideration three different cases: that of ‘physical reproduction’ by direct labour, that of physical reproduction ‘by way of exchange’ and that of ‘economic’ reproduction by substitutes. In this way, the theory highlighted the fact that value is grounded on utility and subjective opportunity costs, clearly foreshadowing marginalist analysis.

**The institutionalization of economics in the liberal age (1860–1922)**

The epoch that followed the unification of the country in 1860 was decisive for the consolidation of economic studies. Chairs of political economy were introduced in the more than 20 law faculties that existed at the time. In 1876, new university regulations added the teaching of statistics and public finance. The latter was established as a compulsory course in 1885. Likewise in the 1880s, two Higher Schools of Commerce were created in Genoa and Bari, similar to the first institution of this kind, which had been founded in Venice in 1868. This expansion multiplied the opportunities for economists to obtain university positions, and well before the end of the 19th century the social identity of the economist could be largely identified with the academic profession. But a decisive stimulus to the professionalization of economics was provided in the mid-1870s by the explosion of the Italian counterpart of the *Methodenstreit*, the dispute over methods that divided German-speaking economics. All the major economists became involved in it, and opposition between different economic and political conceptions had an important impact on the professional and academic level. These divisions induced economists to devote greater attention not only to the scientific aspects of the profession (training and specializations) but also to academic policy (increase in the number of academic chairs and control over recruitment procedures). This process resulted in a generational change within the ranks of academic staff, leading to a preponderance of the followers of *Kathedersozialismus* or ‘socialism of the chair’ in the German mould.

Another important element is represented by the increasing public role played by economists. The extension of civil liberties, coupled with the institution of a national representative system, gave them an extraordinary opportunity to spread economic knowledge and influence policymaking. Many economists became columnists for newspapers and weekly magazines, while others were active in the foundation of associations of interests, chambers of commerce, saving banks or cooperatives. Lastly, virtually all the leading economists of this age – more than 30 – became members of parliament. And although some of them were involved in parliamentary activities that bore little relation even to the broadest view of the scope of political economy, in the central debates on tariffs and trade, fiscal policies, credit, education, and in inquiries on the condition of agriculture and industry the voice of economists became a typical feature of public life. Some economists were also appointed ministers, while three of them – Paolo Boselli (1838–1932), Luigi Luzzatti (1841–1927), and Francesco Saverio Nitti (1868–1953) – became prime ministers. On the whole, these activities strengthened the scientific and social identity of economists.

The growing professionalization of economists was also reflected in the creation of new societies in which they played a central role. After the first experiments in Turin in the 1850s and early 1860s under the guidance of Ferrara, the Società di Economia Politica Italiana was established in 1868 on the
initiative of the economist Francesco Protonotari, who was the editor of the most important scientific and literary journal of the time, the *Nuova Antologia*. These associations attracted the great majority of academic economists and many representatives of the political elites. The constitution of the Società di Economia Politica significantly opened with the statement that the Society's mission was to ‘promote and disseminate economic studies’. However, very soon its activities were dominated by more practical discussions on parliamentary debates and government economic policy. Conflicts concerning the new orientation of the society's purposes led to a gradual slowdown in the pace of activities.

It was against this backcloth that the *Methodenstreit* arose, breeding the projects of two rival associations. The former, dubbed Società Adamo Smith, was set up in Florence in 1874 on the initiative of Ferrara and several laissez-faire economists and politicians belonging to the group of the so-called ‘Tuscan moderates’. The aim of the Society was that of ‘promoting, developing and defending the doctrine of economic liberties’, and of assuming the character of a scientific body, excluding from debate all that could be more properly described as political. The latter society, called Associazione per il Progresso degli Studi Economici, was created in January 1875 by a group headed by Luigi Cossa (1831–96), a powerful academic of the university of Pavia, Fedele Lampertico (1833–1906), an influential senator of the Venetian area, and by Luzzatti and Scialoja. Responding to Ferrara's splinter-group tendency, these economists had drawn up a document, known as the ‘Padua circular’, which marked the start of the counteroffensive by ‘socialists of the chair’. The society set itself the task of promoting social studies, to be accomplished partly through extension of its organizational structure to different parts of Italy.

Both associations proved to be short-lived, but the overall effect of their activities over roughly a 30-year period was that of ushering in a profound change in the institutional set-up of economic studies, reinforcing the academic and public background of the economists’ activities. This new condition was reflected in the world of publishing. To begin with, while scientific–literary journals continued in their tradition of hosting writings on economic themes, more specialized journals were established. Characteristically, in the 1870s almost all of the economic journals exhibited very close links with one or the other of the conflicting schools of economic thought. Thus, orthodox liberals used as their mouthpiece the journal *L'Economista*, created in 1874, whereas ‘socialists of the chair’ founded one year later the *Giornale degli economisti*. Rather than a genuine forum for scientific debate, however, such journals tended to become tools with which to enter the political fray. This characteristic was to a lesser extent replicated by the new journals that appeared in the 1890s, despite their more scientific and academic nature: the most important among them were the socialist periodical *Critica sociale*, directed by Filippo Turati (1857–1932), the *Rivista internazionale di scienze sociali e discipline ausiliarie*, edited by the Catholic economist Giuseppe Toniolo (1845–1918), and *Riforma sociale* (1894–1935), edited at first by Nitti, and later by Luigi Einaudi (1874–1961). Perhaps the first journal of economics in the modern sense may be considered the new series of the *Giornale degli economisti*, started in 1890 and managed by Maffeo Pantaleoni (1857–1924), Antonio De Viti de Marco (1858–1943) and Ugo Mazzola (1863–99). This journal voiced the radical laissez-faire approach of its editors, while becoming the forum of academic research and the main vehicle of penetration of marginalist theory in Italy.

Even outside the world of journals, greater attention began to be paid to the promotion of economic studies. For instance, after the first two series of the *Biblioteca dell'economista*, edited by Ferrara and published in the 1850s and 1860s, a third series was entrusted to Gerolamo Boccardo (1829–1904) in the 1870s, and a fourth and fifth series were continued by Salvatore Cognetti de Martiis (1844–1901) and...
Pasquale Jannaccone (1872–1959) up to 1922. With its 71 volumes containing more than 150 classics of economics, the *Biblioteca* was extremely successful and became a unique tool for those who wanted to update their knowledge in this field. Economists also popularized their doctrines through dictionaries and encyclopaedias; the most important of them was the *Dizionario della economia politica e del commercio*, published in 1857–61 by Boccardo, who was also the editor of the *Nuova enciclopedia italiana* (1875–88).

Undoubtedly the main instrument for the spread and institutionalization of political economy was the large number of treatises, manuals and popularizations that were published during this period. The authors of these texts were both major economists and a host of lesser-known scholars, philanthropists and schoolteachers interested in the popularization of political economy. The number of works published – almost 300 from 1840 to 1920 – reveals that there was a pervasive ‘need’ for political economy, considered as a discipline that could educate the younger generations of administrators and politicians, instruct public opinion and enlighten the working classes. To judge from the number of editions, the most popular manuals were Cossa's *Primi elementi di economia politica* (1875, 17 re-editions), Emilio Nazzani's *Sunto di economia politica* (1873, 16), Boccardo's *Trattato teorico-pratico di economia politica* (1853, nine), Camillo Supino's *Principii di economia politica* (1904, nine), Achille Loria's *Corso completo di economia politica* (1909, seven), and Augusto Graziani's *Istituzioni di economia politica* (1904, six).

At the same time, the scientific quality of the work was high. Italian economists rapidly assimilated international economic debates, and in some cases they became important protagonists. The quantitative approach to statistics initiated by A. Quetelet and E. Engel was largely accepted in the mid-1860s thanks to the contributions of Angelo Messedaglia (1820–1901), whose methodological works influenced a whole generation of economists, Emilio Morpurgo (1836–1885), and Luigi Bodio (1840–1920), who organized the Central Statistical Office and was elected secretary of the International Institute of Statistics on its foundation in 1885. Some years later, Cossa, Lampertico and Luzzatti were instrumental in familiarizing Italian scholars with the methodology of the German Historical School and the social views of socialism of the chair. These economists promoted a renewal of economic studies along inductivist and quantitative lines, and adopted a critical stance vis-à-vis economic liberalism in matters of social policy. They were called the ‘Lombard–Venetian School’ since most of them taught at the universities of Pavia and Padua.

An even more vigorous and original response to outside stimuli was represented by the penetration of marginalism. Pantaleoni's *Principii di economia pura* – a work largely inspired by Jevons, Edgeworth and Marshall – dated from 1889, but the same author had already published in 1883 a work on public finance based on marginalist notions. Pantaleoni encouraged Vilfredo Pareto's (1848–1923) conversion to the new approach some years later. In 1893, the latter succeeded Walras at the chair of economics in Lausanne. In his *Cours d’économie politique* (1896–7), and more radically in *Manuale di economia politica* (1906), he revolutionized utility theory, laying the foundations of modern microeconomic analysis. A third representative of Italian marginalism was Enrico Barone (1859–1924), whose article on ‘The Ministry of Production in the Collectivist State’ (1908) was included by Hayek in his 1935 anthology on economic planning. Interesting applications to public finance were also provided by Barone himself and by De Viti and Mazzola. Their contributions lay the foundation of an original school of thought whose analysis of taxes, public expenditure, and of the political context in which fiscal structures operate, has been recognized by James Buchanan as the starting point of the development of...
modern public finance theory. A distinctive feature of Italian marginalist economists was their practical and ideological commitment: they engaged themselves in political and editorial activities, staunchly defending a radical laissez-faire view. The socialists Arturo Labriola (1873–1959) and Enrico Leone (1875–1940) attempted to find a compromise between marginalism and Marxism. In the first decade of the 20th century, neoclassical economics had already become the orthodox approach.

Less vigorous, albeit no less original, was the Italian contribution to Marxist revisionism. In *La rendita fondiaria e la sua elisione naturale* (1880), Loria (1857–43) attempted to explain the functioning of a capitalist economy as a result of the structure and evolution of landed property. The historical and theoretical weaknesses of Loria's approach were then attacked at the end of the century by the Marxist philosopher Antonio Labriola (1843–1904), but his efforts to convince Benedetto Croce (1866–1952) to join his camp resulted in a relaunching of revisionism: Croce considered Marx's notion of surplus value as a simple 'mental abstraction' which could not explain the essence of capitalist production. On the other hand, Antonio Graziadei (1873–1953) argued that the labour theory of value was useless to explain the genesis of surplus value and the formation of market prices.

**From corporatism to Keynesianism and neo-Ricardianism**

After an early phase of authoritarian laissez-faire policy delegated by Mussolini to the economist and minister of finance Alberto De’ Stefani (1879–1969), a turn towards a corporatist organization of the economy was accomplished in 1926. The introduction of corporatism was the result of political decisions rather than of scientific debate, although corporatist currents of Catholic and socialist ascendancy had existed since the late 19th century. The fascist regime organized two national conferences in 1930 and 1932 to stimulate a debate on corporatist economics, but they ended up with the defeat of those intellectuals who stood for a more radical transformation of economic relationships along corporatist lines.

On the whole, only from 1925 to 1934 did corporatist economics enjoy some popularity. Its partisans proclaimed that the *homo corporativus* should replace the individualist *homo oeconomicus*, but they failed to produce significant achievements in economic theory. Orthodox economists like Einaudi and Jannaccone, initially forced into a tactical retreat, took back the lead in debate after 1934. Most academic economists – Gustavo Del Vecchio (1883–1972), Marco Fanno (1878–1965), Costantino Bresciani Turroni (1882–1963), Giovanni Demaria (1899–1998), and others – put aside their laissez-faire beliefs and attempted to interpret corporatist economy from a marginalist viewpoint. Corporatism was thus reduced to a case of economic policy, which did not modify the content of pure theory. A characteristic that distinguished these and other economists was their firm attachment to Paretian general equilibrium analysis, which they developed in a dynamic sense elaborating some suggestions derived from Pantaleoni's writings and from Pareto's sociology. At the same time, forced to defend orthodoxy against ideological attacks, these economists largely ignored or misunderstood the nature of the Keynesian revolution.

This success of orthodoxy can be mostly explained by institutional factors. The Fascist government tried to reform the organization of university studies, in 1935 transforming the teaching of economics into that of ‘corporatist political economy’. However, orthodox economists jealously defended their academic autonomy, and the younger generation they recruited was composed of disciples whose career was generally not obstructed by political intrusions. The efforts of the Fascist regime concentrated on
the creation of special schools and research institutions – such as the School of Corporatist Sciences of the University of Pisa, directed by Giuseppe Bottai (1896–1979), the Labour School of Florence, headed by Gino Arias (1879–1942), and the National Institute of Agrarian Economics, directed by Arrigo Serpieri (1877–1960).

Likewise, the major publishing houses – in particular Einaudi in Turin and Laterza in Bari – actively supported orthodox economics. The publisher that more actively sponsored corporatist economics was Sansoni in Milan, which issued a series connected to the Pisa Corporatist School, containing works on corporatism and economic planning. The lobbying activity of liberal economists also succeeded in modifying the editorial project of the Nuova collana di economisti stranieri ed italiani (1932–7), originally conceived as a sequel of the Biblioteca dell'economista and as the seal of Fascist economic culture. As a matter of fact this collection was open to recent international literature (Pigou, Sraffa, Hicks, Frisch, Hayek, Robertson and Keynes), and made no room for corporatist economics. Even the major cultural enterprise of the Fascist regime, the Enciclopedia Italiana edited by Giovanni Gentile, was quite impartial in the choice of authors for its economic entries.

Conversely, Mussolini’s government was able to impose a considerable control over the periodical press. On the one hand, it created its own ideological mouthpieces – such as Gerarchia and Critica Fascista – and favoured the rise of economic journals – such as Economia, founded in 1923, and Nuovi studi di diritto, economia e politica, started in 1927 – that stimulated a considerable debate around the implications of corporatist economics. On the other hand, it extended its repression of journals of the liberal camp. Both La Riforma sociale and the Giornale degli economisti were discontinued for political reasons, in 1935 and 1942 respectively.

One of the costs of the Fascist years was a limited but significant ‘brain drain’: among those who were forced to emigrate were Bresciani Turroni, Umberto Ricci (1879–1946), Piero Sraffa (1898–1983), and the young Franco Modigliani (1918–2003).

The evolution of the economics profession in the post-war period was substantially influenced by the restoration of liberal-democratic institutions. First and foremost, the recovered political freedom favoured the rise of a network of centres of research and advanced studies (the Centre of Specialisation and Economic–Agrarian Research of Portici, the Svimez in Naples, the Istao in Ancona, the Research Department of the Bank of Italy in Rome) and of university departments. Scholarships were granted to young scholars who wanted to continue their studies abroad, encouraging the opening of frontiers to international debate after the relative isolation of the Fascist period. The main economic journals were restructured and new specialized periodicals emerged, adopting international standards. Another crucial event was the creation in 1951 of the Società Italiana degli Economisti, whose constitution stipulated a full economics professorship as a criterion for admission.

The new political context soon stimulated many economists to return to their traditional public vocation. Einaudi, Labriola and Nitti sat in the Constitutional Assembly (1946) with other economists of the younger generation, including Epicarmo Corbino (1890–1984), Amintore Fanfani (1908–1999), Antonio Pesenti (1910–1973), Paolo Emilio Taviani (1912–2001) and Ezio Vanoni (1903–1956). A special Commission on economic and social affairs nominated by the government was chaired by Demaria and composed of the most eminent amongst his colleagues.

It was mostly from the political side that Keynesianism made its entry into the Italian debate in the early 1950s, despite the persisting reluctance of economists to accept its theoretical underpinnings. Some Catholic economists engaged in politics, such as Fanfani and Giorgio La Pira (1904–77) declared...
themselves to have been inspired by Keynes when, as members of the cabinet, they introduced a plan for subsidized housing to reduce unemployment. But a Keynesian flavour could also be discerned in the ‘Plan for labour’ propounded in 1948 by the CGIL, the communist and socialist trade union. Likewise, the ‘Scheme for the growth of employment and income in Italy in the decade 1955–1964’ presented by Vanoni was explicitly inspired by Harrod's growth model. Finally, the debate of the 1960s on economic planning, in which Ferdinando di Fenizio (1906–74), Pasquale Saraceno (1903–1991), Giorgio Fuà (1919–2000), Paolo Sylos Labini (1920–2005) and Federico Caffè (1914–1987) participated, was clearly dominated by Keynesian assumptions. This does not mean that Keynes's theory was not present in more academic debates. The second edition of di Fenizio's Lezioni di teoria economica (1948) reflected the neoclassical synthesis arguing that the Keynesian approach was complementary rather than alternative to classical theory. Also Caffè and Vittorio Marrama (1914–82) published a series of theoretical contributions on Keynesian economic policies. Finally, Keynesianism exerted a considerable influence on the Italian public finance tradition, especially thanks to the works of Sergio Steve (1915–2006).

The 1960s were also marked by the impact on Italian economics of works of Sraffa, who since the 1920s had migrated to Cambridge. His article on ‘The Laws of Return under Competitive Conditions’ (1926) – preceded by a paper published in 1925 in the Giornale degli economisti – had criticized Marshall's equilibrium analysis and paved the way for research in imperfect competition. In Production of Commodities by Means of Commodities (1960) Sraffa expounded an alternative to general equilibrium analysis based on a reformulation of the classical and Marxian notion of surplus. This work originated a school of thought, the neo-Ricardians, that exerted a powerful influence on international scientific debates and on Italian academic life for a couple of decades. Among its main representatives one should count Pierangelo Garegnani and Luigi Pasinetti.

The strength of neo-Ricardian economics has probably been the last distinctive feature of Italian economics, at least in its most theoretical departments. In recent decades, the growing internationalization of this discipline has caused Italian economics to move towards the American-based mainstream of economics, with its typical formalistic and quantitative features. This change has been symbolized by the move to English as lingua franca not only of economic discussion but also of Italian journals, conferences and Ph.D. programmes.

Article

Historian of economic thought whose important contributions were to the study of the work of Léon Walras, Jaffé was born in Brooklyn on 16 June 1898 and died in Toronto on 17 August 1980. He graduated from City College of New York with an AB degree in classics and English (1918), from Columbia University with an MA in history (1919), and from the University of Paris with a Docteur en droit in economics and political science (1924). He taught economics at Northwestern University (1928–66), and at York University in Ontario (1970–80). Jaffé translated Walras's Eléments d'économie politique pure into English (Walras, 1954), thereby providing a major stimulus to the study of his work; edited and exhaustively annotated Walras's scientific correspondence and related papers (Jaffé, 1965a), thereby furnishing an encyclopedic storehouse of information about his writings; and wrote many essays on Walras's economic ideas (Walker, 1983). Jaffé believed that, even in its scientific aspects, a writer's work reveals the influence of his normative views and intellectual environment, and that to understand his work fully it is therefore necessary to study his biography and the era of which he was a part (Jaffé, 1965b). He applied this thesis to the study of Walras's work, examining the aspects of his biography that had a bearing on his theories, explaining the antecedents of his scientific ideas and the philosophical sources of his normative conceptions, and interpreting and assessing his theories of demand, exchange, production, capital formation, money, tâtonnement, and general economic equilibrium.

In an extreme change of opinion, Jaffé came to believe, in the last seven years of his life, that Walras's theory of general equilibrium was intentionally a normative scheme, and that his theory of tâtonnement was intentionally a normative exercise in static analysis (Jaffé, 1980; 1981). It would be a disservice to Jaffé and a denial of his scholarship not to recognize that his soundest judgements on Walras were made during the first 43 years of his study of Walras' work, when he regarded Walras's economic theories as positive in intent and character and the theory of tâtonnement that Walras espoused during most of his career as an attempt to describe the general features of the dynamic adjustment of the market system.
toward equilibrium (Jaffé, 1967).

Abstract

Economics in Japan seems to have developed in two major different ways, political economy and neoclassical economics. The traditional notion of ‘administering the nation and relieving the suffering people’ continued to exert a strong influence on political economists. The German Historical School and then Marxian economics also maintained their very strong traditional hold up to the 1960s, as in other late-developing countries. Neoclassical and Keynesian economics began to develop in the 1930s. Some theoretical economists began to make international contributions to studies of the general equilibrium approach, welfare economics, and trade theory in the 1950s.

Keywords

Economics and economic thought in Japan have changed and progressed in response to various phases of Japanese historical and social development. The Meiji Restoration of 1867 and the Second World War were the two most obvious phases. Before the Meiji Restoration, there were very marked differences between Japanese and Western approaches to economic problems, though even in the Tokugawa era (1603–1867) problems common to East and West seem to have generated some similar economic answers. When Japan opened up to the West in 1867, and when the state came to play a vital role in retaining national independence and promoting rapid industrialization, it is hardly surprising that the ideas of laissez-faire had less appeal than the nation-centred developmentalism of the German Historical School, which was propagated largely from (Tokyo) Imperial University (founded by the government). However, there also existed in Japan a tradition of British liberal economics, especially at the private universities (such as Waseda) and the Higher Commercial Schools (such as Hitotsubashi) (founded by the private citizens). Further, the traditional Japanese notion of the ‘economy’, as it says in Confucianism, ‘administering the nation and relieving the suffering people’, continued to have a strong influence on Japanese political economists even after the Second World War, while the notion of economics as ‘science’ rather than an ‘art’ – the modern neoclassical view of economics – was, with a few exceptions, generally put to one side, particularly before the Second World War.

From the Meiji Restoration to the First World War: the making of modern economic thinking in Japan

With the Meiji Restoration, the flow of Western ideas into Japan turned into a flood, and the study of Western economic ideas and institutions was incorporated into Japan's new knowledge. Though Western economic liberalism awakened modern Japanese intellectuals, it is helpful to think of pre-Meiji traditions of knowledge as providing the framework that determined the types of Western ideas that were widely accepted. Japanese thinkers selected certain parts of Western knowledge as relevant to their interests and gave them a Japanese interpretation.

For the economic thinkers of the early Meiji era, the simultaneous introduction of an industrial capitalist system and its institutions and of Western theories was to create formidable intellectual problems. Two major intellectuals, Yukichi Fukuzawa (1835–1901) and Ukichi Taguchi (1855–1905), were deeply committed to the so-called ‘civilization and enlightenment’ movement and interested not just in economic thought, industry and trade, but in a wide range of subjects related to the humanities and morality. Fukuzawa aimed to promote civilization by advocating ‘wealth’ and ‘virtue’ as means of retaining national independence and of making Japan develop into a strong and wealthy nation, and so suggesting a protectionist policy. His attempt to provide a realistic response to Japan's situation meant...
that his views and ideas were complex, but this very complexity fostered many good economists, industrialists and businessmen, who studied at Keio Gijuku (later Keio University), which he founded in 1858.

On the other hand Taguchi (1878), the author of Japan's version of 'Manchesterism', believed in a harmonious natural law and the universal applicability of free trade. He took forward the banner of laissez-faire doctrine in Meiji Japan with his journal *Tokyo Keizai Zasshi* [Tokyo Economist], which was founded in 1879 and remained active until 1923. Another major journal, *Toyo Keizai Shinpo* [Oriental Economist] was founded just after the Sino–Japanese war (1894–5), at the time of Japan's first industrialization, and edited by people such as Tameyuki Amano (1859–1938), a liberal economist at Waseda who had translated J.S. Mill's *Principles*, and by his pupils. This journal propagated the ideas and policy of new liberalism in Japan, and from 1924 was edited by Tanzan Ishibashi (1884–1973). Ishibashi was active in debates on lifting the gold embargo and later became finance minister (1946–7); he was sympathetic to the economic ideas of J.M. Keynes.

From the late 1880s to the mid-1890s (the second decade of the Meiji period), Japan's economic studies increasingly moved away from English liberal economics towards the German Historical and Social Policy School. This new historical and ethical thinking and the adoption of German financial science in Japan first came about through the 1880 English translation of *Guida allo Studio dell' Economia Politica* (1876) by Luigi Cossa (1831–96, Italian historical economist), and the books by R.T. Ely (1854–1943, American historical economist and a founder of the American Economic Association). Economic discourse by H.C. Carey (1793–1879) and the English translation of *Das nationale System der politischen ökonomie* (1841) by Friedlich List (1789–1846) were propagated through the Japanese National Economics Association (Kokka Keizai Kai, established in 1890), and appealed to those concerned with national independence and the protection of infant industries.

The Meiji governments promoted a developmental state policy that followed the Prussian model of rapid modernization and industrialization; but this caused social problems. The (Tokyo) Imperial University (so called after the Imperial University Act of 1886) became the centre for the dissemination of German ideas in Japan, largely through the *Kokka Gakkai Zasshi* [Journal for State Science], which was founded in 1887. In 1888, Kenzo Wadagaki (1860–1919), who succeeded Ernest Fenollosa, the first professor of economics in Japan, wrote a pioneering article titled ‘Kodan Shakaito’ [The Socialist Party of the Chair]. Noboru Kanai (1865–1933) was instrumental in implanting the German Historical School in Japan and in establishing its theories and policies. Marshall and Mill were still studied, however, at private universities, and Hitotsubashi. T. Inoue (at Waseda) translated Marshall's *Elements of the Economics of Industry* (1896) into Japanese; this soon became a best seller and in 1902 went into its 11th edition.

The Japanese Association for the Study of Social Policy was set up in 1896 to investigate factory laws abroad. Faced with domestic labour problems, the Association, which was opposed to laissez-faire liberalism and to socialism, aimed to prevent class conflict and to sustain social and industrial peace by means of economic freedom and state intervention. Its thinking reflected the pre-Meiji tradition of 'administering the nation and relieving the sufferings of the people', and it considered that economics was interwoven with moral and political issues and embodied the duty of the government to be concerned for the social welfare of its subjects. The Association organized an annual conference and discussed not only labour, but also tariff problems, small industries, the peasantry, and other issues.

Iwasaburo Takano (1871–1949), a core member of the Association who studied with Georg von Mayr, founded a strong tradition of social statistics in Japan and later directed the Ohara Institute for Social
Research (which had been founded by a cotton giant in 1918), which the Marxists expelled from Tokyo University were to make into a centre for Marxian studies before the Second World War. In 1906, following the Russo-Japanese war, the Kokumin Keizai Zasshi [Journal of National Political Economy], co-edited by the staff of the Higher Commercial Schools at Hitotsubashi and Kobe, first appeared. This became Japan's first proper economics journal and a de facto organ of the Association. While Kanai and his followers at Tokyo Imperial University moved towards Adolph Wagner's style of state socialism, Tokuzo Fukuda (1874–1930) at Hitotsubashi and his followers at the Higher Commercial Schools were sympathetic to ‘reform liberalism’ and were closer to the ideas of British political economists. In the Higher Commercial Schools business economics, industrial studies (particularly in small-scale industries) and financial and monetary studies were also well developed. Such a monetary economics tradition made a good basis for the introduction of Keynesian economics into Japan. Keynes's Treatise on Money was translated into Japanese in 1932–4, and the ‘fever’ of the General Theory took hold at Hitotsubashi soon after the book's publication, giving rise to the formation of a group of Keynesian economists.

Teijiro Ueda (1879–1940) studied ‘business policy’ in England with W.J. Ashley, and in 1909, on his return to Japan, he began to lecture on business administration. Highly impressed by Ashley's 'The Enlargement of Economics' (1908) and his proposal for making ‘business economics’, Ueda wrote about and tried to create a business economics aimed at high efficiency rather than high profit, and a science of socially efficient management similar to that established by German business economists such as H. Nicklish. He subsequently lectured on joint stock companies, social reconstruction and the role of managers, stressing ‘the duties of managers’. Ueda published Shakai Kaizo to Kigyo [Social Reconstruction and Business Enterprise] (1921), Shinjiyushugi [New Liberalism] (1927), and others, issuing his own journal titled Kigyo to Shakai [Business Enterprise and the Society]. He actively pursued free trade, and was opposed to socialism, protectionism and the imperialist economic blockade in the 1930s.

In the 1920s, while Marxist studies flourished in academic circles in Japan, particularly at the imperial universities, business economics and management studies also prospered against the background of the rapid development of the corporate economy after the First World War. Ueda's business studies were followed and developed by Y. Masuji at Tokyo and Y. Hirai at Kobe, while F. Muramoto, the first Japanese MBA from Harvard, began to lecture on scientific management at Osaka Higher Commercial School in the very early 1920s. Ashley's pioneering efforts in creating the study of business economics, which were not followed up in Britain, developed at the expanding Higher Commercial Schools and the universities of commerce in Japan. In 1926, the year Ashley's Business Economics was published, the Japanese Society of Business Administration was founded, its original membership numbering 342. Before the Second World War, the Higher Commercial Schools and the universities of commerce played a significant role in the development of economics and business studies. Until Marxian economics became dominant in the 1920s, economics in Japan was very much in a tradition of the German Historical and Social Policy School in broad sense. Japanese economists caught up with many developments very early on, and were innovators as well as consumers of foreign ideas, though they did not develop systematically or perceive the whole economy as a single system.

Fukuda, Kawakami and the Marxian tradition
During the years of the Taisho democracy movement, the Russian Revolution, and rice riots after the First World War, Marxism emerged and began to flourish among Japanese intellectuals, quickly replacing the Historical School. The establishment of economics faculties at the imperial universities in Tokyo and Kyoto and the inauguration of Tokyo University of Commerce took place at about the same time. Initially, Hajime Kawakami (1879–1946) at Kyoto and Fukuda were the leading figures in the study of Marxian economics, whereas Fukuda pioneered the study of welfare economics and the welfare state against Marxism. The newly created economics faculty at Tokyo produced and was dominated by a number of eminent Marxian economists, such as Hyoe Ouchi, Moritaro Yamada, Hiromi Arisawa and Kozo Uno. Many young scholars went to study in Germany.

While Fukuda and Kawakami were initially heavily influenced by the German Historical School, they began to develop original perspectives by assimilating various new trends in economics. Fukuda had been inspired by Roscher and Marshall since his student days, and in Germany studied with Brentano, with whom he co-authored *Rodo Keizairon* [Labour Economics] (Brentano and Fukuda, 1899), discussing working conditions, productivity and the working people's welfare. Fukuda's economic studies covered a wide range of subjects, the most important of which were probably welfare economics and social policy. Though he studied the orthodox welfare economics of Marshall and Pigou, it was from J.A. Hobson that Fukuda learned most about the ethical and humanist approach to welfare economics. Just like the American Institutionalists, Fukuda became openly sympathetic to the idealist, historical and ethical approach of the Oxford economists (or 'London School Institutionalists'), rather than to the so-called neoclassical Cambridge School of utilitarian economists.

Fukuda contended for social policy (or welfare economic studies) as an alternative to Marxism, and proposed a welfare struggle, not a class struggle. Inspired by Lorenz von Stein and Anton Menger, Fukuda developed the theory of social rights, particularly the right to live (needs), and made it the foundation of social welfare policy. This was similar to the Webbs's 'national minimum'. The art of economics would be to provide the economic basis for the minimum human life and to make cultural and moral development possible, as Fukuda learnt from his contemporaries such as A. Marshall and C.J. Fuchs. These ideas lay at the root of Fukuda's welfare economic studies, and formed the basis for the welfare state, as evaluated by people like Yuzo Yamada (1902–1996), who followed and developed Fukuda's ideas in the theory of economic planning and national income, and Ichiro Nakayama (1898–1980), who applied and extended Fukuda's ideas after the Second World War, stabilizing industrial relations in order to increase productivity and proposing the doubling of wages, which formed the basis of the income-doubling policy in the high-speed economic growth of the 1960s.

The transition to Marxism and political activism in the 1920s is well illustrated in the career of Kawakami. Initially idealistic and much concerned with problems of morality, rather like Noboru Kanai, Kawakami was deeply disturbed by the poverty that he encountered in the slums of London (see his best-selling book *Binbo Monogatari* [A Tale of Poverty], 1917). He argued that production in the capitalist system was designed not to fulfil human needs: the basic needs of the poor were ignored because they were not expressed in term of monetary demand, which led to over-consumption by the rich. Kawakami linked modern economic analysis to the moral precepts of Tokugawa philosophers such as Banzan Kumazawa, whose ‘frugality’ of the rich and proposals for the nationalization of industry and state-run welfare schemes reflected a late-Tokugawa agriculturalist Nobuhiro Sato's egalitarian nationalism. For Kawakami, the ultimate object of economics was to make human beings more fully human. Despite its wide popular appeal, *A Tale of Poverty* was criticized by younger scholars, such as his former student
Tamizo Kushida (1885–1934), whose debates were to play a vital role in developing Marxian economics among the younger generation. Marxist ideas have had their greatest impact on the peripheral nations of the capitalist world such as Russia. Japan was a latecomer in the industrialized world and had large agrarian sectors in the pre-war period in which the pre-capitalist remnants were slowly disappearing. Marxist economic thought became entangled in questions of political strategy and generated a debate over the possibility of ‘premature’ revolution within a semi-developed capitalist society. The Koza (Lecture) School, named after the *Nihon Shihonshugi Hattatsushi Koza* [Lectures on the Historical Development of Japanese Capitalism] (1932–3), defined as its objectives the bourgeois democratic reforms that must precede a future socialist revolution. Moritaro Yamada (1897–1980) was influential in developing the distinctive Koza School approach. This was criticized by the Rono (Worker–Farmer) School, which had separated from the Communist Party and aimed to create a mass organization of workers, peasants and others that would evolve into a revolutionary movement to overthrow capitalism.

The influence of Marxism on Japanese intellectual life reached a high point in the decades after the Second World War. During the Allied occupation, many of those who had played prominent parts in Marxist debates and who had been expelled from their chairs re-emerged as dominant figures in the economics faculties of universities. Yamada suggested that the Allies’ occupational reforms had brought about Japan's long-delayed bourgeois democratic revolution, and he sat on the Land Reform Committee for creating the landed farmers and democratizing the farmland system. The Otsuka School of economic history, which emerged from the Koza School and was led by Hisao Otsuka (1907–96), and the Civil Society School led by followers of Adam Smith studies like Zenya Takashima (1904–90) and Yoshihiko Uchida (1913–89), also played an important role in the post-war modernization and democratization of Japan. Adam Smith studies constituted a strong tradition in the development of Japan’s economic thought.

The years immediately after 1945 were marked by the active participation of economists in policymaking, and ‘Marxian’ economists made a disproportionate contribution. Among them were Hyoe Ouchi (1888–1980) and Hiromi Arisawa (1896–1988), who, together with Ichiro Nakayama and Seiichi Tobata, were important members of a research committee of the Foreign Ministry that published *Nihon Keizai Saiken no Kihon Mondai* [The Basic Problems of Reconstructing the Japan's Economy] (1946), stressing democratization and advocating the importance of government planning and intervention for the recovery of the Japan's economy. Arisawa, who had stressed the concept of socialization since his studies in Weimar Germany in the mid-1920s, in 1946 proposed to the Cabinet the priority of producing coal and steel, based on the Austrian idea of roundabout production and Marx’s two-sector production model. He had developed his ideas of a managed economy and also generated a theory of ‘dual structure’, namely, the coexistence of large-scale and small-scale industries; the gap between them was a structural problem that was also the problem of employment and wage structure. Such a structural gap was also seen between the modern industrial sector and the pre-modern agricultural sector, which had a large underemployed labour force. The theory of dual structure was developed into a theory of wages differentials and value-added differentials across industries based on empirical and statistical studies by Miyohei Shinohara (born 1919) in the high-speed economic growth era from around 1960. Shinohara, who ‘formed his analytical framework, taking in Keynes, Hayek, Marx, properly revised, and making the reality as the last resort’ (Shinohara, 1987, vol. 4, p. 395), had studied Nakayama's economics and
Kaname Akamatsu's synthetic dialectics and soon worked with Kazushi Ohkawa (1908–93) and the Hitotsubashi group of the Institute of Economic Research on *Choki Keizai Toki* [Long-Term Economic Statistics in Japan] (14 volumes, 1965–88), which was inspired by Yuzo Yamada's *Nihon Kokuminshotoku Suikei Shiryo* [A Comprehensive Survey of Japan's National Income Data] (1951). Along with these studies on national income statistics, advances were made in empirical, quantitative and theoretical studies on the Japanese economy.

**The spread of neoclassical economics**

Fukuda was the economist most responsible for introducing many of the latest economic trends into Japan. He advised his students to translate *Das Kapital* almost in parallel with Marshall's *Principles*, whose full translation came out in 1926. In the late 1920s he created a system of parallel lectures in economics, that is, Marxian and modern (neoclassical) economics, a system that was retained at most Japanese universities until the 1980s. From about 1930 international journals were another important source for the spread of neoclassical economics in Japan. Some Japanese economists were regular readers of *Zeitschrift für Nationalökonomie* (1930–), *Econometrica* (1933–), and the *Review of Economic Studies* (1933–). In 1934, the Japanese Economic Association was established by leading theoretical economists, and in 1997 the Association was re-founded, its tradition thus maintained and even expanded.

General equilibrium theory was introduced through four channels in the 1920s. First, from 1921 to 1922, Fukuda advised his student Nakayama to study Cournot, Walras and Gossen, the classics of mathematical economics. Second, Alfred Amonn (1883–1962), a Czech who had studied at the University of Vienna, explained Cassel's simplified system of general equilibrium in classes at the Imperial University of Tokyo between 1926 and 1929. Third, J.A. Schumpeter, admirer of the general equilibrium theory, had some influence on Japanese economists in the 1920s and 1930s. Two Japanese economists, Tobata and Nakayama, who later became influential in Japan, had studied under him in Bonn. Schumpeter's *Das Wesen und der Hauptinhalt der theoretischen National-ökonomie* [Essence and Main Content of Economics] (1908) was translated into Japanese: there is no English edition.

Schumpeter advised two other young economic theorists, Miyoji Hayakawa (1895–1962) and Takuma Yasui (1909–95), to begin with Walras. Fourth, Cassel's system was also taught by Yasuma Takata (1883–1972) at Kyoto Imperial University after 1929. Thus general equilibrium theory circulated in Japan a little earlier than in the English-speaking world.

In 1929, Takata began to publish his *Keizaigaku Shinko* [New Lectures in Economics] (1929–32). This constituted a survey of what was happening in economics, including a discussion of both general equilibrium theory and partial equilibrium theory. Succeeding Fukuda, Nakayama lectured in neoclassical economics and statistics at Hitotsubashi, and his textbook *Junsui Keizaigaku* [Pure Economics] (1933), contributed to the popularizing of general equilibrium theory and the basic concepts of neoclassical economics in Japan. He explained the methodology of pure economics or general equilibrium theory, then the theory of economic development, following the Schumpeterian path.

Nakayama further tried to take in Keynes's theory of the investment multiplier as an analytical means to connect dynamic and static aspects of economy in his *Hatten Katei no Kindo Bunseki* [Equilibrium Analysis of the Developing Process] (1939).
Some good statistical studies were made relating to rice. Yoshinosuke Yagi (1895–1944) conducted a full-scale statistical study of rice by surveying current studies. He confirmed that King's Law or the law of demand existed in the case of rice, and showed that Engel's law also held true. Yagi calculated not only the demand elasticity of rice with respect to the price, but also constructed the price and quantity indices following W.M. Persons's method. Excellent econometric studies were carried out in the 1930s as an application of Marshallian economics. Eiichi Sugimoto (1901–52), who studied under Fukuda and taught Marxian economics at Hitotsubashi, was very Marshallian and stressed partial equilibrium, time elements and elasticity, and criticized pure economics. In his Beikoku Juyo-hosoku no Kenkyu [Study on the Law of Demand for Rice] (1935), Sugimoto regarded per capita consumption of rice as the demand for rice following the cobweb theorem that the points on the demand curve were realized in the case of disequilibrium. Following H.L. Moore's extension of Marshallian demand analysis (1929), Sugimoto included not only the price of rice but also the prices of all other commodities and time as variables in the rice demand function. He judged that the effects of the changes in the prices of non-rice commodities on the demand for rice should cancel each other out because there were neither close substitutes nor complimentary goods for rice. He divided the rice price index by the general price index and got the rice rate to remove the effect of the changes in the other prices on the rice price. Then he estimated the demand function for every seven years using the least squares method. These early econometric works prompted the study of neoclassical theory of demand and supply.

In 1930 Kei Shibata (1902–86) at Kyoto examined Cassel's ‘mechanism of price formation’ (Shibata, 1930) and explained one of the formal problems in Cassel's simplified system of general equilibrium three years earlier than H. von Stackelberg. Shibata created numerical examples and counter-examples, and published a series of theoretical papers in English in Kyoto University Economic Review. It is also noteworthy that Shibata's review article (1937) of Keynes's General Theory (1936) included Keynes's own comments on the draft and was praised by D. Dillard's in The Economics of John Maynard Keynes (1948), although it was critical of Keynes's macroeconomic analysis for lacking technological changes in production and the transmission mechanism from the increase in savings to the increase in investment. Takuma Yasui (1909–95) can be called the Japanese Samuelson. He attended Amonn's lectures at Tokyo and studied the work of Nakayama and Takata. He began to publish a series of papers on the Walrasian general equilibrium framework in 1933. In his article ‘Juyo no hosoku nitsuite’ [On the law of demand], Yasui (1940) developed a sophisticated analysis of consumer behaviour, generating the law of demand along the lines of Slutsky, Hicks and Allen. He made a step forward in obtaining the universal law of demand and tried to clarify the conditions under which the demand curve is convex or concave. Masazo Sono (1886–1969), a mathematician at Kyoto, discussed the separability of goods in his ‘Kakaku hendo ni tomonau bunrikanouzai no jukyu hendo’ [Effect of price changes on the demand and supply of separable goods] (1943). By discussing J.R. Hicks's definitions of substitutability and complementarity among commodities, Sono developed the idea of the separability of commodities in terms of utility. The English version of Sono's paper, which appeared in the International Economic Review in 1961, anticipated similar studies published later in English.

The study of general equilibrium theory

It is well known that a number of Japanese economists began to contribute to the study of mathematical
In retrospect, this happened earlier: from around 1930 onwards Japanese mathematicians spread contemporary mathematical knowledge by producing new textbooks in Japanese. In the 1940s several Japanese economists made important contributions to stability analysis, mostly in Japanese but comparable to the studies developed in North America and Europe in the 1950s. The economists Takuma Yasui, Hideo Aoyama (1910–92) and Michio Morishima (1923–2004) and the mathematician Masazo Sono studied stability analysis and the problem of the market mechanism and economic dynamics, discussing not only the mathematical implications of the economic models but also the economic meanings of the mathematical models. By 1950, Yasui and Morishima had studied the conditions for the stability of a competitive equilibrium with the use of a system of ordinary differential equations and reached the qualitative theory of stability developed by A.M. Liapunov, who was gaining popularity outside Russia but was as yet little known to Western economists. As a result of this research, Takashi Negishi wrote his famous and influential article ‘Stability of a competitive economy: a survey article’ (1962), which provided a good survey of stability analysis.

At Kyoto Hideo Aoyama studied the dynamics of economic exchange. His article ‘Mirudaru no keizai hendo riron’ [Myrdal's theory of economic fluctuation] (1938b) started with the cumulative processes of inflation and deflation, which were articulated in Wicksell's monetary economics. He elaborated D.H. Robertson's step-by-step analysis and the period analysis by Myrdal, Lindahl and Ohlin. Aoyama also traced differential–difference models, which were set out by R. Frisch, H. Holme and M. Kalecki. Aoyama later published the English version ‘A Critical Note on D.H. Robertson's Theory of Savings and Investment’ (1940).

In his ‘Seigakuteki ippankinkoron to dogakuka no mondai’ [Static theory of general equilibrium and its dynamization] (1938a) Aoyama picked on the concept of momentary dynamic equilibrium in Frisch's ‘Statikk og dynamikk’ [Statics and dynamics] (1929) and discussed a sequence of momentary equilibrium that was established in a Walrasian exchange economy with multiple commodities. In his ‘Gendai keiki riron niokeru hanro hosoku no mondai’ [On the law of market in the contemporary theories of business cycles] (1942) he examined the concept of general dynamic economic equilibrium and pointed out that Hicks's ‘temporary equilibrium’ was the same notion as Frisch's ‘momentary dynamic equilibrium’ and La Volpe's ‘general dynamic economic equilibrium’.

In the 1950s, the proof of the existence of a general competitive equilibrium utilized set theory and convex set method, and a fixed-point theory. Around 1954, Hukukane Nikaido (1923–2001) in Tokyo made a special study of the existence question independently of K.J. Arrow and G. Debreu's ‘Existence of an equilibrium for a competitive economy’ (1954). Nikaido's ‘On the classical multilateral exchange problem’ was published in Metroeconomica of 1956. Nikaido formulated the basic propositions of the existence of general equilibrium as a theorem relating to the excess demand correspondence in the case of multilateral exchange of many commodities. Resorting to slightly more restricted assumptions than Arrow and Debreu, Nikaido proved this with the direct use of Kakutani's fixed-point theorem.

Hirofumi Uzawa (born 1928) proved in his ‘Walras's existence theorem and Brouwer's fixed-point theorem’ (1962) that the two theorems in the title were equivalent. He noted that it had already been well established that Brouwer's fixed-point theorem implies Walras's existence theorem. He constructed an excess demand function, which satisfied the conditions describing Walras's existence theorem. By dividing a price by the summation of prices, Uzawa neatly proved that Walras's existence theorem implies Brouwer's fixed-point theorem. Though he was at Stanford University, the paper appeared in
Kikan Riron Keizaigaku [Economic Studies Quarterly], which was the formal journal of the Japanese Association of Theoretical Economics and the Japanese Econometric Society (now the Japanese Economic Review, published by the Japanese Economic Association).

In the 1950s, Japanese economists such as Nikaido, Uzawa, Kenichi Inada (1925–2002), Hajime Oniki (born 1933) and Takashi Negishi (born 1933) joined K.J. Arrow's project at Stanford backed by the Office of Naval Research. They played active roles in the study of the existence and stability of a general equilibrium in a competitive economy, two-sector growth models and welfare economics. The mathematician David Gale visited Japan, stayed at Osaka University and studied with Nikaido, Shin-ichi Ichimura (born 1925) and Morishima in the mid-1950s. The Japanese dream of intellectual cooperation with Western economists finally became a reality.

Moreover, the generous provisions of the fund for the Government and Relief in Occupied Areas (GARIOA) and, later, the Fulbright scholarship programme brought Japanese youth to the United States and to other countries for advanced study. Ichimura, Tsunehiko Watanabe (born 1926), Tadao Uchida (1923–86), and Ryutarō Komiya (born 1928) were fascinated by American empirical studies, such as the inter-industry analysis originated by Leontief and econometric modeling by Chenery. Returning to Japan, they not only taught American economics but also conducted important econometric works in making economic plans and predictions in the 1960s. Hiroshi Furuya (1920–57), who studied at Harvard from 1952 to 1954, not only strongly advised economics students to study mathematics, but also invited mathematics students such as Hirofumi Uzawa and Ken-ichi Inada to study economics. Moreover, Morishima studied at Oxford and enjoyed attending the meetings organized by J.R. Hicks in 1954 and 1955.

Trade and development

In international economics and economic policy, Japanese economists emphasized different factors from those emphasized by economists in other countries. For example, the Japanese economists who took an interest in policy issues between the 1930s and the 1970s were most interested in the relationship between economic development and international trade. While they shared interests in shifting comparative advantage, dynamic internal economies, and the protection of infant industries, we can usefully divide them in two groups by considering to their backgrounds. First, some Japanese economists had strong connections with the German-speaking community of economists. Kaname Akamatsu (1896–1974) became known to non-Japanese audiences thanks to his flying-geese-pattern theory (Ganko Keitai Ron) after his paper in English ‘A theory of unbalanced growth in the world economy’ (1961) was published in Weltwirtschaftliches Archiv. Akamatsu invented the theory in the 1930s, based on his empirical studies of Japan's wool industry and later applied it to industries related to cotton yarn, cotton cloth, spinning, weaving machinery and general machinery industries between 1870 and 1940. In the mid-1920s, having spent almost two years in Heidelberg, he garnered ideas about how to do empirical work (business barometers and case study method) during a short stay at the Harvard Business School.

Akamatsu drew three time-series curves denoting the import, the domestic production, and the export of manufactured goods in a plane with time on horizontal axis and the yen value on the vertical axis. He realized that the import curve usually increases until it reaches a peak and declines with the increase of domestic production, at which time the exports increase. This means that many import curves had a
mountain-shape with one peak. This pattern might appear to be similar to that suggested in a Hecksher–Ohlin trade model with many goods. As capital accumulates, there is shifting comparative advantage over time. Originally it was described as the ‘flying-geese-pattern’ theory of industrial development, or the ‘catching-up product cycle’ theory of development, as phrased more accurately in English. Akamatsu believed that his findings for Japan could be generalized into a theory for many countries, especially developing countries or late developers. His development theory has been applied to a picturesque description of a group of developing countries and has led to the discussion of which country is the front flyer.

Hiroshi Kitamura (1909–2002) was, like Akamatsu, critical of the Ricardian theory of free trade and the international division of labour. He left Japan for Europe in 1931, studied economics at the University of Berlin, and specialized in international economics and foreign investment at the University of Basel. In 1941 he published Zur Theorie des internationalen Handels: Ein kritischer Beitrag [On the Theory of International Trade: A Critical Contribution]. He developed an early macro-dynamic theory, which was considered to be more appropriate for developing countries than advanced countries, and he supplied theoretical support for protectionist policy such as that advocated by Friedrich List. He brought the theory of trade and development from the German-speaking world back to Japan in 1948 and then he was sent to the United Nations Economic Commission for Asia and the Far East from 1957 to 1969. Other Japanese economists had close connections with English-speaking economists like Murray C. Kemp. For example, Kemp collaborated with Takashi Negishi, Michihiro Oyama (born 1938), Kouji Shimomura (1952–2007), and Masayuki Okawa (born 1953), and Inada, Uzawa, and Yasuo Uekawa (1925–94) visited the University of New South Wales. Uekawa edited the Japanese version (1981) of Kemp's Pure Theory of International Trade and Investment (1969). Kemp's books referred to a number of Japanese works, some of which had been published in international economics journals, others in Japanese university journals or as mimeos. Among them, Negishi (1972) was interested in the possibility of the protection of an infant industry and debated with Max Corden. Corden and Kemp were critical of the so-called Mill–Bastable case for protecting infant industries, and in response Negishi argued for the protection of the infant industry with emphasis on dynamic internal economies. He maintained that if Bastable's test is understood in terms of increases in social welfare in some sense, then it by no means requires private profitability, and so Kemp's test is not necessary (though it is sufficient) for protection.

The social activities of Japanese economists

The first task for Japanese economists after 1945 was to hasten the recovery of the nation's ruined economy. Japan's top economists joined the Economic Stabilization Board, which was organized on the instruction of the Supreme Commander of the Allied Powers (SCAP) and later reorganized into the Economic Planning Agency. Shigeto Tsuru (1912–2006) joined the Board after he returned from Harvard, where he was trained both in Marxian and neoclassical economics. He brought not only a cosmopolitan attitude but also American economic language into the community of Japanese economists. Tsuru and Saburo Okita (1914–93) co-authored the famous first White Paper on the Japanese economy in 1947, where Tsuru's training as an economist with pragmatic inclinations was vividly revealed. Okita and other officials were trained as economists through working for the Board. Okita was sent to the Economic Commission for the Asia and the Far East (ECAFE), and he was the
chestival economic analyst for the Commission in 1952–3. For many years he represented ‘the able Japanese bureaucracy’.

Japan returned to the international community on the basis of the Peace Treaty of 1952, which marked the end of 15 years of central control over the Japanese economy. Governmental agencies such as the Ministry of International Trade and Industry (MITI), the Ministry of Finance (MOF), and the Ministry of Agriculture and Forestry (MAF) began to regulate the economy. For example, the power industry was run by the government from 1939, but in 1951 nine private companies took their businesses back with the slogan of ‘democratization’ or participation. They used a neoclassical-econometric analysis to make a report for MITI on the necessary increase in installed capital, based on estimates of economic growth and the increasing demand for electricity. Neoclassical and Keynesian economists began to collaborate with MITI to rationalize the power industry more thoroughly in 1954. MITI, MOF and MAF made input–output tables of the Japanese economy independently of each other in 1951, which were completed respectively by 1956. They believed that the tables were useful in regulating the economy and in mediating between consumers and producers when Japan began to take growth-oriented policies.

The MITI project was the biggest project undertaken, and was led by Shin-ichi Ichimura, who was trained at MIT. In the process of constructing the tables, the quality of the statistical data for national income and wealth was greatly improved. The agencies decided to cooperate with each other beyond bureaucratic sectionalism to make a single 1955 input–output table. From about 1960 they asked neoclassical and Keynesian economists to discuss the economic issues in making policies and to teach mainstream economics to government officials in MITI and other ministries.

The first econometric model of the Japanese economy was made by Isamu Yamada (1909–86) in 1948. After 1957, those who had been trained in the United States began to build econometric models one after another. In 1960, the Ikeda Cabinet decided on the Income Doubling Plan, that is, the economic plan of doubling per capita national income in a decade. After 1960 they asked econometricians to prepare the mid-term plan. A variety of macroeconometric models of the Japanese economy were constructed for various purposes, such as long-term economic forecasts, business cycles explained by changes in investment, and the Klein–Goldberger-type model of the Japanese economy. Tadao Uchida (1925–86), Tsunehiko Watanabe (born 1926), Masahiro Tatemoto (born 1925), Kei Mori (1932–90) and Shuntaro Shishido (born 1924) played leading roles in simulating government policies with the use of the latest computer technology.

The Japanese enjoyed a new way of life, equipped with an increasing number of durable consumer goods, which were the fruits of high-speed economic growth. Yet by 1970, when Japan had become one of the advanced countries, several negative external effects were found in the environment, such as mercury poisoning caused by drainage, air pollution and traffic jams in large cities. It was also realized that the welfare system was not sufficiently developed to provide for an enjoyable retirement. Japanese economists studied a number of problems similar to those that had interested American and European economists.

Tsuru, who had been committed to the basic tenets of Marxian political economy since the late 1920s and who had studied under Schumpeter at Harvard, wrote ‘‘Kokumin Shotoku’ gainen heno Hansei’ [Reflections on the ‘national income’ concept] in 1943, when he was first employed by what later became the Institute of Economic Research (at Hitotsubashi). This was a critique of the market-oriented concept of national income, which would not be a good indicator of welfare. This became his major concern in subsequent years and led to ‘In Place of GNP’ (1971) and formed the basis of Kougai.
no Seijikeizaigaku [Political Economy of Environmental Disruption] (1972), by pointing out that environmental pollution was not counted negatively in the system of national accounting. He took the initiative in organizing an interdisciplinary Research Committee on Environmental Disruptions in 1963, which was widely supported by economists such as Ken-ichi Miyamoto and Hirofumi Uzawa. Tsuru was involved in a series of international academic activities, culminating in the presidency of the International Economic Association (IEA) from 1977 to 1980.

In terms of international activities, the Econometric Society holds regional meetings in East Asia. The first Far Eastern meeting was held in Tokyo independently of the Society in 1950, although its report appeared in *Econometrica* in 1951. Formal annual meetings were held in Japan from 1966 to 1970. After a long break, biennial meetings have been held every other year somewhere in East Asia since 1987. In July 1997, the fifth meeting was held in Hong Kong, which had been returned to the People's Republic of China a few days earlier. In August 1995, the World Congress of the Econometric Society was held in Tokyo.

**After the turning point of 1985**

The year 1985 was an important turning point for Japanese economists. American economists, including Paul R. Krugman, were the first to become interested in US–Japanese trade frictions and examined Japanese trade and industrial policies. Japanese economists were then forced to pay attention to the results of this research and the trade dispute itself. They felt obliged to make some response even though they had previously ignored criticism by American politicians and officials, and began to think that some applied economists should come out of their ivory towers, arm themselves with relevant facts and ideas, and face American professional economists in a policy debate. However, the East Asian financial crisis of 1997 made them more concerned about the inter-linkages of national economies and inclined them to conceive of a kind of transnational community or forum for regional economic stability. Although the idea of establishing an Asian Monetary Fund was rejected by the United States and China in 1997, Japanese economists aim to integrate the Chinese economy into international settings. A good economist today may have to handle Chinese, English and Japanese if he or she wants to be active in Japan.

Research administrator and expert in national accounts. Born in Budapest, Jaszi attended Oberlin College, the London School of Economics (BSc, 1936) and Harvard (Ph.D., 1946). He was employed by the Bureau of Economic Analysis (or its predecessors) in its National Income Division 1942–59 (Division Chief 1949–59), as Assistant Director 1959–62, and as Director 1963–85. Jaszi helped develop the US national income and product accounts that were introduced gradually during the Second World War and fully in 1947. The accounts for the government sector were his unique contribution. One aspect of this is that all government purchases, like other purchases not for resale, are counted as final products. For four decades Jaszi influenced the United Nations standardized system in addition to guiding the United States accounts. His firm grasp of the national income and product accounts as an integrated system and of the principle that they must rest upon quantifiable concepts made him particularly skilful in explaining and vindicating the 1947 system and its subsequent improvement. Jaszi's (1958) exposition of the accounts and responses to critics at a 1955 conference and his (1971) critique of comments by 46 economists were masterful. Elsewhere (1964), Jaszi showed that hedonic and conventional methods of allowing for quality change in output measurement are conceptually equivalent. During 1963–85 Jaszi directed all the varied statistics and analyses of the Bureau of Economic Analysis – international, national and regional. Many improvements were introduced during his tenure. He closely supervised BEA's Survey of Current Business and co-authored its ‘Business Situation’ section. His talks (for example, Jaszi, 1972) helped balance exaggerated claims of (a) damage introduced into policy formulation by errors of estimate in the NIPA and (b) the possibility of greatly reducing such errors.

The J curve is the description of an empirical phenomenon: the trade balance worsens immediately after a depreciation of the exchange rate, to improve in the longer term. This pattern can be ascribed to different speed of adjustment of trade prices and volumes to changes in exchange rates. Several models have been put forward, suggesting explanations for these lags that are not mutually exclusive. While the empirical evidence is not conclusive, to assess the existence of a J-curve adjustment path is relevant since the J-curve may induce dynamic instability in the exchange rates.

Keywords
balance of trade; common pool problem; consumption habits; currency depreciation; hysteresis; J-curve; Marshall–Lerner conditions; real business cycles; structural vector autoregressions; sunk costs; technology shocks; terms of trade

A depreciation of the domestic exchange rate is expected to improve a country's trade balance. It has been observed, however, that in reality the trade balance often worsens immediately after depreciation. Only in the longer term, if at all, does it improve. The combination of a negative short-run effect together with a subsequent positive long-run effect of a devaluation of the exchange rate on the trade balance is referred to as the ‘J-curve’ due to the similarity of the current-account behaviour to a ‘J’. To assess the existence of a J-curve adjustment path is relevant, since, under most circumstances, the J-curve may induce dynamic instability in exchange rates (see Beenstock, 1990; Levin, 1985). If depreciation worsens the trade balance in the short run, the exchange rate may fall further (depreciate more). Although export volumes may rise and import volumes fall, import values tend to grow faster than export values and the exchange rate instability persists. This instability may be neutralized by speculators having rational expectations. In this case, agents know the dynamics of the J-curve and allow
for it in their speculative behaviour, thereby eliminating the potentially destabilizing influence of the J-curve itself.
The J-curve is the description of an empirical phenomenon, first discussed after the 1967 devaluation of the pound sterling in NIESR (1968) and analysed in a seminal paper by Magee (1973). Theoretical models have been developed, building on some kind of frictions, such as pre-existing contracts, asymmetric use of domestic currency and foreign (international) currency, sluggishness in adding new productive capacity and sunk costs.
The lags in the adjustment can be ascribed to trade prices adjusting faster than trade volumes to changes in the exchange rate. The currency in which imports and exports are denominated, which is likely to be determined by the relative market power of traders, plays a crucial role. When both import and export contracts are expressed in domestic currency, following an unexpected devaluation, the value of existing imports rises due to the increased cost of an unchanged quantity of imports, while the value of existing exports remains constant (the price of exports in domestic currency does not change). The existence of lags on consumers’ and producers’ side induces stickiness and a worsening of the trade balance, until higher export and lower import volumes eventually, and on the assumption that import and export demand elasticities are sufficiently elastic to exchange rate changes so that their sum is higher than 1 (that is, the Marshall–Lerner conditions hold), generate a favourable trade balance response (that is, a J-shaped path). When both import and export contracts are expressed in foreign currency, if the value of contracts denominated in foreign currency is higher for imports than for exports, the J-curve will always ensue. On the other hand, the trade balance would improve immediately after devaluation if import contracts are denominated in domestic currency and export contracts in foreign currency.
Quantities may not adjust rapidly to exchange rate changes, since domestic demand for imported goods may be fairly inelastic due, for instance, to a reputation or brand and/or domestic supply may be a poor substitute for imported goods. Furthermore, producers may not be able to reallocate expenditure between foreign and domestic goods since most import and export orders are placed in advance (before depreciation). In the long run, however, quantities tend to adjust and, if the value of elasticity satisfies Marshall–Lerner, the trade balance improves.
Several models have suggested not mutually exclusive reasons for a short-run deterioration of the trade balance following depreciation. Knetter (1993, p. 473) maintains that: ‘sellers reduce markups to buyers whose currencies have depreciated against the seller, thereby stabilising prices in the buyer's currency relative to a constant markup policy’, that is, follow a ‘local currency price stability’ and differentiate between markets (pricing to market). Some models rely on the small open economy hypothesis and emphasize intertemporal substitution. Bacchetta and Gerlach (1994) challenge the view of a rapid pass-through of exchange rates to import prices, showing that the J-curve can arise even if import prices are sticky. In an intertemporal framework, an anticipated rise in future import prices after depreciation provides agents with an incentive to decrease their current expenditure and therefore revise their future purchases, eventually displaying a J-shape dynamics of trade balance.
In a continuous time open-economy framework, Mansoorian (1998) shows that a trade balance deterioration following depreciation can be due to persistence of consumption habit, on the assumption that the utility function depends not only on current consumption but also on standard of living. Similar conclusions have been recently reached by Cardi (2005) who derives a J-curve due to the ‘strength’ of consumption habits and capital investment ‘inertia’, following an unanticipated terms of trade deterioration.
Tivig (1996) solves an intertemporal maximization problem in a dynamic oligopoly contest. In a two-period model of duopolistic competition without entry, regardless of the degree of capital mobility, she provides sufficient (at least) conditions on import demand elasticity for short-run ‘perverse’ price reactions, following temporary changes in the exchange rates, so that a temporary devaluation may initially worsen and later improve the trade balance.

Tornell and Lane (1998) use political economy considerations to explain the J-curve pattern; their model with ‘voracity effects’ suggests that a positive real trade shock may exacerbate the common pool problem, leading to a more than proportional increase in public transfers and then to a social loss. Because of this effect, the impact of an unexpected improvement in the terms of trade may lead to deterioration in the current account.

Recent literature in dynamic general equilibrium depicts an S-curve as a dynamic response of the trade balance to technology shocks. Backus, Kehoe and Kydland (1994) find that the trade balance is negatively correlated with current and future movements in terms of trade, but positively correlated with past movements. Using a two-country version of Kydland and Prescott’s (1982) closed economy model, in which each country produces imperfectly substitute goods with capital and labour, they claim that, after a once and for all positive shock to technology, domestic output increases, its relative price falls and domestic investment increases, inducing a fall in net exports. With time, the rise in investments decreases and the trade balance moves into a surplus. This dynamic gives rise to an S-curve consistent with the J-curve, since the initial deterioration and subsequent improvement of the trade balance may well deliver also an S-shaped cross-correlation function of the trade balance and the terms of trade. Senhadji (1998) extends the Backus, Kehoe and Kydland analysis to document business cycle features of several developing countries. Within a set-up with a downward sloping export demand function and limited access to international financial markets for capital formation, he shows results completely supportive of the findings of Backus, Kehoe and Kydland.

Finally, the J-curve can be due to hysteresis (cf., for instance, Baldwin, 1988; Dixit, 1994). In the presence of sunk costs, to export is an ‘option’ and consumers value the alternative of ‘wait and see’ before reacting to exchange rate changes. The presence of a threshold induces non-standard behaviour of the trade flows when the exchange rate depreciates.

Over the years, an extensive empirical literature has emerged. Results are not conclusive. As stated by Bahmani-Oskooee and Artatrana (2004, p. 1389), ‘the general consensus is that the short run response of the trade balance to current depreciation does not follow a specific pattern’ but, if a J-curve exists, the perverse effect has a duration of one to three years (see Junz and Rhomberg, 1973; Baldwin and Krugman, 1987; Spitaller, 1980; Moffett, 1989). Koray and McMillin (1999) use a structural VAR model to show that the pattern of the trade balance after a negative monetary shock exhibits the traditional J-curve behaviour. Support for the J-curve hypothesis has been found also by Bahmani-Oskooee and Alse (1994), Marwah and Klein (1996) and Hacker and Abdulnasser Hatemi (2003). Leonard and Stockman (2002) find a weak positive evidence of the J-curve, but document strong violations in the distributional assumptions that underline previous works. More interestingly, their evidence on the J-curve is inconsistent with traditional theoretical explanation (real business cycle models included), since they present evidence that current account surpluses are usually associated with low real GDP.
Other studies have challenged the existence of a J-curve: Rose and Yellen (1989) and Rose (1990; 1991) maintain that, if import prices adjust slowly to exchange rate changes, the initial negative effect embodied in the J-curve may not occur: the value of imports does not increase and, ceteris paribus, the trade balance does not worsen. More recently, Demeulemeester and Rochat (1995), Hsing and Savvides (1996), Shirvani and Wibratte (1997) using different methodology, different data-set and estimating over different periods, found no evidence of a J-curve in the data.

Article

Jenkin was a distinguished engineer whose wide interests and clarity of mind enabled him to make notable contributions to economic analysis. Jenkin received his early education at Edinburgh Academy, but financial exigencies forced the family to move first to France and then to Italy. Consequently, Jenkin graduated from the University of Genoa in 1850. Returning to England in 1851, he spent ten years with various engineering firms working on the design and laying of submarine cables. In 1859 he became associated with William Thomson (Lord Kelvin) and frequently collaborated with him in later years, especially in contributing to the work of the British Association's Committee on Electrical Standards. In 1866 Jenkin was appointed Professor of Engineering at University College, London, and moved to a similar chair at the University of Edinburgh in 1868. Apart from his work in civil and electrical engineering, Jenkin distinguished himself as a critic of Darwin's theory of evolution, as an advocate of improved urban sanitation, and for the development of the system of monorail electric transport called telpherage.

Between 1868 and 1872 Jenkin published three economic papers whose theoretical quality and practical value have since earned him a deserved place in the history of economic thought. Recognizing that in current debates on trade unions ‘the principles of political economy though often quoted are little understood’, Jenkin set himself in his first paper to examine their application to the labour market. In the process he revealed the emptiness of the wages-fund concept, refuted the view that trade unions could not materially benefit their members and made the first clear statement in English economic writing of the concept of supply and demand as functions of price. These ideas he further developed and generalized in his 1870 paper, in which he analysed fully the determination of market price using diagrams to present the supply and demand functions in the form of intersecting curves. Jenkin specifically noted that in the long-run cost of production chiefly determines the price of manufactured
goods, but stressed 'how much the value of all things depends on simple mental phenonema, and not on laws having mere quantity of materials for their subject' (1887, vol. 2, p. 93).

In a third paper Jenkin applied his techniques of supply and demand analysis to the problem of tax incidence, stating the concept of consumers’ surplus previously developed by Dupuit but apparently without knowledge of Dupuit's work.

Jenkin left two further essays on economic issues, which were published posthumously in his collected Papers, Literary, Scientific, &c. In ‘Is one Man's Gain another Man's Loss?’ (1884) he used a simple form of closed circuit diagram to illustrate the exchange process and its results. ‘The Time–Labour System’ contained an acute diagnosis of the differences between goods markets and labour markets with a proposal to improve the operation of the latter through what was in effect a system of guaranteed annual wages.

All Jenkin's economic writings were characterized by a striking combination of precise and lucid analysis with tolerant understanding of the facts of daily life in both the workshops and the counting-houses of the world he knew. In view of this their influence in his own time was surprisingly limited, although his ‘Graphic Representation’ (1870) does seem to have afforded the stimulus which led W.S. Jevons to publish his Theory of Political Economy in 1871.

Jevons, William Stanley (1835–1882)

Harro Maas
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article examines William Stanley Jevons's life and work against the background of Victorian disputes over the appropriate method of political economy. Jevons is commonly known as one of the founders of marginalist analysis in economics. As a genuine Victorian polymath, Jevons undertook research in many different fields of the sciences, meteorology, statistics and political economy in particular. This article shows how Jevons transposed his training in the natural sciences to political economy, in the process shifting from a labour to a utility theory of value and mathematizing the discipline as well.

Article

Stanley Jevons is generally known as one of the ‘fathers’ of the so-called marginal revolution in economics of the last decades of the 19th century. In his *Theory of Political Economy* (1871), with its ‘mechanics of utility and self-interest’, he analysed decisions of economic agents by means of the calculus, in terms of deliberations over marginal increments of utility. Economic agents – whether in their role as consumers, workmen or other – came to be seen as maximizing utility functions. Jevons is thus commonly considered to have broken with the labour theory of value of the classical economists. Value came to be identified with exchange value, and Jevons identified this with what we now call marginal utilities, not with costs of production. Jevons is also remembered for his innovative contributions to the empirical (statistical) study of the economy. He much favoured the use of graphs to picture and analyse statistical data. He introduced index numbers to make causal inferences about economic phenomena such as changes in the value of gold following the gold discoveries in California and Australia. In short, there is no particle of economics, theoretical or empirical, to which Jevons did not make important contributions that even in the 21st century are considered to have altered the field of economics in revolutionary fashion.

Though this short summary of Jevons's accomplishments makes him one of the fathers of modern economics, Jevons was in many respects heavily indebted to Victorian ways of practising the natural sciences. This transpires from his commitment to a Baconian view of the natural and social sciences and the typical Victorian use of mechanical analogies to understand the world. Just as William Thomson, the later Lord Kelvin, argued that the making of a mechanical model was the ultimate 'test' of intelligibility of a natural object, so Jevons relied on mechanical models to understand the social world. For Jevons, human individuals were little machines driven by pleasures and pains; they were not rational and autonomous decision-makers. In his influential essay on the nature of political economy (first edition 1932) Lord Robbins perceived clearly that Jevons's analysis was not just rooted in Bentham's hedonics, but in psycho-physiological explanations of human conduct. Jevons's new theory of value was not a theory of rational choice. The common perception of Jevons's utility theory as a theory about individual *decision*-making is therefore not quite accurate.

This article, in following Jevons's life and work, aims to show how Jevons translated his knowledge of methods of research in the natural sciences to political economy and thus to...
radically transform the scientific image of economics. The radicalism of Jevons's new approach to political economy will be better understood against the background of Victorian discussions of its proper method.

Early years

Stanley Jevons was born in Liverpool as the ninth child in a well-to-do Unitarian family. In 1882 he drowned near Hastings at the age of only 47, leaving his wife Harriet Taylor and three children. Good biographical essays are Black and Könekamp's introduction to the papers and correspondence (1972–81), Schabas's 1990 monograph, and Mosselman and White's introduction to their recent edition of Jevons's major works. The liveliest introduction to his biography is still to be gathered from his own *Letters and Journals* (1886), chosen from his *Nachlass* by his wife Harriet.

Jevons's father, Thomas Jevons, was an iron merchant with utilitarian sympathies who is said to have invented the first floating iron ship. His mother, Mary-Ann Roscoe, was the daughter of William Roscoe, a Liverpool banker and important collector of Flemish and Italian masters. Like the Booth, Hutton and Martineau families to whom they were related, the family formed part of the self-confident Unitarian circles in the heartland of the industrial revolution that shared a belief in rational argument and the advancement of science to promote the common good. It is therefore unsurprising that Jevons's early education was predominantly in the natural sciences, first at Liverpool Mechanics' High School, and, after an interlude at a grammar school that was less to his liking, at the preparatory school of University College London. In 1851 he enrolled at University College itself to study mathematics and chemistry.

Jevons's youth was not without difficulty. His mother died in 1845, his much beloved eldest brother, Roscoe, went insane in 1847; on top of this, his father's iron business went bankrupt in 1848 due to the great railway crisis the previous year. Forced to move to Manchester, the Jevons family never recovered from these financial difficulties, which lifted Stanley and his siblings from the commercial elite to what has been called the ‘uneasy classes’ – intellectually gifted, but without the means to leisurely pursue their interests. As we will see, the family's financial difficulties greatly influenced Jevons's early intellectual career.

At University College, Jevons enrolled in courses in experimental philosophy and chemistry, and the mathematics class of Augustus De Morgan, the first mathematics professor at University College who taught the by far most demanding course in mathematics in England at the time. De Morgan was a great propagator of French analysis, a mathematics that by 1850 was still received with considerable scepticism in the Oxbridge system because of the strong mechanical worldview that went with it. De Morgan would prove to be one of the most enduring influences on Jevons's intellectual life. Though Jevons performed well, he never considered himself a mathematician (and was not so considered in his lifetime).

Jevons's forte was in chemistry and the experimental sciences. During these first years of study Jevons won several medals, a gold medal in chemistry amongst others. In 1853, through the intervention of his cousin Harry Roscoe, the later professor of chemistry at Owens College, Manchester, Jevons was offered the opportunity to become gold assayer at the newly established Mint in Sydney. After some hesitation (and persuasion by his father) Jevons accepted the offer, because the job paid extremely well (£675 a year), and thus helped to alleviate the financial burdens on the family. Jevons sailed off to Australia in 1854 to stay there for a five-year period.

Jevons's Antipodean interlude

There has been quite some discussion about the importance of Jevons's ‘Antipodean interlude’ for his further intellectual career (see the relevant essays in Wood, 1988). Not only did the work at the Sydney Mint offer Jevons ample opportunities to pursue his manifold scientific interests, but the social environment of the Mint itself was highly favourable to the pursuit of science. The newly created philosophic society of New South Wales, of which Captain E.W. Ward, director of the Mint, was office bearer, provided Jevons and his colleagues ample opportunities to develop their scientific interests and to publish on them. As a typical Victorian colonial institute the Mint thus functioned as a nucleus of scientific activity that turned its ‘imperial gaze’ upon Australian nature and society.

The most important Australian science periodical was the *Sydney Magazine of Arts and Sciences*, to which Jevons made several contributions, most of them on meteorology. Jevons published on experiments on the formation of clouds, in which he attempted to reproduce clouds on a miniature scale in accordance with the existing classification of clouds. He made these experiments on strong mechanical assumptions and in the hope of rendering his results in mathematical form – something that proved far too difficult. His aim was to mimic the process of cloud formation in another medium (fluid rather than air) and so to uncover its underlying mechanism. It is worth noting that Jevons's experiments did not go completely unnoticed: Lord Rayleigh, the later Nobel laureate in physics, reproduced Jevons's experiments in the early 1880s at the Cavendish laboratory at Cambridge in order to study diffusion processes in fluids and gases. Jevons also contributed to Waugh's statistical almanac, in which he extensively reported on his statistical observations on the Australian weather.

Jevons's cloud experiments and his work in meteorology are best covered by Raymond Schmitt (1995) and Neville Nicholls (1998).

In the 1830s Lancashire Unitarians had been instrumental in setting up statistical societies to study the ‘moral and physical condition of the working classes’. In a similar vein Jevons had wandered through the poor working men's districts of London – the ‘dark alleyways of Spitalfields’ – to study the moral condition of the working poor during his early years of study in London. In Australia Jevons resumed these wanderings and started work on a social survey of Sydney. He published his findings in the *Sydney Morning Herald*. Though
only fragments of the original survey remain, it is clear from his notebooks that Jevons considered his survey the beginning of a ‘science of towns’ that itself was a prelude to a general ‘science of man’. A very good recent study of Jevons's survey (Davison, 1997–8) has shown interesting parallels with the much better-known work of Henry Mayhew on the London poor and Charles Booth's famous late 19th-century social survey of London. Jevons's social survey may serve as early witness of how he transported his natural and acquired skills in decomposition and classification of natural phenomena to the social sciences, and how he translated visualizing techniques used in the natural sciences to the social domain. Another fine example, from the same Sydney period, of Jevons's use of visualizing techniques to classify social phenomena, recently explored by White (2006), is his stratigraph of the ‘industrial system of society’. Jevons classified the various occupations of Australian society in different layers corresponding to a system of human needs and to the classical distinction between productive and unproductive labour. This kind of diagram had only recently come to be used by geologists to picture the composition of the underground. It is noteworthy that the subtitle of Jevons's last great work (or rather project), the unfinished and posthumously published Principles of Political Economy, shows his lifelong concern with the ‘industrial mechanism of society’.

Jevons not only explored the urban wilderness of Sydney but also made excursions into New South Wales, for example to the newly discovered gold mines. Sometimes he made these trips alone, because others found them too dangerous. The barometer and thermometer always accompanied him, and his notebooks are filled with pages of meteorological observations made during these trips. Apart from his extensive and innovative use of visualizing techniques, his appetite for the experimental method in the sciences, and his sometimes daring and innovative collection and analysis of statistical facts, Jevons also pioneered in photography, which was facilitated by his knowledge of chemistry and the ease with which he could lay hands on chemical materials equally needed in photography and gold-assaying. In 2004 the Sydney Powerhouse Museum organized an exhibition on Jevons's life and work in Australia that wonderfully brought all these different influences and materials together, thus showing vividly the rich background and context of Jevons's scientific work. For a brief description of this exhibition see Barrett and Connell (2005).

Historians of economics have commonly taken Jevons's enthusiasm for a lecture on Bentham's utilitarian ethics as a decisive moment in his turn to the social sciences and to political economy in particular. Jevons's appraisal of this lecture is seen as a premonition of the hedonic theory of value that was to become the core of his Theory of Political Economy (1871). In addition to this, reference is often made to the interest Jevons took in the Australian railway debate (to which he made some contributions in the Empire, an Australian newspaper) and his interest in Lardner's Railway Economy, a book that was influenced by the work of Cournot on oligopolies. From the above it should be clear that Jevons's studies in social statistics and political economy were wide in scope. From a very young age he aimed at all-embracing explanations of society that were deeply rooted in a thorough engagement with statistics and fuelled by a predilection for mechanistic explanations.

This short summary of Jevons's scientific pursuits in Australia shows him to be the kind of Victorian that felt more indebted to the Belgian astronomer and revolutionary of statistics Adolphe Quetelet than to John Stuart Mill or August Comte. In a short essay on Comte for Nature (1875), Jevons explicitly paid tribute to Quetelet as the “true founder” of the social sciences, because of his endeavours to discover, like an astronomer, regularities in the avalanche of social statistics. According to Jevons, by focusing on average values, rather than on particular data, the mechanisms could be uncovered that governed the natural and the social world. Mathematics, when properly targeted, spelled out this mechanism. When Jevons wrote from Australia to his sister Henrietta that he considered devoting his life to political economy it was not so much an application of Bentham's hedonic calculus to economics he had in mind, but rather his aim to explain the ‘industrial mechanism’ of society. The consequences of Jevons's attitude to science for political economy would become spelled out only after his return to London to take up his studies at University College, London.

The mid-century split between theory and statistics

Jevons returned to England in 1859. He once again enrolled at University College, now to study political economy, but he quickly became disappointed in the way the topic was taught by Jacob Waley, whom he considered ‘prejudiced’ against opinions and ideas that went contrary to the Mill–Ricardian orthodoxy. As in the early 1850s, Jevons most enjoyed his mathematics classes with Augustus De Morgan. Jevons completed his BA in 1861 and received his MA in 1863. Jevons's disappointment was not just a matter of (emerging) diverging insights about one of the cornerstones of classical economics, the theory of value; it was also disappointment with its methods of research. Mid-century political economy was characterized by a sharp split between economic theory and statistics. In his writings on the definition and method of political economy, J.S. Mill (and in his footsteps John Elliot Cairnes) had ardently defended the so-called deductive or a priori method of political economy in opposition to the inductive (statistical) method. Mill had done so in his seminal essay of 1836 ‘On the Definition of Political Economy; and on the Method of Investigation Proper To It’ that was reprinted in his Essays on Some Unsettled Questions of Political Economy (1844) and in the famous Book VI of Logic (1843) that was devoted to the method of the ‘moral sciences’. Mill wrote his essay in a deliberate defence of Ricardian economics, which in the early 1830s was actually on the wane. Mill was adamant there was nothing wrong with Ricardian economics. Indeed, what was considered its most distinguishing ‘vice’ – its deductivism – was just the way the science should proceed. Mill's argument for this was quite innovative and had little to do with Ricardian theory per se. Leaning on the philosopher of mind Dugald Stewart, Mill sharply distinguished between two different fields of science, the natural and the mental (or ‘moral’, as was used somewhat equivalently at the time). Political economy was interested only in a limited set of mental motives on which observations could be made within the ‘private economy’ of one's own mind. Therefore, political economy was a science of tendency laws the consequences of which could be deduced with the same certainty as the laws of physics. Mill repeatedly emphasized that what we nowadays call ‘introspective’ observations on mental states were as good as the methods of 'observation
and experiment’ used in the natural sciences. Mill's defence of (Ricardian) political economy proved extremely successful. After the publication of his own *Principles of Political Economy* (1848) debates on the proper method of political economy certainly shifted in favour of Mill.

Following Mill, the Irish political economist John Elliot Cairnes argued in his lectures on the method of political economy (1857) that a political economist did not need the ‘tedious route of induction’ practised by the statistical societies. Political economy was an a priori science and the ‘business’ of the political economist was finished once he had traced an event back to a mental motive. More explicitly than Mill, Cairnes argued that political economy lacked the exactness of the natural sciences, because principles of the mind, by their nature, were not the kind of material fit for measurement and hence quantification. Cairnes’s lectures reflect the ‘curious separation between abstract theory and empirical work’ in which the work of political economists and statisticians were worlds apart (Blaug, 1976), much in contrast with Jevons's own practice in Australia.

Much of Jevons's mature work in economics and statistics can be seen as a deliberate transgression of this division between (inductive) statistics and (deductive) theory. In his 1870 opening address as president of Section F of the British Association for the Advancement of Science (BAAS), Jevons explicitly argued that a ‘scientific treatment’ of social facts consisted in inductive and deductive processes, just as in the ‘other branches of the sciences’. Jevons used his mechanical world view to cut through the distinction between theory and statistics and in the process mathematized the discipline.

**Jevons's publications in the 1860s**

In the early 1860s Jevons worked in frenzy on a variety of subjects. He devoted much of his time to the development of an alternative to George Boole's algebraic logic, on which he published a small tract in 1863 that received little attention. He worked on what he called his ‘Statistical Atlas’ project, a large-scale project clearly started in the spirit of William Playfair's *Commercial and Political Atlas* (1801), which was the first application of the graphical method to social statistics. He presented its outline and first plates to William Newmarch, then one of the leading statisticians, but Newmarch hardly paid attention to it, and Jevons ended up publishing two of his plates at his own expense. He wrote several entries for Watts’s *Dictionary of Chemistry and of the Allied Branches of the Other Sciences* (1863–8) on various measuring instruments, such as the balance and the thermometer, but also on topics such as cloud formation. He wrote a short outline of a mathematical theory of political economy, read to the British Association for the Advancement of Science in 1862 and published 1866 as the *Brief Account of a Mathematical Theory of Political Economy*. It was as poorly noticed as his work in formal logic, and it is understandable that Jevons's diary at the end of 1862 showed some frustration about his worldly accomplishments. The best essay on Jevons's first brief mathematical outline of economics is by Grattan-Guinness (2002).

Jevons's first success came with his study of the fall of the value of gold, published in 1863, and republished in his *Investigations in Currency and Finance* (1884). Apart from giving an imaginative survey of the various causes of price fluctuations, it is noteworthy for the use of index numbers to assess the change in the value of gold. The question was whether the value of gold had changed as a result of the gold discoveries in California and Australia. The study can be seen as an application of a version of the quantity theory of money, but, more interestingly, Jevons compared the quantity theory equation of exchange with a mechanical balance and asked what was the more probable: that a tip of the balance had come from a variety of causes influencing individual prices on the one side of the balance, or from just one cause on the other side, that is, an increase in gold bullion. On this analogous reasoning Jevons constructed an unweighted index number, arguing that the geometric mean gave the best approximation for the ‘true’ fall in value (and so a rise in the general price level). Whatever its technical limitations (many of which Jevons acknowledged himself), the study was a genuine accomplishment and it was immediately recognized as such. It was well received by Cairnes, who wrote approvingly that he had come to similar conclusions though using the a priori method of research; for Cairnes, statistical data did not play any formative role in his argument.

The favourable reception of Jevons's essay on the value in the fall of gold of 1863 was even surpassed by that of *The Coal Question* in 1865. This soon made Jevons's professional frustrations vanish. Already elected a member of the London Statistical Society in November 1864, by 1865 Jevons could notice in his diary that he was considered ‘by reviews of authority, a competent statistician’. *The Coal Question* was Jevons's definitive breakthrough. Using extensive statistical resources, the book addressed the question of England's wealth in the face of the inevitably rising costs of coal extraction. It is still excellent reading for those interested in environmental economics. It led J.S. Mill to ask questions in *The Wealth of Nations* (1848) debates on the proper method of political economy certainly shifted in favour of Mill. 

In the second half of the 1860s Jevons continued to publish in statistics and formal logic, on the development of his logical machine in particular. He presented his own formal logical system in *The Substitution of Similars* (1869) and his proposal for a mechanical representation of this system in *The Mechanical Performance of Logical Inference* (1870), both reprinted in *Pure Logic and Other Minor Works* (1890). He also published statistical investigations on seasonal variations, using ratio charts to thresh out seasonal patterns. At the end of the 1860s, Jevons was predominantly known for his work in formal logic and statistics, not as a theoretician, and it may be for that reason that political economists such as Mill and Cairnes were somewhat puzzled by the *Theory*. Given their views on the method of political economy, they substantially disagreed with Jevons's transgression of the dividing line between the natural and moral sciences, and with his concomitant use of formal methods in political economy. Jevons gave his general defence of a unified scientific method in his major work, *The Principles of Science*, published in 1874.

Formal logic and the mechanics of the mind

To understand the impact of the emergence of formal logic in Britain, pioneered by Boole, De Morgan and Jevons, it is important to invoke the distinction between the moral (or mental) and natural realm that dominated Victorian discourse from the publication of Mill's Logic onwards. Quantitative methods of research – mathematics and statistics – were considered fit for the natural realm, but the realm of the mind could (and should) be explored introspectively. Logic, until then, was considered a branch of the sciences of mind, not of the natural sciences, and so the idea of using mathematics for its study was considered a violation of the distinction between these realms (Richards, 2002).

Earlier in the 19th century Babbage's famous calculating engines had opened up debates in which the idea was explored that our mind was, after all, no more than a calculating machine. Challenging the distinction between mind and matter, such thoughts (and machines) also challenged one of the backbones of Victorian moral philosophy, the notion of freewill. A variety of authors who agreed on next to nothing found themselves in the same camp on this issue: William Whewell, J.S. Mill, the utilitarian philosopher James Martineau and the common sense philosophers William Hamilton and Henry Longueville Mansel all argued against the use and usefulness of algebraic methods for the study of logic, precisely because this was felt to threaten the notion of free will, and more generally the foundations of moral agency.

Augustus De Morgan was of opposite opinion. In his writing on Boole's algebraic logic and in his own formal logic, he emphasized the connections between an algebraic treatment of logic and mechanical theories of the working of the mind. In his own work in formal logic, Jevons followed De Morgan's lead. Jevons enthusiastically referred to Boole and Babbage and promised a logical machine of his own 'which shall not only solve Aristotle's dilemma's, but shall exhibit to the eyes the working of Boole's logic the most general and perfect system of logic yet proposed'. Jevons worked on such a machine in the mid-1860s and wrote several articles to describe its working. To emphasize the relation between the machine, formal logic, and the method of science, he used an image of the machine as a frontispiece to his own magnum opus on scientific method, The Principles of Science (1874). Jevons once described this book to his brother Herbert as a work on formal logic 'in disguise'.

It is worthwhile quoting from De Morgan's Formal Logic (1847) and Jevons's The Principles of Science (1874) to see the similarities between their endeavours. De Morgan wrote that 'with respect to the mind, considered as a complicated apparatus, we are not even so well off as those would be who had to examine and decide upon the mechanism of a watch, merely by observation of the function of the hands, without being allowed to see the inside'. Jevons similarly wrote that 'we are in the position of spectators who witness the productions of a complicated apparatus, but are not allowed to examine its intimate structure'. These extracts show not only their similarities, but, more importantly, how Jevons's reliance on mechanical analogies shifted the grounds for studying the laws of mind from an introspective to an outsider's perspective; the emergence of formal logic challenged introspection as a viable route of discovery in the realm of the mind.

So what alternatives did Jevons propose for discovery in the moral sciences? Essentially, his general answer was: statistics and mathematics; the specific answer was: psychophysiology. The first answer related to Jevons's view that all sciences were quantitative in nature and that one needed proper instruments to measure these quantities. The second related to contemporary developments in the work of the physiologists William Carpenter, Henry Maudsley and others, work that seemed to promise the unravelling of the physiological groundwork of human agency. For Jevons these developments pointed in the direction of a mathematical theory of human agency, which was to be made exact with the help of statistics. I will first discuss the relation of Jevons's logical machine to his theory of induction and then discuss the relation of his reading into psychophysiology to his new theory of value.

Rethinking induction

To see the relationship between Jevons's logical machine, statistics and induction we need a brief outline of the machine's working. The logical machine had the appearance of a small piano. Its keys were either terms in a logical proposition or operations like 'and', 'or', and 'is'. Though the machine was of limited capacity, Jevons used it as an illustration device of the more general process of logical inference. One of his examples was 'Iron is a metal', or in Jevons's formalism '$A = AE$', and 'a metal is a good conductor of electricity', formally '$B = BC$', an example that referred back to Hans Christian Oersted's famous thought experiment on the relation between electricity and magnetism. Once these propositions were fed to the machine, a tip on the 'finis' key made the machine 'reason upon' them. Thus, Jevons argued, just as Babbage had created 'in the wheels and levers of an insensible machine' a 'rival' of the human mind, so his logical machine 'really accomplishes in a purely mechanical manner … the true process of logical inference'. All conclusions that could be drawn appeared on the display at the front of the piano (in the example given, there are eight valid conclusions). The list of conclusions would grow exponentially with the number of propositions.

At the time, the fact that the machine showed all logical conclusions was seen as a disadvantage. Jevons turned this disadvantage into a clue about induction. He believed that observations should be considered as the conclusions poured out by the fundamental machinery of nature. The task of the scientist was to infer back from the avalanche of conclusions to the fundamental propositions underlying them – in the example given, the scientist should infer back from the eight conclusions to the two producing propositions or 'laws'. Jevons called this process 'indirect deductive inference'. When facing nature's complexity, such indirect deductive inferences could only be hypothetical; there was no unambiguous procedure to know with certainty that the correct fundamental propositions were touched upon.
If nature’s conclusions were quantitative, then the fundamental laws were quantitative as well. Jevons gave an example that Babbage had discussed in his *Ninth Bridgewater Treatise*, Bernoulli numbers. Behind a seemingly capricious array of numbers there was a simple mathematical formula generating them all. Once one left the realm of pure mathematics and entered the real world, however, an additional complicating factor entered the scene that related to the process of scientific observation itself. According to Jevons, all scientific observations were loaded with error, so the laws of nature could never fully account for individual observations, but should always relate to average values. Errors in measurement cancelled out in the average. For this reason Jevons never considered the target of scientific explanation a mathematical form fitting all individual observations; rather, science should find the ‘rational formula’, that is, the mathematical form that explained the phenomena behind the data. This is exactly the procedure Jevons followed in his own statistical investigations, and it put him at a large distance from Mill. As explained best by Sandra Peart (1995), Mill’s ‘disturbing causes’ were for Jevons just ‘noxious errors’. Jevons's investigations into the ‘black art of induction’ were thus closely related to his investigations in formal logic and the logical machine. They gave a pivotal role to the manipulation of statistical data in discovering the underlying laws producing these data ‘in the average’.

Mathematics and the ‘physiological groundwork’ of economics

In the *Principles* Jevons illustrated his meaning with reference to a series of (self-) experiments on the relationship between work and fatigue, which he published in *Nature* (1870). Jevons made these experiments using proxies for physical labour (holding weights, lifting weights with pulley and block, throwing weights) to show how, contrary to the opinion of political economists like Mill and Cairnes, the investigation of the ‘physical groundwork of economics’ could be mathematized. Thus, these experiments form an interesting link between Jevons’s views on the role of statistical data as evidence for theories, and his views on the nature of political economy.

In his lectures on the method of political economy, Cairnes had discussed two authors in particular who proposed to ground economics in the mechanics of man’s physiology, Richard Jennings and Henry Dunning Macleod. Cairnes observed that ‘every economist, so soon as an economic fact has been traced to a mental principle, considers the question solved’, and so did not need to take recourse to a superfluous examination of mankind’s physiology. These authors thus transgressed the limits Mill had set on political economy. Referring to Jennings’s *Natural Elements of Political Economy* (1855) in particular, Cairnes argued that he could not see how an examination of the ‘afferent trunk of nerve-fibre’ would clarify, for example, the phenomenon of consumption. If political economy consisted in the study of man’s physiology, Cairnes complained, ‘it is evident that it will soon become a whole different study from that which the world has hitherto known it’.

Jevons read Cairnes’s lectures intensely, but he did not approve of its conclusions. In contrast with Cairnes, Jevons enthusiastically embraced Jennings’s suggestion to ground the laws of political economy in man’s physiology. In the *Theory* Jevons wrote that Jennings ‘most clearly appreciated the nature and the importance of the laws of utility’ by treating the ‘physical groundwork of Economy, showing its dependence on physiological laws’. While Cairnes dismissed Jennings’s suggestion to ‘exhibit’ the ‘result of the principles of human nature … by the different methods of Algebra and Fluxions’, Jevons considered this ‘a clear statement of the views which I have also adopted’.

In a series of excellent essays, Michael White has explored the relation of Jevons’s *Theory* to his engagement with psychophysiology and his closely related interest in the emerging theory of thermodynamics (see in particular White, 1994a; 2004; also Maas, 2005). From White’s investigations the following image emerges. In his early years back in London, Jevons explored the meaning of value in economics using two resources, Bentham’s felicific calculus of pleasures and pains, and contemporary research in psychophysiology, in particular the work of William Carpenter, which built on Marshall Hall’s theory of reflex action of the 1830s. These investigations brought him to the idea that value, or what he later called the ‘final degree of utility’, could be examined by means of functional analysis. Jevons’s own work on his highly successful *Coal Question* (1865) importantly contributed to his own awareness of the importance of the newly emerging discourse of thermodynamics. The incorporation of the new discourse of energy already transpired from the *Theory* itself, in particular from his theory of labour supply, and is even clearer in his (unfinished) *Principles of Economics*.

In June 1860 Jevons famously wrote to his brother Herbert that he had found the decisive elements of his new theory of utility, especially ‘the most important axiom’ of the declining degree of what he then called the ‘ratio of utility’, and the assumption that, ‘on an average’, this ratio of utility was ‘some continuous mathematical function of the quantity of commodity’. According to Jevons, political economists had assumed this law ‘under the more complex form and name of the Law of Supply and Demand’. Hence, Jevons’s engagements with psychophysiology and his attempt to mathematize the theory of value were intimately connected. Psychophysiology made Jevons think of a mechanism of pleasures and pains, which expressed itself in market prices.

Jevons’s first airing of his new mathematical theory of value was the short *Notice* of 1862 that was read to the BAAS and published in 1866 as the *Brief Account*. Though Jevons had been thinking about his theory throughout the 1860s, he felt prompted to write it down after William Thornton’s challenge to the classical wages fund theory in 1867. Thornton’s challenge led to Mill’s famous recantation and to vehement debates as to the character of the ‘laws of supply and demand’. Jevons’s extensive exchange of letters with the engineer Fleming Jenkin on this topic was the immediate reason to speed up publishing a written version of his mathematical theory of utility. When Jenkin published a paper in 1870 called the ‘Graphical Representation of the Laws of Supply and Demand’, Jevons clearly feared that priority in a mathematical theory would escape him, and in just half a year he completed the *Theory*.

This book seriously transgressed the limits set by Mill on political economy's methods and subject. In his *Essay* of 1836 Mill had relegated the ‘laws of the consumption of wealth’ to outside the domain of political economy. Jevons, by contrast, made these ‘laws of human enjoyment’ the cornerstone of his new theory. To articulate these laws, Jevons used...
Bentham's felicific calculus, but he grounded this calculus in man's physiological dispositions. Rather than thinking of pleasures and pains as motives on which the mind decides, Jevons transformed them into physical forces that drive a mechanical balance to equilibrium. Figure 1 sums up the main characteristics of Jevons's utility theory.

Figure 1

Note: Jevons's diagrammatic representation of the utility adjustments of an individual ('trading body') to the optimum at $m$, at *given* market prices of two commodities $x$ and $y$. The utility curve $p' r'$ for commodity $y$ is inverted and superposed upon the utility curve $pr$ for commodity $x$. *Source:* Jevons (1871).

In Figure 1, two utility curves for two commodities $x$ and $y$ of one person ('trading body') are superposed and inverted upon one another. Utility is measured on the vertical axis, commodities on the horizontal. The diagram shows how this person would make a net gain in utility by extending trade from $a'$ in the direction of $m$, and would lose in utility when trading beyond that point. Hence, there automatically emerges an equilibrium for this individual at $m$.

This balancing model was taken to represent the individual's balancing of pleasures and pains at the margin. As Jevons put it in the *Theory*: 'the will is our pendulum and its oscillations are minutely registered in the price lists of the markets'. This theory enabled Jevons to state relative prices in terms of relative marginal utilities. What it did not show was how an equilibrium price was actually obtained through price adjustments, something that had been pointed out to him earlier in correspondence with Fleeming Jenkin. Hence, Jevons's theory did not explain price formation; it only showed how individuals adjusted their demands at a *given* price.

In the *Theory* Jevons suggested that numerical precision could be given to his theory by taking the so-called King–Davenant Price Quantity Table as an example, just as he used his experiments on work and fatigue to show that in principle numerical precision could be given to his theory of labour. This small table was found in the work of the 17th-century political arithmeticians Gregory King and Charles D'Avenant and allegedly contained statistical data on prices and quantities of wheat. Through the 19th century it had been widely used to argue for or against the possibility of mathematizing political economy, for example by Thomas Tooke, William Whewell, but also by Cairnes (Creedy, 1992). Jevons showed

how this table could give numerical exactness to the notion of the final degree of utility, the ‘all important element of political economy’, and so how statistical data could give precision to theory (Stigler, 1994; White, 1989).

The remainder of the book contained Jevons's theory of rent and capital that are interesting in their own right, but it was undeniably his theory of utility, worked out in his theory of exchange and labour, that brought Jevons the fame he hoped for. But not immediately.

In a letter to Cairnes of 5 December 1871 (Mill, 1972, pp. 1862–3), Mill wrote that he certainly would agree with Cairnes's negative judgement on the book:

I have not seen Jevons's book, but as far as I can judge from such notices of it as have reached me [in Avignon], I do not expect I shall think favourably of it. He is a man of some ability, but he seems to have a mania for encumbering questions with useless complications, and with a notation implying the existence of greater precision in the data than the questions admit of. His speculations on Logic, like those of Boole and De Morgan … are infected in an extraordinary degree with this vice.

Interestingly, Mill considered Jevons's mathematical endeavours in economics on a par with his ‘speculations in logic’. Behind Mill's irritation we may guess a genuine concern with mechanistic theories of the mind, which Mill feared were a degradation of man's most ‘ennobling’ characteristics. It is only after Jevons's strong mechanistic image of man as a balance of pleasures and pains and the Victorian obsession with the problem of free will waned that his ‘mechanics of utility and self-interest’ could be considered to deal with rational choice. One will search in vain for this notion in Jevons's original work, however.

Jevons's later years

The publications dating after the Theory and Principles are generally thought to be of much less importance. Jevons turned his attention to his notorious sunspot studies, in which he attempted to establish a causal connection between solar activity and commercial crises. Though these studies were generally seen to be failures, the famous astronomer William Herschel had in fact voiced similar ideas on the relationship between agricultural output and the activity of the sun in the early 19th century. Jevons had to make increasingly far-fetched assumptions as to the causal mechanism involved, which cast doubt on the whole enterprise. Jevons also wrote a number of highly successful primers; the primer on logic went through numerous reprints (up to 1931), and his Money and the Mechanism of Exchange (1875) sold well too. Jevons also worked on the second edition of the Theory, which appeared 1879 and which contained an extensive survey of precursors in mathematical economics. In The State in Relation to Labour (1882) and a posthumous collection of essays on social reform (1883), Jevons turned his attention to the social and political issues of his day, issues that had been close to his mind from his formative years in Australia. At the end of the 1870s he wrote a number of vehement attacks on Mill's philosophy that, given the towering status of Mill as a political economist and philosopher, actually harmed Jevons's own intellectual status. Having moved from Owen's College to University College, London, in 1876 to take up the professorship in political economy, he resigned in 1880, partly because of problems of health but more importantly to be able to devote all his time to writing. His untimely death in 1882 left his last large project, the Principles of Economics, unfinished. It was published, with some additional essays, in 1905.

Jevons's investigative spirit

Jevons's statistical work in the 1850s and 1860s, his imaginative, though less well-known, work in formal logic, and in particular of course his Theory of Political Economy and Principles of Science stand out as landmark contributions to economics and to the philosophy of science. A genuine Victorian polymath, Jevons worked in many different fields of the sciences, all of which he engaged in the same investigative spirit. Though some of his work in the 1870s was quite successful, some lacked the sharpness and acuity of his earlier work. Equally well at home in theory as in the ‘black arts of inductive economics’, Jevons was, as Keynes noted in his 1936 obituary, ‘the first theoretical economist to survey his material with the prying eyes and fertile controlled imagination of the natural scientist’.

Jevons's investigative spirit, with its typical belief in the power of mathematics to capture the mechanical principles of the subject under study, irrevocably altered the image of economics, and is perhaps still with us. In many of the sciences, a satisfactory explanation nowadays requires the description of a mechanism, and economics is no exception to this. Nobel laureate Robert Lucas once described economic theory as providing an ‘explicit set of instructions for building … a mechanical imitation system’ (1980, p. 697). In retrospect we may hear the echo of Jevons's approach to economics in these words.

Jewkes was educated at Barrow Grammar School and Manchester University. His first job was as Assistant Secretary of the Manchester Chamber of Commerce, 1925–26. He was then appointed lecturer in economics at Manchester University, and stayed there for three years. Following a period in the United States, he returned to Manchester as Professor of Social Economics in 1936. After holding this chair for ten years, he was appointed Stanley Jevons Professor of Political Economy at Manchester. In 1948 he became Professor of Economic Organization at Oxford, and a Fellow of Merton College, and held this chair until his retirement in 1969. His professional contacts, however, remained mainly outside Oxford. Jewkes had a distinguished wartime career. He became Director of the Economic Section of the War Cabinet Secretariat in 1941, and was appointed Director-General of Statistics and Programmes at the Ministry of Aircraft Production in 1943. This was followed by other posts, and after his return to university life he was a member of a number of royal commissions and other official committees.

Jewkes's Manchester roots, together with his wartime experience, made him a powerful advocate of free-market solutions. His first notable book on this subject was *Ordeal by Planning* (1948), followed by *Public and Private Enterprise* (1965), *New Ordeal by Planning* (1968), and *A Return to Free Market Economics?* (1978). In these works he advocated the virtues of the free market, as opposed to government ownership or government planning, as a fruitful background for economic efficiency and individual initiative. He argued that government efforts to replace the market had produced one debacle after another, and also that economists claimed too much for their subject, thus reducing their potential usefulness. Before the Second World War Jewkes's work had concentrated on detailed studies of the economic and social problems of Lancashire – as, for example, in his *Wages and Labour in the Cotton Spinning Industry* (1935, with E.M. Gray). Some of his work after the war also concentrated on detailed problems, but in a national or international context. For example, he published studies, jointly with his wife Sylvia, on medicine and the National Health Service, arguing that the state-operated National...
Health Service had displayed many weaknesses. A notable contribution to the literature on innovation was his *The Sources of Invention* (1958, with David Sawers and Richard Stillerman). This was one of the earliest attempts at systematic investigation in this field. It successfully established the importance of the small-scale inventor, and showed that many notable 19th- and 20th-century inventions were essentially the work of one or two individuals, working with limited resources. This may well prove to be his most lasting contribution.

Jim Crow South

Gavin Wright
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The US South maintained a distinctive economic and political structure from the demise of slavery in the 1860s to the Civil Rights revolution of the 1960s. Racial wage differentials in the unskilled labour market were small. But blacks were virtually absent from higher-paying skilled jobs. Disfranchisement led to a drastic fall in relative expenditures on black schooling between 1890 and 1910. The effort to protect cheap labour reinforced regional isolation, depriving the South of dynamic stimulus from new migrants, enterprise and ideas. Conflicts between recruitment of capital and demands for racial justice were resolved only by federal intervention.

Article

‘Jim Crow’ was a blackface caricature from a minstrel show that pre-dated the US civil war. The term came to represent the regime of racial segregation that became entrenched in both law and custom by the end of the 19th century in the US South.

From the demise of slavery in the 1860s to the Civil Rights revolution of the 1960s, the southern states maintained a distinctive economic and political structure. This historical episode raises a number of issues of general interest for economics, among them the effects of segregation on efficiency, and the impact of the segregationist regime on the economic progress of the region as a whole.

Jim Crow segregation did not emerge full-blown in the aftermath of war and emancipation, but instead had its own evolution. Appearing in the midst of the school segregation debate of the 1950s, C. Vann
Woodward’s classic *The Strange Career of Jim Crow* (1955) overturned the myth that the races had ‘always’ been separated in the South, noting that explicit racial codes did not appear in most states until the 1890s. Blacks participated actively in Southern politics during Reconstruction (the period of federal military control, 1865–77), and longer in many states. Only when it became clear that neither the federal government nor the Supreme Court would intervene were Southern states emboldened to disfranchise black voters, using a variety of ostensibly non-racial devices (such as poll taxes and literacy tests) whose racial intent was barely disguised. Mississippi’s constitution of 1890 was the first statewide disfranchisement programme, and by 1910 the exclusion of blacks from Southern politics was nearly complete. Legally mandated segregation soon followed disfranchisement, ultimately extending not only to schools, churches, eating establishments and recreation, but to public transportation, hospitals, prisons, cemeteries and other avenues of life. Although all were aware that it was honoured more in the breach than the observance, the ‘separate but equal’ principle was upheld by the US Supreme Court in the famous 1896 case, *Plessy vs. Ferguson*.

Even more onerous than the demand for physical separation were brutal features of the Jim Crow South, such as lynching (extra-legal executions) and convict labour (leasing of prisoners to private contractors). Neither of these phenomena was exclusively racial, but their impact fell most heavily on black Southerners.

**Segregation and labour markets**

Extensive as the scope of legal segregation became, its limits were equally notable. Racial aspects of employment and work relations were virtually unregulated. The only industrial segregation laws of any importance – a North Carolina statute requiring separate toilets and a South Carolina law requiring segregation in cotton textiles – were adopted only in 1913 and 1915, respectively – long after prevailing racial patterns were established – and were not imitated elsewhere. Yet, despite the absence of legal enforcement, segregation was the norm in Southern industries. In his study of Virginia firms in 1900 and 1909, Higgs (1977, p. 241) found that ‘occupational workforce segregation was overwhelmingly the rule’. Interestingly, racial separation was more prevalent and more clearly delineated by industry than by location. White cotton mills and black tobacco factories coexisted in places like Durham, North Carolina, and Danville, Virginia; in Birmingham, Alabama, where two-thirds of iron and steel workers were black, the Avondale cotton mill was 98.1 per cent white.

Explaining segregation in labour markets does not pose a serious challenge for economic theory. The models of Becker (1957) and Arrow (1973), among others, show that, if whites demand a premium for working in close association with blacks, segregation dominates mixed alternatives. The issue that economists have wrestled with is not segregation per se, but wage discrimination: did segregation serve to support an ‘unjustified’ wage differential, or was it merely the market's way of avoiding the costs of mixing the races? The perhaps surprising finding of numerous studies is that, despite the prevalence of racism in the Jim Crow South, racial wage differentials in the open (unskilled) labour market were small or non-existent.

In agriculture, wage labour coexisted with sharecropping and other forms of tenancy. Although whites had a large overall advantage in farm property and incomes, whites as well as blacks could be found at all stages of the ‘agricultural ladder’. With rare exceptions, black and white farm labourers were paid the
same wage. For example, in 1887 the North Carolina Bureau of Labor Statistics posed the question of racial wage differences to landlords as well as to tenants and labourers. In 94 of the 95 counties, the landlords reported ‘no difference’ between the races, and in 77 of the 95 counties the tenants and labourers gave the same response (cited in Higgs, 1978, p. 310). Even more remarkable, evidence from pre-First World War Virginia indicates that unskilled wages were equilibrated for black and white labourers, even across highly segregated industries such as cotton textiles and tobacco manufacturing (Whatley and Wright, 1994). The large intermediating agricultural sector may have been important in maintaining this equilibration for men, because the same data suggest a 25 per cent wage gap in favour of white over black women, who did not have access to farm labour jobs.

Equally noteworthy, however, is the virtual exclusion of blacks from higher-paying skilled jobs in Southern industry. Within agriculture, blacks were often able to rise up the ladder of accumulation, from wage labour to tenancy and even to farm ownership, albeit usually on a small scale. Such advancement opportunities were rare in non-agricultural sectors. In some cases, such as railroads, barriers to black promotion were enforced by all-white craft unions (Sundstrom, 1990). Elsewhere blacks were held back even in the absence of unions and even where skills were largely acquired on the job. Promotion of blacks to supervisory positions over whites was widely seen as unthinkable. Thus, despite the efficacy of labour markets in equilibrating unskilled wages, access to skilled positions was distinctly unequal between the races.

Race and schools

One direct consequence of disfranchisement was a drastic fall in relative expenditures on black schooling. The inequity was most extreme in the black-majority counties of the lower South, where funding was simply diverted from white to black schools. For example, in Mississippi in 1907 predominantly white counties spent $3.50 per school-age child on blacks but $5.60 on whites; in predominantly black counties, $2.50 was spent on blacks but $80.00 on white children. Black schools were also characterized by lower teaching salaries, higher student-teacher ratios, shorter terms and lower educational levels of teachers (Bond, 1934).

Economists often identify poor schooling as the primary explanation for low black incomes throughout the Jim Crow era (Smith, 1984). This interpretation meshes comfortably with the perspective emphasizing that barriers to black progress operated through political channels rather than through discrimination in markets. Economic historians, however, generally interpret the politics of Jim Crow as part of a larger political-economic package.

Landowning planters actively opposed higher spending on black schools, not just because funding could be diverted towards white children but because ‘educated Negroes, in nearly all cases, become valueless as farm laborers’ (quoted in Anderson, 1988, p. 96). As one Arkansas planter put it in 1900: ‘My experience has been that when one of the younger class gets so he can read and write and cipher, he wants to go to town. It is rare to find one who can read and write and cipher in the field at work’ (quoted in Wright, 1986, p. 79). In other words, restricting black education was a way of preserving the agricultural labour force.

Even outside of agriculture, exclusion of blacks from skilled jobs exercised a feedback effect on the demand for education. When the Rosenwald Fund sought to provide funding for black high schools in
the South during the 1920s and 1930s, it learned that there were no black jobs for which a high-school education would be useful. Thus, black schools typically did not offer training in such subjects as stenography, accounting, bookkeeping, printing or typing. The fund's curriculum expert acknowledged: ‘If commercial courses were offered in the Negro school there would no doubt be tremendous pressure to get into them and the only result would be keen disappointment for nearly everyone’ (quoted in Anderson, 1988, pp. 223–4).

Because of this mutual interaction between schooling and labour markets, the interwar years saw the opening of a racial wage gap for entry-level positions, in contrast to pre-First World War patterns. Proximate reasons for divergence include stagnant world demand for cotton during the 1920s, disproportionately affecting blacks, and an upward shift of real wages in the all-white cotton textiles industry, initially because of wartime inflation, and subsequently resistant to reduction for both internal and external reasons. The long-term consequence was that racial segregation took on a different economic character, becoming more a ‘vertical’ support for wage differentials than a ‘horizontal’ separator of the races as in the earlier period. According to a 1937 survey (Perlman and Frazier, 1937), firms hiring only blacks paid starting wages one-third lower than those hiring only whites; of those hiring both, nearly 30 per cent paid blacks a lower starting wage. In contrast, no explicit racial wage differential was reported in Northern firms. The ‘separate wage rates for Negroes’ that Southern observers took to be ‘a fixed tradition’ had in reality developed and become institutionalized only in the 20th century (Whatley and Wright, 1994). Margo (1990) finds that employment segregation increased between 1900 and 1950, even after racial differences in schooling are controlled for.

**Economic development in the Jim Crow South**

Granted that the Jim Crow regime adversely affected African Americans, the question may be posed: what was its effect on economic development in the region? Although theory suggests that racial discrimination is inefficient, it is not straightforward to detect inhibiting effects on the growth of major Southern industries. Cotton textiles, the most racially exclusive of them all, surpassed the historic New England branch by the turn of the 20th century. Rapid growth in such diverse industries as iron and steel, fertilizer, tobacco manufactures and furniture did not seem to be hindered by the colour line in employment, and Southern value-added in manufacturing grew faster than the national average throughout the Jim Crow era. Nonetheless, per capita income in the South was roughly half the national average as of 1880, and this ratio had barely changed by 1940. Can this failure to converge on national norms be tied to Jim Crow institutions?

Growth-accounting analysis attributes much of the regional income gap to low levels of education in the South (Connolly, 2004). Underinvestment in human capital extended to Southern whites as well as blacks, a phenomenon that was also historically linked to race. Disfranchisement of blacks deprived many lower-income whites of the vote at the same time, preventing a class-based political mobilization that might have overcome planter opposition to funding for public schools (Kousser, 1974). In the classic analysis of political scientist V.O. Key (1949), regional unity on the race issue led to one-party politics, depriving the South of the popular political participation that elsewhere supported public schools and other measures favoring economic development.

Perhaps the worst effect of Jim Crow on economic development was that the effort to protect cheap
regional labour led to regional isolation, depriving the South of dynamic stimulus from new migrants, enterprise and ideas. In 1910, just two per cent of Southern residents were foreign-born, the lowest share in the nation. Connolly (2004) finds that low levels of human capital did not just lower average incomes in the South but also slowed the diffusion and generation of new technologies. In the 1930s, when regions were actively competing for newly available federal funds, the states of the South – the most solidly Democratic in the country – received the lowest levels of federal support per capita. One main reason was that Southern political and business leaders feared the effects of federal funding on wages, labour discipline and race relations.

The demise of the Jim Crow South

The Jim Crow world crumbled under federal pressure during the 1960s. But this political revolution was preceded by an earlier regime change in economic policy, occurring between the 1930s and the 1950s. At that time the South began its modern economic take-off, an acceleration of growth dated from approximately 1940. As a case study in economic modernization, the episode is highly unusual in that the acceleration coincided with massive outmigration from the region in question. Low-income, poorly educated Southerners left the countryside for cities in both North and South, while professionals and retirees began to move Southward, into fast-growing cities and sunbelt retirement areas. Migration was racially as well as economically selective. Net Southern white outmigration all but ended by the 1950s, while blacks continued to leave the region in large numbers through the 1960s.

With the advent of the national minimum wage (and related labour market regulations) in the 1930s, and the renewal and extension of these policies in 1950s, it was clear to business leaders of the South that an Asian-style industrialization based on cheap labor within US borders was not going to be politically acceptable. At roughly the same time, full mechanization of cotton growing became feasible, and was all but complete by 1960. Together, these developments tipped the political balance towards vigorous efforts to attract business through tax breaks, municipal bonds for plant construction, industrial development corporations, research parks and expenditures on publicity far beyond those of other regions. James C. Cobb (1982) calls it the ‘selling of the South’.

One might suppose that enlightened Southern businessmen should have led the way in breaking down racial barriers, but the evidence suggests that most were extremely reluctant to do so. In city after city, business leaders weighed in on the side of compromise, but only after political turbulence reached the point where it threatened the flow of investment capital. For their part, employers had no strong economic motives for challenging racial norms, since low-end wages were governed by federal law, and few blacks were qualified by education or experience for high-end jobs. This perverse regional equilibrium might have survived indefinitely on purely economic grounds. But ultimately the irresistible force of economic progress came into collision with the immovable object of Jim Crow.

The leverage of the movement derived from the fact that competition for outside capital required Southern leaders to present their towns and cities as safe, civilized communities, with a labour force that was well-behaved and eager for work. The most famous case in point was Little Rock, Arkansas, where a promising post-war development programme came to a standstill when Orval Faubus called out the National Guard to block court-ordered school integration in 1957. Although the city had attracted eight new plants in 1957, not a single new plant came to Little Rock during the next four years. A widely discussed Wall Street Journal headline for 26 May 1961 read: ‘Business in Dixie: Many Southerners
Say Racial Tension Slows Area's Economic Gains.' In her systematic review of Southern businessmen's response to the desegregation crisis, Elizabeth Jacoway writes, ‘In the 1950s and 1960s, white businessmen across the South found themselves pushed – by the federal government and civil rights forces as well as by their own economic interests – and values – into becoming reluctant advocates of a new departure in southern race relations’ (Jacoway and Colburn, 1982, p. 1). In a sense they had to be coerced to act in their own economic interest! Although few were willing to say so in public, many local leaders and business proprietors were privately grateful for civil rights legislation of the 1960s, at least after the fact. These measures largely put an end to disputes over public accommodations and employment segregation, while providing managers the ready-made excuse that the matter was no longer in their hands (Wright, 1999).

Since then, the South has been the most rapidly growing region in the United States. The political revolution has generated economic gains for blacks as well as whites. After the political breakthroughs of the 1960s, more than 50 years of black outmigration came to an end, and blacks have been moving into the region ever since. Net black migration into the South amounted to more than 500,000 between 1990 and 2000, whereas net black migration was negative for each of the other census regions. The attraction of the New South for blacks has economic as well as cultural, political and geographic aspects. As of 1977, the majority of the nation's black-owned businesses were in the South. Median black income grew faster in the South than elsewhere, and by the end of the 20th century equalled or surpassed median black income in the north-eastern and the mid-western regions.

Article

Johansen was born in Eidsvoll, Norway, on 11 May 1930 and died in Oslo on 29 December 1982. He entered the University of Oslo in 1948, and received the equivalent of a Master's degree in economics (cand.oecnom.) in 1954. He was awarded a doctors degree (dr. philos) in 1961, for a dissertation with the title ‘A Multi-Sectoral Study of Economic Growth’.

In 1951 Johansen became research assistant to Ragnar Frisch. After graduation the university awarded him a research fellowship. In 1958 he received a Rockefeller Fellowship, which he held until in 1959 he was appointed Associate Professor of Public Economics at the University of Oslo. On the retirement of Frisch in 1965, Johansen became Professor of Economics at the University of Oslo, with the special duty of lecturing on macroeconomic planning.

Johansen's first important work is his doctoral dissertation, mentioned above. This book (1960) builds a bridge between the theory of economic growth, which had become fashionable in the 1950s, and Leontief's input–output model, which at the time was widely used in economic planning and forecasting. The choice of dissertation topic was undoubtedly influenced by Johansen's two mentors, Frisch and Trygve Haavelmo, who were then both working in these fields.

In the dissertation Johansen presented a theoretical model, and applied it to Norwegian data. He analysed a 23-sector model of the economy, and it seems that at first this empirical part of the work was considered the more important.

After a few years, however, it became clear that the model, often referred to as the MSG-model, had considerable merits in itself. It became the basis for long-term planning by the Norwegian Ministry of Finance, and over the years it was developed and extended. Johansen took an active part in this work. It seems that the model also influenced planning methods in several countries, and a new and enlarged

The laws of production must play an important part in any growth model, and Johansen continued and extended the pioneering work of Frisch on production functions in a series of articles which had considerable influence. The main results in these papers are brought together and generalized in the book from 1972: Production Functions: An Integration of Micro and Macro, Short Run and Long Run Aspects. The subtitle indicates the high aspiration level of the book, and it did present production functions which were realistic and so general that they could be used in multisectoral planning models. Johansen was a member of the Communist Party of Norway until he died, and he participated actively in some election campaigns. However, his political views have hardly left a trace in his professional writing. An unformed reader will be at loss to divine which political opinions – if any – the author holds. Johansen seems to have written relatively few papers on planning in eastern Europe and on Marxist economic theory, and none after 1966. His objectives seem to be to inform and explain, rather than to convert, and often it seems that these papers are written on request – for instance his paper ‘Labour Theory of Value and Marginal Utilities’ (1963). This is an extension and clarification of some short comments he made in a discussion the year before. It shows that under certain circumstances the two theories can be reconciled. Johansen served on a number of expert committees appointed by different Norwegian governments, and was accepted as the objective scientist who would point out logical inconsistencies but never let his personal views influence the recommendations he made. There is, however, little doubt that Johansen's political opinions had a marked effect on his career. Under the rules in force in the 1950s and 1960s it was impossible for him to obtain a visa to the USA. He therefore did not have the opportunity of spending some of his formative years at an American university. Such opportunities were regularly offered to bright young academics in western Europe and usually had a profound influence on their later work. Johansen missed this experience, and in fact never visited the USA. He remained a European, and principally a Norwegian. Most of his work was published in Europe, and about half of it was written in Norwegian. Johansen's political views did not affect his scientific work, but his views did inevitably influence his opinions as to which economic problems were important and which should be studied. His views naturally led him to study economic planning, and this subject remained Johansen's main interest during most of his professional life. His two-volume Lectures on Macroeconomic Planning (1977 and 1978) is a landmark. It is essentially a textbook which gives a balanced overview of the major issues in the economics of planning, integrating the results Johansen reached over 25 years with those of the many others who contributed to the development of the subject. As often Johansen appears as a master in reconciling different views and approaches. A third volume was in preparation at the time of Johansen's death, and this might have rounded off the work, and removed the many gaps and omissions which reviewers found in the presentation.

Economic planning is closely related to, if not a part of, the subject which has become known as ‘public economics’. The subject may not be very well defined, and its contents have certainly changed over the years. The central topics, however, remain taxation, public expenditure and social welfare. When Johansen began to lecture on the subject at the University of Oslo in 1960, there was no single book which covered this heterogeneous subject. He published his own textbook in Norwegian in 1962. A revised and extended edition appeared in 1965, and was translated into English in the same year as Public Economics. The book did not give any clear definition, nor did it define the limits of the subject. Perhaps too tailor-made for his students at the University of Oslo, it deals very briefly with topics.
covered by other courses in the curriculum. The book did, however, have an impact, and helped to establish ‘public economics’ – suitably defined – as a recognized part of economics. Johansen was one of the founders of the *Journal of Public Economics*, which first appeared in 1972. He served as co-editor from the beginning until his death, and he contributed the opening article of the new journal. Its title, ‘On the Optimal Use of Forecasts in Economic Policy Decisions’, indicates how broadly Johansen tended to view the subject of public economics.

In his later years Johansen developed a strong interest in game theory. He seems to have been led to this subject by Arrow's proof that non-dictatorial and efficient decisions were impossible, and he wrote a penetrating paper on the subject in 1969. A model of central planning will naturally be compared – for efficiency and fairness – with a model of free competition. The assumptions leading to neoclassical equilibrium are generally considered to be unrealistic, and game theory, with its different solution concepts based on compromises between coalitions, were developed as a generalization of the standard market model. The same idea can be applied to a central planning model. Plans are rarely drawn up and executed by a consistent single-minded dictator. Usually they appear as a compromise between different interest groups (coalitions) in society, or within a bureaucracy.

Johansen's first publication on game theory seems to be a short article in Norwegian with the title ‘Plans and Games’ from 1970, contributed to a Festschrift with the general title ‘Economics and Politics’. Here he shows that, if there are several independent decision makers, with different preferences, the collective decision must necessarily be a compromise.

In the following years Johansen published a few papers in Norwegian along similar lines. His first paper on a game theory in English is ‘A Calculus Approach to the Theory of the Core of an Exchange Economy’, published in 1978. Debreu and Scarf (1963) proved that the core of a market game would, under certain conditions, shrink to the competitive equilibrium, as the number of players increased to infinity. Their proof, as well as the ones given by others, depends heavily on topological or measure theoretical arguments, which make the results inaccessible to most economists of the older generation. Johansen shows that the result can be reached by elementary methods, under the assumptions conventionally made in neoclassical economic theory. The paper does not appear to be much cited, and its main effect may have been to give Johansen a deeper understanding of the subject.

Game theory is closely related to bargaining theory, and Johansen's next paper on the subject is ‘The Bargaining Society and the Inefficiency of Bargaining’ (1979). Here he wrote: ‘I consider the game theory approach to economic problems to be the most appropriate paradigm as soon as we go beyond mere accounting and description of production technology and want to include various aspects of economic behaviour.’ The conclusion of the essentially verbal discussion in the paper is that bargaining is not an efficient way of making social decisions. At the time of writing Johansen did not seem to be aware of the concept of ‘bargaining sets’ introduced by Aumann and Maschler (1964). The different bargaining sets include the core if it is not empty, and also some subsets corresponding to the cases in which the players fail to agree on a Pareto optimal outcome.

In one of his last papers, ‘On the Status of the Nash Type of Noncooperative Equilibrium in Economic Theory’ (1982), Johansen argued that the theorem of Nash (1950) has often been misinterpreted and misused in economic literature. The theorem just states that every \( n \)-person game has at least one equilibrium point in mixed strategies. In this purely mathematical context equilibrium point means what in mechanics is called a ‘dead point’, where the forces are in equilibrium. There are few reasons to assume that a point with this property should have any economic optimality property. Johansen
observes, inter alia, that in the game known as the 'Prisoner's Dilemma' the only equilibrium point is the worst possible of all outcomes. 

During his last years Johansen came to look at game theory as a general theory of economic behaviour, which contains as special cases the two extremes: completely centralized decision making and perfect competition. His work during these years showed that Johansen as always was a quick learner, and that at his death at the age of 52 he had gained mastery of the relevant parts of game theory. One can only make guesses about the general theories he might have developed if he had been given a few more years to live.

American Economic Association; Clark, J. B.; exploitation; institutional economics; Johnson, A. S.; marginalist economics; protection; welfare economics

Article

Alvin Johnson was born on 18 December 1874 near Homer, Nebraska, and died 7 June 1971 in Upper Nyack, New York. He received a BA (1897) and MA (1898) from the University of Nebraska and a Ph. D. from Columbia University (1902). His varied teaching career included Bryn Mawr, Columbia, Nebraska, Texas, Chicago, Stanford (twice), Cornell and the New School for Social Research of which, in 1919, he was a founder and, beginning in 1923, director. He was president of the American Economic Association in 1936 and of the American Association of Adult Education in 1939. He was active in the struggle for academic freedom and other civil rights and in providing a haven, at the New School, for refugee scholars. His students included Walton Hale Hamilton, Frank H. Knight and James Harvey Rogers.

Johnson also had an active and varied editorial career. He was assistant editor of the Political Science Quarterly, founder and editor of Social Research, associate editor of the Encyclopedia of the Social Sciences, economics editor of the New International Encyclopedia, political science editor of the American edition of Nelson's Encyclopedia, and on the editorial council of the Yale Review. He also was a founder and member of the editorial staff of The New Republic.

Johnson, who also published novels and short stories, wrote as an economist on a wide range of theoretical and policy problems. He was also the author of a popular and respected principles text which went through several editions. As a student of (and secretary to) John Bates Clark, Johnson adhered to his marginalist approach to economic theory but combined his neoclassicism with social and institutionalist elements. His dissertation on rent theory stressed inter-product competition and tried to develop a non-Marxian conception of exploitation (30 years prior to Joan Robinson's work). His early economic nationalism encompassed a limited pro-protectionist argument. In various writings he argued that labour-saving machinery did not necessarily raise wages; that forward shifting of the corporate
income tax requires price to be a function only of cost of production, which he deemed not prevalent; and that arguments against the minimum wage were based on static assumptions. He considered that prevailing theory offered only universalist, formal explanations to problems of price formation, whereas he found that price phenomena were also the product of a multiplicity of complex variables, and called for greater realism and empiricism. Following Clark, Johnson also anticipated Pigovian welfare economics arguing, in effect, that public ownership could be a solution to cases in which, because of non-approbriables, marginal private benefits fell short of marginal social benefits. For many years he was active in the land reclamation movement.

In general, Johnson was a cautious reformer, advocating reform within the existing social order through the expansion of non-property rights as both a corollary to the security of property itself and a mark of a progressive economy.

Johnson, D. Gale (1917–2003)

John M. Antle
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

D. Gale Johnson, an intellectual leader in agricultural economics in the mid- to late 20th century, was an early critic of the parity price concept. His case against agricultural subsidies helped bring agricultural trade policy into the international policy arena. Johnson was a long-time observer of the Soviet Union and Chinese agricultural reforms. His analysis showed that investment in agricultural research, including biotechnology, primarily benefited the poor through lower real food prices. He argued that market and policy failures, not population growth, were the root causes of environmental problems in developing countries.

Article

David Gale Johnson is widely regarded as one of the intellectual leaders in the field of agricultural economics in the mid- to late 20th century. Born and raised on an Iowa farm, in the early 1940s Johnson was an assistant professor at Iowa State University, where Theodore W. Schultz was department head. Due to a dispute over academic freedom, in 1943 Schultz resigned from Iowa State and moved with several junior faculty, including Johnson, to the economics department at the University of Chicago. Johnson became one of the founders of the Chicago School's ‘oral tradition’ and the workshop system that trained many recognized economists. In addition to his scholarly work and mentoring of students, Johnson served the University of Chicago in various capacities, as Department Chair, Dean of Social

Sciences, and Provost. He was President of both the American Farm Economic Association and the American Economic Association, served on numerous national advisory committees, and was an adviser to many governments and international agencies. He was the editor of *Economic Development and Cultural Change* from 1985 until 2003.

Over the course of his career Johnson's research addressed important topics related to the economics of agriculture in both industrialized countries and developing countries. Johnson emphasized both the welfare effects of agricultural policies on farm and rural people, and their effects on the efficiency of resource allocation within agriculture and between agriculture and other sectors of the economy. His early work focused on domestic agricultural policy design. In his influential 1947 book, *Forward Prices for Agriculture*, he provided both a critique of the parity price concept that dominated agricultural policy debate in the post-war era, and an alternative to it based on understanding the dynamics of the agricultural sector. Another focus of his early work was the role of labour resources in agriculture. His classic 1950 paper on resource allocation under share contracts anticipated much of the debate about their efficiency that was to follow in the 1970s and later. In his equally important 1950 paper on the agricultural supply function, Johnson laid the intellectual groundwork for the extensive literature on agricultural supply that would come in later decades. Importantly, this paper also debunked the claim by J.K. Galbraith and J.D. Black (1938) that the elasticity of agricultural supply is near zero, an argument that was used to rationalize the use of agricultural price supports.

From the 1950s, Johnson's attention moved increasingly to the international policy arena. Perhaps his best-known and most influential work was his 1973 book, *World Agriculture in Disarray*. In this book, Johnson used a general equilibrium model of a growing economy as the basis for his analysis of the impacts that domestic and trade policy interventions have on welfare and resource allocation. Using both theory and data, he showed that output price policies have little or no effect on the returns to the mobile resources engaged in farming (capital and labour), and that it is through the factor markets that returns of farming and other sectors of the economy are equalized. A major conclusion of Johnson's analysis is that the primary effects of subsidy programmes for agriculture is to increase the returns to and price of land, to expand agricultural output, and to induce governments to interfere with international trade. Johnson's work was highly influential in bringing the issue of agricultural trade policy into the international policy arena.

Johnson was recognized as one of the leading experts on agriculture in China, the Soviet Union, and other centrally planned economies. He was one of the first Americans to tour Russian farms in the mid-1950s and point out the inefficiencies of the communal farm system. Four decades later, he would conclude that the cost of the failed Soviet agricultural policy was a major factor in the ultimate demise of the Soviet Union. Johnson and his students were also close observers of the Chinese agricultural economy, the reforms that began in the late 1970s, and the rapid economic growth that followed those reforms.

In the 1980s and 1990s, Johnson focused an increasing amount of his research on the role of agriculture in economic growth during the 19th and 20th centuries, and its relationship to population growth and the improved well-being of the human population in both industrialized and developing countries. His approach to this topic was a direct extension of his vision of agriculture and its role in economic growth. Johnson's investigation of US agricultural incomes in the 1930s and 1940s was essentially a study of the economics of agriculture in a developing economy. Later Johnson applied insights from his earlier work to analyse economic development in an international context. His work on economic development
emphasized the contributions of improvements in agricultural productivity to economic development, the falling real price of food and consequently to improving food security. A further consequence of growing agricultural productivity, combined with the low income elasticity of demand for farm products, was migration out of agriculture.

Throughout his career, Johnson emphasized that the per capita supply of agricultural commodities has been increasing for more than a century, despite the fact that this period has experienced the highest population growth rates in human history. Johnson frequently emphasized that, since at least the 1860s, the long-term trend in the real price of agricultural commodities has been downward, and at an accelerating rate. Between 1866 and 1996, for example, the real price of wheat declined at an annual average rate of 0.89 per cent, but between 1955 and 1996 the annual rate of decline in the real price of wheat was 2.69 per cent. Combined with the fact that the poorest people of the world spend much more of their income on food than richer people, Johnson inferred that gains from agricultural growth had been widely shared and had actually benefited the poor most.

Johnson's ability to disentangle long-run trends from short-term shocks made his advice valuable to governments, but it was often at odds with conventional wisdom. For example, during the 1970s many commentators, politicians and economists thought that a new era of resource scarcity was emerging. Projections were for high and rising farm prices. Farmers were encouraged by farm price-support policy and exhortations from the Secretary of Agriculture to plant ‘fence-row to fence-row’. Johnson was one of the few voices urging caution and more appreciation of the long history of falling real farm commodity prices. Only when prices collapsed in the early 1980s and, inevitably, the budget costs of farm subsidy programmes exceeded all government projections was Johnson's message appreciated. A similar episode, concerning China's role as a grain importer, occurred almost two decades later. Again, Johnson, the source of careful economic logic and sound data analysis, pointed out the sloppy thinking behind the dramatic pronouncements like ‘Who will feed China?’ Within a few years Johnson had been again proven right as China has continued to be a significant grain exporter. Johnson summarized his views of the agricultural supply pessimists as follows; ‘…those who make their living by presenting the future of food supply in very negative terms should be called upon to show conclusively why the remarkable record of the recent past will not continue’ (Johnson, 1999, p. 23).

Johnson also addressed the issue of population growth, and chaired a National Research Council (NRC) committee whose 1986 report, *Population Growth and Economic Development*, proved to be controversial. Contrary to the conventional wisdom of the time (or of today), this report argued that population growth per se was not a major cause of low rates of economic growth or environmental problems in developing countries. The arguments in the NRC report were straightforward implications of economic reasoning. First, the report pointed out the various economic arguments, such as agglomeration economies, scale economies, and the arguments of endogenous growth theory, which suggest that higher populations and higher population densities may increase productivity. Second, the report made the point that environmental degradation is caused not by population per se but by the lack of appropriate institutions, including well-defined and legally defensible property rights. Third, the report emphasized the substitutability of many resources and the role of prices in signalling resource scarcity and in leading to requisite adjustments in resource utilization and innovation. Given the importance that Johnson attributed to agricultural technology as a source of improvement in human well-being since the Industrial Revolution, he also argued forcefully against anti-technology sentiments. In particular, Johnson expressed concern about the potential negative impact that regulation
of biotechnology could have on the well-being of the world's poor. He outlined these concerns in one of his last publications (Johnson, 2002). He pointed out that the costs of regulating genetically modified organisms, such as bio-fortified foods, will be borne largely by the world's poor, as they are the only ones who spend a significant share of their income on food and would benefit most from an increased availability of micronutrients at a low cost. In addition, he argued that regulations on biotechnology would discourage investment in research, and he noted that biotechnology could bring significant benefits by providing natural substitutes for synthetic pesticides that are costly for poor farmers and have well-known adverse health and environmental impacts.

Article

Harry G. Johnson was born in Toronto, Canada on 26 May 1923 and died in Geneva, Switzerland on 9 May 1977. Throughout his professional career he was a recognized leader of the economics profession in the United States, Britain and Canada, though his influence extended worldwide. He wrote prodigiously: 526 professional scientific articles, 41 books and pamphlets and over 150 book reviews. In addition, he edited 27 books and wrote numerous pieces of journalism. His writings are characterized by creative insights and by a unique capacity to synthesize; both clarify apparently untidy and unyielding masses of seemingly unrelated and abstruse contributions. His impact on the economics profession was enhanced by his ceaseless participations in conferences around the world, and by his willingness to lecture even at the smallest campus or institute, both of which he perceived as a professional obligation. He graduated from the University of Toronto in 1943 and then spent a year at St. Francis Xavier University in Nova Scotia as Acting Professor of Economics (at the age of 20). After military service in the Canadian Infantry, he proceeded to Cambridge, England, obtaining his BA in 1946. He taught in the following year at the University of Toronto, where he also received his MA, specializing in economic history. He then spent 1947–8 at Harvard, followed by a year at Jesus College, Cambridge and then election to a Berry-Ramsey Fellowship at King's College in 1949. He was to remain a Fellow of King's, teaching also at the London School of Economics, until he left Cambridge for the University of Manchester as Professor of Economic Theory in 1956. In 1959 he joined the University of Chicago as Professor of Economics, later becoming the Charles F. Grey Distinguished Service Professor of Economics, and remained there until his death. He was soon to combine the professorship at Chicago
with a chair at the London School of Economics (1966–74) and then with the Graduate Institute for International Studies in Geneva, Switzerland (1976–7).

These shifts in location and the associated changes in intellectual environment shaped his character as a cosmopolitan economist. The years in Cambridge and in Chicago were to be the most significant. For both campuses had, in addition to Johnson himself, remarkable figures in economic science such as Dennis Robertson, Richard Kahn, Nicholas Kaldor and Joan Robinson in Cambridge, and Milton Friedman, George Stigler and Theodore W. Schultz in Chicago. The strong professional and political views and interests of many of these economists must have deepened Johnson's interest in developing theory as a tool of policymaking, and influenced the evolution of his own views and attitudes toward the various approaches to economics.

His writings span the entire range of the economics discipline: from the history of economic doctrines to the economics of the price of gold; from the theory of international commodity agreements to the theory of preferences and consumption; from an analysis of Keynesian economics to the theory of income distribution. They cover, too, the economics of reparations, the theory of productivity, growth and the balance of payments, the theory of tariffs, economic policies for Canada, Britain, the United States and developing countries, the theory of excise taxes, the economics of public goods, the economics of common markets, the economics of monetary reform, the theory of inflation, the theory of index numbers, the theory of nationalism, the state of international liquidity, the theory of advertising, the relationship between planning and free enterprise, the theory of the demand for money, the choice between fixed and floating exchange rates, the economics of basic and applied research, the economics of the brain drain, the economics of poverty and opulence, the theory of distortions, the theory of money and economic growth, the theory of effective protection, the theory of human capital, the economics of bank mergers, an analysis of efficiency of monetary management, the economics of the North–South relationship, an analysis of minimum wages, the economics of student protest, an analysis of the infant-industry argument for protection, the economics of the multinational corporation, the economics of universities, the economics of libraries, the economics of international monetary union, the economics of dumping, an analysis of the role of uncertainty, the economics of smuggling, an analysis of income policy, the economics of speculation, an analysis of mercantilism, the economics of bluffing, an analysis of equal pay for men and women, an analysis of monetarism, an analysis of buffer stocks, the economics of patents, licences and innovations, an analysis of legal and illegal migration, the economics of welfare and reversed international transfers, the monetary approach to the balance of payments, and the monetary approach to the exchange rate.

Four areas of interest and impact were clearly the most important and deserve to be highlighted: (a) the pure theory of international trade, (b) macroeconomics, (c) international monetary theory, and (d) economic policies and issues of political economy.

Johnson's work on trade theory constitutes perhaps his most important scientific contribution. His early work in this area is collected in International Trade and Economic Growth (1958). This book contains his important and highly original papers in the theory of trade and growth (1953a; 1954). These articles, written at the time of the dollar shortage after the war, were to address the issues from the viewpoint of differential growth of productivity among trading countries, and were to put the whole theoretical discussion into a form that dominated the work of trade theorists for years.

His writings on the general equilibrium analysis of international trade include two influential companion papers on income distribution (1959b; 1960b). In addition, among his notable contributions are those
that belong to what James Meade called the theory of trade and welfare. Four are particularly noteworthy. In chronological order, these are: his classic paper (1953b) on optimum tariffs and retaliation; the cost of protection and the scientific tariff (1960a), building on his earlier work measuring the gains from trade; optimal trade interventions in the presence of domestic distortions (1965a); and the possibility of income losses from economic growth of a small, tariff-distorted economy (1967d).
The paper on optimum tariffs and retaliation addresses the issue of whether a large country which exercises its monopoly power can be made worse off because of foreign retaliatory tariffs. Using a Cournot-type retaliation mechanism, Johnson showed that the country that initially imposes an optimal tariff can wind up better off than under free trade despite foreign tariff retaliation. From the viewpoint of Johnson's evolution as an economist, this paper is notable for two things. First, the early vintage Johnson was intrigued by analytical complexities of the kind that he found much less interesting later. Second, the policy implication of this early vintage analysis was to resurrect the classic case for the exercise of monopoly power by a large country; Johnson’s later writings tended to go in the opposite direction, highlighting the great potential cost of departing from truly free trade.
The shift in Johnson's emphasis to the advantages of free trade is seen most directly in his work on the theory of optimal policy intervention in the presence of distortions and in his work on the theory of immiserizing growth. In both instances, Johnson opposed the use of tariffs, utilizing the insights of the theory of second best as applied to problems of trade and welfare.
Finally, the impact of Johnson's paper on the scientific tariff (1960b) was in two areas: (a) the measurement of the cost of protection and (b) the analytical propositions regarding optimal tariff structures. Johnson's theoretical contributions influenced empirical work on measuring the cost of protection, and on measuring the gains or losses to Britain from joining the EEC. Many of his contributions to the theory of tariffs and commercial policy are reprinted in his Aspects of the Theory of Tariffs (1971a).
Johnson's early contributions to macroeconomics were made during his tenure at Cambridge. In ‘Some Cambridge Controversies in Monetary Theory’ (1951b) he clarified the essence of the controversy between the Keynesian and the Robertsonian approaches to key issues like loanable funds versus liquidity preference, the savings–investment identity and the Gibson paradox, and he clearly demonstrated his talent for distilling and integrating complex issues into a coherent framework. His major contributions during that period, however, were his study of the implications of secular changes in the UK banks’ assets and liabilities consequent on the replacement of private by public debt (1951a) and his active participation in the discussion surrounding the revival of monetary policy in the UK. Johnson was critical of the quality of British monetary statistics and in a series of articles attempted to make the case that improved monetary statistics were essential for well-managed monetary policy. In ‘British Monetary Statistics’ (1959a) he published his own labouriously constructed monetary aggregates for the period 1930–57, which stimulated further research.
Johnson’s move to the University of Chicago (to which he was invited as the ‘Keynesian’) marked an increased research interest in monetary theory. His major contributions in the early 1960s are ‘The General Theory After Twenty Five Years’ (1961), the survey article ‘Monetary Theory and Policy’ (1962b) and ‘Recent Developments in Monetary Theory’ (1963a). These three contributions have since become classics in the field of monetary economics. They established Johnson's reputation as a scholar with a rare breadth of knowledge and with broad scientific and historical perspectives. The survey article is widely acclaimed as a masterpiece in scholarship and its contribution went far beyond
surveying the ‘state of the art’. Johnson's survey suggested a list of issues that would benefit from further research. In retrospect, this list seems to have served as the research agenda in the subsequent 15 years. One of the notable issues on the list was his early scepticism on the stability of the Phillips curve in the face of changes in macroeconomic policies. His evaluations of the major developments in monetary economics (as of the early 1960s) have been influential and perceptive. These developments were the application of capital theory to monetary theory and the shift from static analysis to dynamic analysis. These contributions, along with others, are reprinted in *Money, Trade and Economic Growth* (1962c) and *Essays in Monetary Economics* (1967b) that also include his important contributions to the topic of money and economic growth.

As a result of his interest in the Keynesian revolution and his deep historical perspective, Johnson wrote his controversial article ‘The Keynesian Revolution and the Monetarist Counter-Revolution’ (1971b) which was first presented as the Richard T. Ely Lecture in 1970 and was reprinted in his *Further Essays in Monetary Economics* (1972a). This article is an exercise in the history of economic thought and scientific evolution. His interest in the various aspects of Keynes and his economic thought resulted in a series of provocative articles, some of which appeared posthumously in his joint book with his wife Elizabeth Johnson, *The Shadow of Keynes* (1978b).

Johnson's major criticism of the Keynesian model was its failure to deal with the problem of inflation at the levels of both economic theory and economic policy. He was critical of the ‘sociological’ non-economic theories of inflation, as well as of price controls and incomes policy as remedies for inflation. His analysis of inflation was approached from the perspective of an international economist who views inflation (under a fixed exchange rate regime) as a global phenomenon, a proper analysis of which requires a shift of focus from the concept of monetary developments in individual countries to the concept of the aggregate world money supply. Johnson's view of world inflation is best exemplified in his *Inflation and the Monetarist Controversy* (1972b) which was delivered as the De Vries Lecture in 1971.

Throughout his professional life, Johnson continued his research on international monetary economics. Three articles in 1950 set the stage for what later on became the typical characteristics of his style of research: courage to take positions not always popular with others, the application of relatively simple economic techniques to a new range of problems with resultant important insights, and a passion for geometry as a tool of analysis. He took an early stand against raising the price of gold in terms of all other currencies (1950a), analysed the destabilizing effect of international commodity agreements on the prices of primary products (1950b) and produced an early diagrammatic analysis of income variations and the balance of payments (1950c) – an analysis which was conducted within the then typical Keynesian framework, a framework which he later criticized.

In his writings on the theory of the transfer problem, originally developed in the context of the post-war reparations, Johnson extended earlier work by P.A. Samuelson, L.A. Metzler, F. Machlup and J.E. Meade and demonstrated the potential provided by his philosophy that individual research effort is most productive when it utilizes the work of previous theorists as a foundation for new construction. Johnson's theme was that of ‘continuity and multiplicity of effort’. In ‘The Transfer Problem and Exchange Stability’ (1956) he demonstrated that the problems of transfers and of exchange stability are formally the same and that all the possible methods of correcting balance of payments disequilibrium can be posed in terms of the analytical apparatus of the transfer problem. Almost two decades later (1974) he returned to the analysis of transfers with greater emphasis on the monetary aspects of the

problem. Johnson's most important contribution to the understanding of international monetary economics is 'Towards a General Theory of the Balance of Payments' printed in his *International Trade and Economic Growth* (1958). His insight was the emphasis on the monetary nature of a balance of payments surplus or deficit. '[A] balance-of-payments deficit implies either dishoarding by residents, or credit creation by the monetary authorities'; the former is inherently transitory and the latter is policy induced. As for policy, Johnson coined the distinction between 'expenditure reducing' policies and 'expenditure switching' policies. The insights contained in this important article are all the more remarkable considering the intellectual environment in the mid-1950s where to a large extent the balance of payments was viewed as a 'real' (in contrast with 'monetary') phenomenon. This article may be viewed as the intellectual precursor of what would be termed 15 years later 'the monetary approach to the balance of payments'.

Over the years, Johnson focused increasingly on policy issues with special reference to Canada (1962a; 1963b; 1965c). He supported the move to a flexible exchange rate regime (1969) but recognized, relying on the theory of optimum currency areas, that there are circumstances under which a small country (like Panama) might be better off maintaining a fixed parity.

His analysis of the international monetary system revealed his strength as a realistic political scientist. Monetary reform is not carried out in a vacuum. It is performed by representatives of independent nation states, to whom international commitments are likely to be secondary to national commitments. This view is reflected in his numerous commentaries on international monetary crises, in his doubts about the prospects of a stable European monetary union, in his appraisal of the Bretton Woods system and in his perceptive article 'Political Economy Aspects of International Monetary Reform' (1972d). He took a hard line on schemes designed to solve the international monetary problems by methods that channel resources to the less developed countries. He was aware that such a stance might be unpopular but his professional integrity determined his position; in his words, 'My reason for refusing to endorse such schemes is not that I am opposed to the less developed countries receiving more development assistance but I think that no useful purpose is served by misapplying economic analysis for political ends' (1967a, p. 8).

As world inflation accelerated in the 1960s Johnson recognized that in a world integrated through international trade in goods and assets, national rates of inflation cannot be fully analysed without a global perspective:

> I have become increasingly impressed in recent years with the conviction that the traditional division between closed-economy and open-economy monetary theory is a barrier to clear thought, and that domestic monetary phenomena for most of the countries with which economists are concerned can only be understood in an international monetary context. (1972a, p. 11)

This perception of world inflation along with the analytical insights from his earlier work 'Towards a General Theory of the Balance of Payments' (printed in 1958) paved the way to his work on the monetary approach to the balance of payments which he viewed as the crowning achievement of his career. The intellectual roots of the monetary approach go back to the classic writers (David Hume and David Ricardo) and its early developments can be found in the work of economists associated with the
International Monetary Fund (for example, Jacques Polak). Johnson, however, along with Robert A. Mundell and other members of the International Economics Workshop at the University of Chicago, introduced new and significant dimensions to the approach. Noting that the balance of payments is essentially a monetary phenomenon, he concluded that balance of payments policies will not produce an inflow of international reserves unless they increase the quantity of money demanded or unless domestic credit policy forces the resident population to acquire the extra money wanted through the balance of payments via an excess of receipts over payments. He saw himself as a missionary; and he was to take the lead in developing and disseminating the approach by encouraging and at times guiding the theoretical and empirical research in this field in various centres such as Chicago, London and Geneva. He co-edited with J. A. Frenkel some of the results in *The Monetary Approach to the Balance of Payments* (1976). The evolution of the international monetary system into a regime of flexible exchange rates led to further extensions of the monetary approach and resulted in a new direction of theoretical and empirical research on the economics of exchange rates. Johnson stimulated much of the early research in the area and co-edited with J. A. Frenkel *The Economics of Exchange Rates* (1978) which contains some of the resulting work.

In addition to his theoretical contributions, Johnson wrote profusely also on policy matters. His *Economic Policies Toward Less Developed Countries* (1967a) analyses proposals such as commodity schemes and preferential entry for manufactured exports of the less developed countries. Similarly, his work on the brain drain (1964; 1967c) propounded the view that the brain drain might be welfare-improving for the countries from which it occurred. This is one example of how, in his later years, his analyses increasingly questioned interventionist policies. Thus, the brain drain was beneficial rather than harmful; the multinational corporations were part of a non-zero-sum game and so on. The United Nations Conference on Trade and Development (UNCTAD), which addresses the less-developed countries’ problems and demands, and which he had looked on rather benignly in the early 1960s, came under his criticism in several writings as he came to feel that professional economists had allowed themselves to be influenced by their sympathies for the poor countries to the point of being led into empathetic and non-scientific research on trade and development.

It is impossible to conclude the brief survey of Johnson's prolific research without highlighting three other important aspects of his contribution. First, he was a humane social scientist who was interested in understanding social phenomena, in contributing to the improvement of welfare, and in understanding the development of knowledge and technological advances. These qualities are particularly evident in his *On Economics and Society* (1975a) and in *Technology and Economic Interdependence* (1975b). Second, he was a gifted teacher with a deep sense of mission and responsibility. He devoted great effort to the preparation of his lectures and always undertook an extremely heavy teaching load. Some of his lucid and insightful lectures are published in *Macroeconomics and Monetary Theory* (1972c) and *The Theory of Income Distribution* (1973). Third, he was widely respected as an editor, who demonstrated both considerable judgement and a talent for recognizing and encouraging the development of new and original lines of thought. He was devoted to his sustained role as an editor of the *Journal of Political Economy*. He also served on the editorial boards of the *Review of Economic Studies, Economica, the Journal of International Economics* and *The Manchester School of Economic and Social Research*. Testifying to Johnson's impact on the economics profession is the number of articles devoted to the evaluation of his scientific contributions. Noteworthy in this respect are the special issues of the *Canadian Journal of Economics* (1978) and the *Journal of Political Economy* (1984) (which also
contain a complete bibliography of Johnson's voluminous writings), as well as the entry in the *International Encyclopedia of the Social Sciences* (Bhagwati and Frenkel, 1979), on which this present article draws.

Many honours came Johnson's way. He was invited to deliver many of the prestigious public lectures in economics: the Ely Lecture, the Wicksell Lectures, the De Vries Lecture, the Ramaswami Lecture, the Johansen Lectures and the Horowitz Lectures. He was elected to the presidency of the Canadian Political Science Association (1965–6) and the Eastern Economic Association (1976–7), was Chairman of the (British) Association of University Teachers in Economics (1968–71), and was Vice-President of the American Economic Association (1976). He was a Fellow of the Econometric Society, the British Academy, the Royal Society of Canada, the American Academy of Arts and Sciences, a Distinguished Fellow of the American Economic Association and an honorary member of the Japan Economic Research Center. He was the holder of honorary degrees from St. Francis Xavier University, University of Windsor, Queen's University, Carleton University, University of Western Ontario, Sheffield University and the University of Manchester, and he was awarded the Innis-Gérin Medal of the Royal Society of Canada, the Prix Mondial Messim Habif by the University of Geneva, and the Bernhard Harris Prize by the University of Kiel, Germany, just prior to his untimely death. The Canadian government named him an Officer of the Order of Canada in December 1976: a fitting tribute from his native country for a fully internationalist economist who had brought great distinction to his profession and his discipline.

Johnson, William Ernest (1858–1931)

S.L. Zabell

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

exchangeability; Johnson, W. E.; statistical inference; subjective probability; utility theory

Article

English logician, philosopher, and economic theorist. The son of the headmaster of Llandaff House, a Cambridge academy, Johnson entered King's College in 1879 on a mathematical scholarship (11th Wrangler, Mathematics Tripos 1882; First Class Honours, Moral Sciences Tripos 1883). Initially a mathematics coach, then lecturer on psychology and education at the Cambridge Women's Training College, Johnson later held a succession of temporary positions at Cambridge (University Teacher in the Theory of Education, 1893 to 1898; University Lecturer in Moral Science, 1896 to 1901), until he was elected a Fellow of King's College in 1902 and appointed Sidgwick Lecturer in Moral Science in the University, where he remained until his death.

In the Cambridge of Johnson's day, economics was included among the moral sciences and, as C.D. Broad remarks, 'it was a subject in which Johnson's mathematical, logical, and psychological interests could combine with the happiest results' (Broad, 1931, pp. 500–1). Although he lectured on mathematical economics for many years, Johnson wrote only three papers on economics (1891; 1894; 1913), of which only the last, 'The Pure Theory of Utility Curves', was published during his lifetime. This latter was, however, an important paper, representing 'a considerable advance in the development of utility theory' (Baumol and Goldfeld, 1968, p. 96), and 'contains several results that should secure for its author a place in any history of our science' (Schumpeter, 1954, p. 1063n). These include an analysis of utility based on marginal utility ratios, and a proof of the consistency of expenditure and convex indifference curves.

Johnson's aversion to publication has been variously ascribed to his 'ill health, diffidence, and a very high standard of achievement' (Broad, 1931, p. 505), and a 'rooted antipathy to publish anything until he was sure of everything' (Braithwaite, 1931). Indeed, between the publication of his treatise on Trigonometry in 1888, and his three volume work on Logic in the 1920s, he published only three papers.
on logic (1892; 1900; 1918) in addition to his paper on utility. Despite such a limited output Johnson retained his fellowship at King's (the continuance of which was periodically reviewed), due to the high regard in which he was held by his colleagues.

Johnson nevertheless exerted considerable influence on his colleagues and students at Cambridge through his lectures and personal interaction. One example, among many, is John Neville Keynes, the father of John Maynard Keynes and an eminent logician in his own right. When the senior Keynes was at work on the successive editions of his *Studies and Exercises in Formal Logic*, Johnson would come to lunch regularly to discuss the work; one result was that among the examples at the ends of chapters ‘the hardest, neatest, and most ingenious problems are marked “J”, which means that they were devised by Johnson’ (Broad, 1931, p. 504). Among his students were John Maynard Keynes, Frank Ramsey, Ludwig Wittgenstein, C.D. Broad and Dorothy Wrinch (an early collaborator of Harold Jeffreys).

Nevertheless, it was only after the publication of his three-volume *Logic* (1921; 1922; 1924) – written only after the encouragement and assistance of his students, in particular Naomi Bentwich – that Johnson gained recognition outside Cambridge: honorary degrees from Manchester (1922) and Aberdeen (1926), and membership of the British Academy (1923). The third volume of the *Logic* concludes with a remarkable appendix on ‘education’, in which Johnson introduced his ‘combination’ and ‘permutation’ postulates. The latter of these was none other than the concept of exchangeability, soon to be independently rediscovered by Haag and de Finetti, and employed by the latter as a key element in his theory of subjective probability and statistical inference (Dale, 1985).

Johnson was one of a remarkable group of English intellectuals – most notably Jevons, Edgeworth, Keynes and Ramsey – who combined in varying proportions interests in economic theory and the philosophical foundations of logic, probability, statistics, and scientific inference. For further biographical details, see the obituary notices by C.D. Broad (1931); R.B. Braithwaite (1931); the unsigned A.D. (1932); and the entry on Johnson by Braithwaite (1949) in the *Dictionary of National Biography 1931–1940*. R.F. Harrod (1951) contains scattered references to Johnson.

Johnson's three papers on economics are reprinted, with brief commentary, in William J. Baumol and Stephen N. Goldfeld (1968). The 1891 and 1894 papers were printed for private circulation, and are virtually unobtainable elsewhere. For a critical discussion of the 1913 paper, see F.Y. Edgeworth (1915).

Due in part to what George Stigler has termed Johnson's ‘concise and peculiar’ style, and in part to the appearance of Slutsky's classic paper two years after the appearance of Johnson's *Economic Journal* paper, there has never been widespread recognition of Johnson's achievement in utility theory, and references to his work in the economic literature are few, brief, and scattered; see, for example Joseph A. Schumpeter (1954).

**Selected works**

In addition to the above, Johnson wrote several critical reviews and a note for *Mind* during the years between 1886 and 1890, and contributed several entries to the original *Palgrave*.

Jones was born at Tunbridge Wells, Kent. After finishing his studies at Cambridge in 1816 he took holy orders and served as a curate at various places in England for the next decade and a half. During this time he developed an interest in political economy which culminated in his *Essay on the Distribution of Wealth: Vol. I. Rent* (1831a). Soon after publication he was appointed Professor of Political Economy at the newly established King's College, London. In 1835, following the death of Malthus, he was appointed Professor in the East India College at Haileybury and remained there until his death in 1855. He took an active part in the commutation of tithes and served as a commissioner of tithes from 1836 to 1851.

Jones never wrote the proposed second volume of his book and published very little else during his lifetime. The lectures he gave at King's College and East India College, together with other sundry essays and notes, were published soon after his death as *Literary Remains* (edited by W. Whewell, 1859). A persistent theme in Jones's work is a critique of the ahistorical, deductivist methods of the Ricardian school of political economy. He argued for a method he called 'inductivist' and was primarily concerned to overturn the Ricardian theory of rent with an historically based theory that distinguished between farmers' rents and various categories of peasant rents. He also developed a number of theoretical propositions concerning population and technology that contradicted the Malthusian orthodoxy.

Jones's iconoclastic theories were not well received by his contemporaries. McCulloch, in an extended review in the *Edinburgh Review* (1831), dismissed Jones's book as 'superficial', 'lacking in originality' and 'signally abortive' in its attempt to overthrow the Ricardian theory of rent. This opinion was generally held in the 19th century. However, Jones has acquired something of a reputation in the 20th century. Marx's favourable review of Jones in *Theories of Surplus Value* (1905–10, ch. 24) has been a
major contributing factor in this rehabilitation. Marx argued that Jones's theories were a substantial advance on Ricardo because, among other things, Jones had a sense of the historical differences in modes of production and was thus able to conceptualize rent as a form of surplus labour. Jones's theory of peasant rents has also attracted much attention. When his book was reprinted for the first time in 1914, for example, only the first half of his book on peasant rents was republished (see Jones, 1831b). Historians of the role of British economic thought in India have shown that his theory of peasant rent had an important impact on policy debates in India in the latter part of the 19th century (Ambirajan, 1978, p. 175) and have assessed his theoretical contribution vis-à-vis the Ricardian school very favourably (Barber, 1975, ch. 12). Jones's approach to understanding the unfamiliar circumstances of rural India continues to have its advocates even today (Hill, 1982, pp. 14–15).

Miller, in two reviews of Jones's contribution to the history of economic thought, has attempted to assess the reputation to which Jones's originality entitles him as distinct from the reputation that he has acquired. He finds that ‘Jones did not really have a distinct inductive approach to offer’ (1971, p. 206) and that his theory of rent ‘largely deserved McCulloch's harsh judgement that it lacked originality’ (1977, p. 360).

Originality is a difficult quality to assess because the theoretical perspective of the observer obviously affects any judgement made. Nevertheless it is clear that Jones's rehabilitation owes more to his advocacy of a method than to his theories. But this method is not ‘inductivist’. Jones, as Miller (1971) correctly points out, employs both inductive and deductive reasoning. This is not evidence of a contradiction in Jones's thought, as Miller would argue. Jones's use of the term ‘inductivist’ is a simple misnomer. What is distinctive about Jones's method is the comparative and historical perspective he adopts. This method is now the basis of many non-neoclassical approaches to the economy. Not only does Jones deserve to be regarded as the founder of the English Historical School (Edgeworth, 1899), he also deserves to be regarded as the founder of the English Comparative Economy School because of his contribution to the theory of peasant economy.

Barber, W.J. 1975. British Economic Thought and India 1600–1858: A Study in the History of

How to cite this article

Joplin was born, probably in Newcastle upon Tyne, England, about 1790, and died in Silesia in 1847. He is important both as a banking pioneer and as a monetary theorist.

Joplin's interest in both banking and money was spurred by the banking failures in Newcastle after 1815. The failure of these partnership banks led Joplin, inspired by the joint stock banks over the border in Scotland, into a campaign for the countrywide establishment of such banks in England, and for the loosening of the Bank of England's monopolistic grip upon this form of banking. Working with enormous energy, and brooking no opposition, he established two major joint stock banks; the Provincial Bank of Ireland and the National Provincial Bank of England. But the financial establishment in London, who would have found Joplin's Newcastle accent impenetrable and his rough manners repellent, froze him out, and he received little financial recompense for his achievements, despite the fact that he laid the foundations of the modern British banking system.

His most striking achievements, from an intellectual point of view, lay in the field of monetary economics. Not only did he comment actively and perceptively on monetary policy – and he has a clear claim to be the single most important influence in the development of the lender-of-last-resort doctrine (O'Brien, 2003) – but he developed a macroeconomic model of quite extraordinary sophistication (O'Brien, 1993). This involved a treatment of the circular flow of income, an income multiplier, a model of the transmission of monetary changes, an analysis of aggregate supply, and an explanation for depression and unemployment. In the course of all this he employed a dual-circulation hypothesis; and this led to an analysis of the operation of the monetary system which was fundamentally subversive of 19th-century monetary orthodoxies.

On the one hand, Joplin was quite clear – unlike the members of the Banking School – that causality ran from monetary disturbance, and the balance of payments, to the level of money income. On the other, he
was equally clear, unlike the Currency School, that controlling the note issue of the Bank of England was not the key to price and balance of payments stability. The Bank of England circulation, he argued, supplied the financial circulation of the country, but this had only a very limited effect on prices. The price level was largely determined by the circulation of the country banks; but, because they held their lending rate rigid and varied the note issue with demand, they failed to vary the note issue in conformity with inflows and outflows of gold resulting from variations in the overall balance of payments on current (the main concern) and capital account. Yet not only would such a response by the country banks be prudent, given that the note issue was convertible into gold, but it was required if variations in the note issue were to be corrective of external disequilibrium. Joplin was one of the earliest to put forward the theory of ‘metallic circulation’ – the idea that a mixed currency of gold coins and notes should vary in amount exactly as an identically circumstanced fully metallic currency would, in an open economy. Such fluctuation was designed not only to correct the balance of payments, through monetary contraction lowering the level of money income when gold was flowing out, and vice versa, but to act counter-cyclically, thus limiting economic fluctuations (O’Brien, 1995).

Joplin argued that the behaviour of the country banks ensured that metallic fluctuation was not achieved. The solution lay in the introduction of a currency system tied closely to gold which would prevent the perverse behaviour of the country banks. Joplin’s view of the operation of the monetary system involved hypotheses about the relationships between basic macroeconomic building blocks, which differed fundamentally from those of the ruling orthodoxies. But methodologically Joplin was far ahead of his time, writing explicitly about the need to formulate hypotheses and test them. The contrast with the apriorism of Ricardo could hardly be greater. Application of modern econometric techniques to the data collected by Joplin, supplemented by other data, not all of which were available in his lifetime, provides remarkable support for his view of the operation of the monetary system (O’Brien, 1993, ch.13; 1997). In particular, it seems clear that changes in the issues of country bank notes affected the price level, while those of the Bank of England, supposedly at the heart of the money supply, did not; that bullion flows across the exchanges did not respond to variations in the Bank of England note issue but were influenced by the country bank issues; that changes in the country bank note issues were the main source of monetary instability; and that the Bank of England note issue did not act as the high-powered money base of the system. Joplin was an important economist, one who also offered important insights into the theory of international trade. But he was treated as an outsider, in both banking and intellectual circles. Neither the Banking School nor the Currency School seems to have deigned to take any public notice of him. Inevitably with Joplin, he did not make any attempt to ingratiate himself with others, and was free with accusations of plagiarism, directed not merely at Francis Horner (Joplin suggested the creation of a word ‘hornering’ to describe such activity) but even at Ricardo. Yet all this was extremely unfortunate; there seems little doubt that, had Joplin had more influence, and his ideas been considered more seriously, the catastrophic liquidity crises of 1847 and 1857 in Britain would have been avoided.

Juglar, Clément (1819–1905)

Murray Milgate

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

business cycles; circular flow; Juglar cycles; Juglar, C.; Mitchell, W. C.; real business cycles; Schumpeter, J. A.; Wicksell, J. G. K.

Article

Like his rather more illustrious compatriot François Quesnay, Juglar is an example of a physician turned economist. The circular flow of economic life – which it is often said Quesnay saw in terms of an analogy to the circulatory system – in Juglar's work seems to have as its counterpart the view of the economic process as one of quasi-rhythmical variations between good and bad trade. This simple idea has been of profound importance in the study of alterations in the conditions of economic prosperity ever since. Both Wesley Clair Mitchell and Joseph Schumpeter in their classic studies of business cycles (in 1927 and 1939 respectively) credit Juglar's contribution as having been seminal in the field. For Mitchell, it was Juglar's recognition of the cyclical character of economic crises that established him as a pioneer (1927, p. 452); for Schumpeter it was Juglar's perception of how theory, statistics and history ought to contribute to the study of industrial fluctuations (1939, pp. 162–3). There is something to each of these claims, but it should not be forgotten that other authors had also done much in both of these areas – one may mention Samuel Jones Loyd, John Wade and Amasa Walker. As theorists of industrial fluctuations, of course, Sismondi, Rodbertus and Marx would also need to be mentioned.

Juglar practised as a physician until 1848. His first work in the social sciences was on the cyclical pattern of birth, death, and marriage rates in France, and it appeared in the Journal des Économistes in October–December 1851 and January–June 1852. He moved on to examine the discount policy of the Bank of France and published his findings in the Annuaire de l'économie politique for 1856 and in the Journal des Économistes for April–May 1857. In 1852 he was elected into the Société d’Économie Politique and he was one of the founders of the Société de Statistique de Paris in 1860. In 1868 he published an account of the policies and practices of the French monetary authorities and their effects on the exchanges.

There is, however, little doubt that Juglar's most important work on business cycles is his Des crises.
Juglar's analysis of crises is essentially a monetary one – protracted periods of inflation and expansion are brought to an end when the banking system initiates a contraction in the face of unacceptable pressures on its specie reserves. This is very like the story Wicksell was later to tell, but without the sophistication of Wicksellian theory. Subsequent theories of the business cycle, which attributed the process to ‘real’ causes, were critical of this aspect of Juglar's argument. The observed periodicity of the cycle – of nine to ten years – is commonly known in the applied literature on business cycles as a Juglar cycle.

The idea of the just price is associated primarily with scholastic economics. The schoolmen suggested two ways of estimating the just price, with reference to cost and with reference to the market. The former originated in reply to some of the Church fathers, who claimed that merchants reaped an unjust profit from the toils of others. Alexander of Hales (d. 1240), Peter Olivi (d. 1298), John Duns Scotus (d. 1308) and other schoolmen together compiled a catalogue of cost elements incurred in trade: transport, storage, risk, costly training, professional expertise and diligence, as well as support of the merchant and his family. The cost estimate was confirmed by the schoolmen's interpretation of the strange formula of exchange appearing in Aristotle's *Nicomachean Ethics*. In Book V, on justice, Aristotle presents a cast of characters – a builder, a shoemaker, a farmer, a doctor. ‘As a builder is to a shoemaker, such and such a number of shoes must be to a house’ (1973, 5: 1133a22–3; author's translation). What could this mean? Albert the Great (d. 1280), the first Latin commentator, and numerous followers, suggested that it might mean equality in proportion to the labour and expenses incurred in the production of the goods offered in exchange. Albert did not merely indicate that economic exchangers deserve cost coverage but that society requires it. If a carpenter (another of Aristotle's characters) is not paid for a bed as much as it costs him to make it, he will stop making beds – a medieval hint about the law of cost. Scotus says much the same about merchants in general. If no one will be a merchant, the authorities must appoint functionaries and pay them accordingly.

The exchange formula in the *Ethics* also gave rise to the market estimate of the just price. According to Aristotle, human need is the cause of exchange. Thomas Aquinas (d. 1274) suggested, and many others agreed, that need is not only the cause of exchange; it is a measure of the value of goods in exchange as well. This could not apply to individual need, as John Buridan (d. c. 1360) points out. It would follow that a poor man should pay more for a measure of corn than a rich man because his need is greater. It
must apply to common need. In the words of Henry of Friemar (d. 1340), the need that measures goods in exchange ought not to be taken partially with regard to this or that person, but universally with regard to the whole community. This value estimate was challenged and confirmed with reference to Roman law. Some early manuscripts of the Digest (a compendium of Roman law compiled in the 6th century ad) contain a gloss stating that a thing is worth the amount at which it can be sold. Seemingly granting unconditional economic power to those in possession of scarce goods needed by others, this maxim was modified by the principle of commonality precisely in line with the Aristotelian formula. In a gloss to the Digest, the Romanist Azo (d. c. 1220) states that a thing is worth the amount at which it commonly can be sold. The canonist Laurence of Spain (d. 1248) confirmed this interpretation, which earned universal acceptance among the schoolmen. A common estimate, based on common need, can mean several things. The schoolmen tended to associate it with the market or, more precisely, with the common, competitive market price. Albert the Great explicitly defined the just price as ‘that price at which the good can be valued according to the estimation of the market at the time of the contract’ (1894, 16: 46, p. 638; author's translation).

The schoolmen envisaged no conflict between the cost and market estimates of the just price. That conflict is of a much more recent date. The two estimates were used interchangeably and are perhaps best understood as complementary and mutually supportive criteria when the market did not function properly. When it did, cost had to adapt to the market anyhow. Does the fact that these estimates were thus associated mean that the medieval schoolmen anticipated modern value theory? Certainly not, but there are suggestions worth noting in some of the Ethics commentaries, where the two principles are textually close. Note may be made of Gerald Odonis (d. 1349), an exceptionally perceptive and original thinker, who applied both principles to the payment of professional services rather than commodities. This is a marginal case, but it points to an important generalization. A price obtained when the market did not function properly owing to monopoly or other market irregularities was held to be unjust because it involved economic coercion. Free consent to the price on the part of both the seller and the buyer was a fundamental requirement of justice in exchange.

Justi, Johann Heinrich Gottlob Von (1720–1771)

K. Tribe

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Justi, J. von; cameralism

Article

Born in modest circumstances in a Thuringian village in late December 1717, Justi is best known today as one of the architects of mid-18th-century cameralism. He studied law at Wittenberg in 1742–4, then embarked upon a career of literary activity and state service. In 1750 he was appointed tutor to the son of Haugwitz, reforming administrator of Maria Theresa, archduchess of Austria, and then later the same year to a post at the Viennese Theresianum, where he lectured on ‘commerce and public economics’ to civil servants of noble descent. The lectures were later published in 1755 under the title Staatswirthschaft, by which time Justi had made a hasty departure from Vienna and taken up a new post as Director of Police in Göttingen. This was associated with a transfer of political allegiance from Vienna to Berlin, which new allegiance forced him to leave Göttingen in 1757 when occupation by the French, allied with the Austrians, threatened. For several years he lived from his writings, before being appointed Prussian Inspector of Mines, Glass and Steel Works in 1765. Embroiled in a financial scandal of obscure origin in 1768, he was imprisoned and died in the fortress at Küstrin in 1771.

Justi's literary output and journalistic activity was extensive, if repetitive, ranging over aesthetics, philosophy, history, politics and economics. His major work is the Staatswirthschaft (1755; 1758), literally ‘state economy’, which details the manner in which a ruler should govern his lands to assure the ‘happiness of the state’ and a flourishing population. Cameralism had begun as a systematization of the principles followed by the administrators of the ruler's domains. In Justi these principles are identified with the management of the absolutist state, in which economic welfare is conceived identified as the path to political power. Welfare and wealth are produced by good government and the implementation of ‘good police’ – Polizei in the 18th-century sense of regulations covering all aspects of social action and public order. The ‘science of police’ is covered in a further textbook, Grundsätze der Policey-Wissenschaft (1756; 1759; 1782), which Justi claimed to be the first systematic treatment of the subject, and which was in fact republished after his death in a revised edition. Justi's influence was strong during
the later 18th century, diminishing only with the general decline of cameralism at the turn of the 19th century.

justice (new perspectives)

Bertil Tungodden
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article provides a survey of recent normative work on justice. It shows how the concern for
distributive equality has been questioned by the idea of personal responsibility and the idea that there is
nothing intrinsically valuable in levelling down individual benefits. It also discusses the possibility of
combining a concern for the worse off with a concern for Pareto efficiency, within both aggregative and
non-aggregative frameworks, which includes a discussion of the arguments of prioritarianism,
sufficientarianism, and welfarism. Finally, the article briefly reviews the modern literatures on rights-
based reasoning, intergenerational justice and international justice.

Article

Modern thinking on justice has been strongly motivated by the work of Rawls (1971; 1993). Rawls not
only developed a prominent theory of justice that has been extensively analysed, he also expressed in a
very powerful way the fundamental role justice has to play in the evaluation of social arrangements.
Rawls argued that justice is the first virtue of social institutions, as truth is of systems of thought. ‘A
theory however elegant and economical must be rejected or revised if it is untrue; likewise, laws and
institutions no matter how efficient and well-arranged must be reformed or abolished if they are unjust’ (1971, p. 3).

The fundamental problem is that there are many divergent views of what constitutes a just society, and thus many divergent views of what are just social arrangements. Rawls introduced the notion of a reflective equilibrium, which, roughly speaking, is attained when our principles and judgements of justice coincide. The normative literature on justice can be seen as part of a process towards such a reflective equilibrium, where the aim is to attain a better understanding of both the consequences and the underlying foundation of various possible conceptions of justice.

Further understanding of different conceptions of justice is also important in the positive analysis of individual behaviour, because it is by now well-established that people in many situations are motivated by fairness considerations (Camerer, 2003). There is a substantial literature in behavioural economics that study in more detail what kind of fairness norms motivate people and to what extent these fairness norms survive in different settings (Konow, 2003), and also an important literature in evolutionary economics that aim at understanding why our concern for justice has evolved (Binmore, 2005; Skyrms, 1996; 2003).

This article is a sequel to Sen's entry on justice in the first edition of The New Palgrave: A Dictionary of Economics (reproduced in this edition), where Sen argues for a broader view of justice than what is captured by utilitarianism (see also Sen, 1979). Sen views utilitarianism as the amalgam of three distinct principles, namely, welfarism, sum-ranking, and consequentialism, and he shows how each of them was contested in the early modern literature on justice. In this article, I survey how these questions have been dealt with in recent normative work on justice. In particular, I focus on the role of distributive equality.

Sen argued convincingly for the need to take explicit note of inequalities in the distribution of utilities or some other equalisandum, and the standard welfare economic view is presently that justice requires a trade-off between equality of utility and the sum of utility. Interestingly, however, the concern for distributive equality has been questioned from different perspectives. First, it has been argued that distributive equality neglects the role of personal responsibility, and, second, it has been argued that distributive equality legitimizes the intrinsic value of levelling down utilities. I review each of these arguments before I move on to the classical question of how to incorporate equality or a concern for the worse off in an aggregative theory of justice. Any aggregative theory of justice, however, faces what I call the tyranny of aggregation, and therefore, inspired by Rawls (1971), there have been many attempts to establish a non-aggregative framework that combines a concern for equality with a concern for Pareto efficiency. I discuss some of the most prominent non-aggregative perspectives and also some recent developments on rights-based non-consequentialistic reasoning. Finally, I review briefly the growing literature on intergenerational and international justice, which raises interesting questions on how to deal with individuals who are in asymmetric relationships to each other.

**Distributive equality and personal responsibility**

Modern egalitarian theories of justice seek to combine the values of equality and personal responsibility. The contemporary focus on this relationship can be traced back to Rawls (1971), but it has historical roots both in the US Declaration of Independence (1776) and the French Declaration of the Rights of Man and Citizen (1789). The American and French societies developed in rather different directions,
though, and, as noted by Nagel (2002, p. 88), ‘what Rawls has done is to combine the very strong principles of social and economic equality associated with European socialism with the equally strong principles of pluralistic toleration and personal freedom associated with American liberalism, and he has done so in a theory that traces them to a common foundation’. The ideas of Rawls have been developed further, notably by Dworkin (1981), Arneson (1989), Cohen (1989), Kolm (1996), Roemer (1993; 1996; 1998), van Parijs (1995), Bossert (1995), Fleurbaey (1995a; 1995b), Bossert and Fleurbaey (1996), and Fleurbaey and Maniquet (1996;1999), where the main achievement has been to include considerations of personal responsibility in egalitarian reasoning. The two basic conditions put forward in this literature are the principle of equalization and the principle of responsibility. The principle of equalization states that if two persons have exercised the same level of responsibility, then justice demands that they should have the same outcome in the morally relevant space. The principle of responsibility states that inequalities due to different levels of responsibility can be justified.

A fundamental question is whether the two basic principles can be combined in a coherent theory of justice. Dworkin (1981) proposes the idea of a hypothetical insurance scheme, where each person makes her choice of insurance behind a thin veil of ignorance where everyone knows his or her own preferences and is in the possession of the same amount of resources. The equilibrium outcome in this insurance market forms then the basis for the just compensation of disadvantages in the actual world. The proposal of Dworkin has been criticized by Roemer (1985), who argues that, if individuals maximize their expected utility in the insurance market, they insure against states in which they have low marginal utility. If low marginal utility happens to be the consequence of some inborn handicaps, then the hypothetical market will tax the disabled for the benefit of the others. Hence, if we do not want to hold people responsible for their handicaps, then this approach violates the principle of equalization in the actual world, even though it satisfies it if we define responsibility in relation to the choices behind the veil of ignorance. For a further discussion of this issue, see Dworkin (2002), Fleurbaey (2002) and Roemer (2002a).

Bossert (1995) and Bossert and Fleurbaey (1996) study the compatibility of the principle of responsibility and the principle of equalization within a model where pre-tax income of each person is determined by a vector of factors and where we hold people responsible for some of these factors (for example, effort) and not for others (for example, family background). They show that, if the principle of responsibility is interpreted as saying that people should be held fully responsible for the actual consequences of changes in their behaviour, then it cannot be combined with the principle of equalization. However, such an interpretation of the principle of responsibility can be questioned because in many cases it may imply that inequalities reflect differences that we do not want to hold people responsible for, including their inborn talent (Tungodden, 2005). However, there are many other possible interpretations of the principle of responsibility which can be combined with the principle of equalization (Fleurbaey and Maniquet, 2008). One possibility is captured by the egalitarian equivalent mechanism, where people face a given reward scheme for their choice of effort and then share equally the deficit or surplus that follows from this scheme.

A basic insight from this literature is that, if we want to satisfy the principle of equalization, then justice requires that people should face the same consequences from the same kind of behaviour. However, this implies that there is a general tension between the just allocation and Pareto efficiency, where the latter requires that people should face the actual consequences of their behaviour. This tension is not present if
one accepts a weaker version of the principle of equalization, which requires complete equalization only
for some level of responsibility (Kolm, 1996). Such an approach is consistent with holding people fully
responsible for the actual consequences of changes in their behaviour, as illustrated by the conditional
egalitarian mechanism introduced by Bossert and Fleurbaey (1996).

Another interesting insight that follows from this framework is that an income tax system may be unjust
in two different ways. First, it may be unjust because it does not equalize sufficiently among people
exercising the same level of responsibility. Second, it may be unjust because it equalizes too much
between people exercising different levels of responsibility. Within the more standard framework of
welfare economics, where considerations of responsibility are not introduced, the second type of
injustice is usually overlooked.

The location of the responsibility cut is essential in any application of a responsible-sensitive egalitarian
theory, which is most easily seen by noticing the implications of two extreme cases. No redistribution
would be justifiable if all factors are responsibility factors, while, ideally, outcomes should be equalized
completely if all factors are non-responsibility factors. If there are both responsibility factors and non-
responsibility factors, however, then the ideal level of redistribution also depends on the degree of
inequality in the non-responsibility factors. However, it is in general not the case that the ideal level of
redistribution is lower if the differences in some non-responsibility factor are eliminated or if we move
to a situation where people are held responsible for more factors. This will be the case only if there are
no negative correlations between various non-responsibility factors in society (Cappelen and
Tungodden, 2006).

The standard way of defining the responsibility cut is to rely on the distinction between choice and
circumstances, where people are held responsible for their choices but not for their circumstances
(Cohen, 1989). However, this approach is controversial and raises metaphysical questions about the
basis for our choices (Dennet, 2003). Alternatively, we may think of the responsibility cut in political
terms, whereby people are assigned responsibility for a particular set of factors without relying on a
particular metaphysical view of individual choices (Fleurbaey, 1995a). The question of where to locate
the responsibility cut then mirrors the political debate on redistribution, where right-wingers argue that
people should be held responsible for a large fraction of the factors influencing their lives, whereas left-
wingers hold individuals responsible for a smaller set of factors.

A further problem in applying this framework is how to obtain a more precise measure of the degree of
responsibility a person has exercised. To simplify, suppose that we consider a case where only labour
effort and talent affect outcome, and where we do not want to hold people responsible for their talent.
Roemer (1993; 1996; 1998) proposes that we partition the population into talent groups, and then
consider two individuals identical in terms of responsibility if they are at the same percentile of the
labour effort distribution within their class of talent. This approach can be generalized to any number of
responsibility and non-responsibility factors by studying conditional distributions more generally.
Roemer combines this framework with a maximin interpretation of the principle of equalization and a
utilitarian interpretation of the responsibility principle. His proposal equalizes as much as possible
among people who have exercised the same level of responsibility, but rewards individuals for
additional labour effort only if this maximizes the total amount of utility (or some other equalisandum)
within the sub-population consisting of those who receive the lowest level of utility at each percentile of
labour effort level. In sum, this provides us with a complete theory of justice, not only the ideal solution,
and Roemer (2002b) illustrates how this framework may be applied in studying redistribution policies. Alternative versions of Roemer's framework are studied in Van de gaer (1993) and Ooghe, Schokkaert and Van de gaer (2006).

### Distributive equality and prioritarianism

A fundamental critique of distributive equality has been launched in the debate on prioritarianism and egalitarianism (Parfit, 1995; Temkin, 1993; 2000; Scanlon, 2000), where it has been questioned whether even in situations where people have exercised the same level of responsibility we should find distributive equality intrinsically valuable.

Scanlon (2000) argues that equality very seldom seems to be what we care about and that our concern for equality in most cases can be traced back to other fundamental values. We care about a reduction in inequality because, among other things, it contributes to the alleviation of suffering, the feeling of inferiority, and the dominance of some over the lives of others. Parfit (1995) questions the intrinsic value of equality by appealing to the levelling down objection. A reduction in inequality can take place by harming the better off in society without improving the situation of the worse off. If equality is intrinsically valuable, then this must be good in some respect. However, to harm everyone cannot be good in any respect, and hence inequality cannot be intrinsically bad.

Parfit (1995) suggests that there is an alternative view, what he calls the priority view, which better captures our concern for the worse off and avoids the levelling down objection. Parfit defines prioritarianism as the view that, the worse off people are, the more important it is to benefit them. This, however, is an imprecise statement which does not clearly set apart prioritarianism from egalitarianism, and it has been questioned in the literature whether it is at all possible to distinguish these two perspectives (Broome, 2007). As pointed out by Fleurbaey (2007), a prioritarian view will always coincide with an egalitarian view that cares both for total utility (or well-being) and equality, and which measures inequality with the same index that is implicit in the prioritarian view. However, it can be argued that the two perspectives reflect different ways of justifying priority to the worse off. The prioritarian justification focuses on the absolute circumstances of the worse off, while the egalitarian justification focuses on the relative circumstances of the worse off (Tungodden, 2003).

### Justice, welfarism and aggregation

A substantial literature has studied how to combine a concern for distributive equality or the worse off with other values, in particular Pareto efficiency. This raises two core questions. First, we need to establish a metric of individual advantage and, second, we need to determine how much weight to assign to distributive equality relative to other values.

Much of this work has rested on the assumption of welfarism, which states that the social ranking of alternatives must depend only on the utility levels of individuals in these alternatives (Arrow, 1951; Sen, 1970a; Bossert and Weymark, 2002). Welfarism may be assumed as a basic assumption or it may be derived from the more fundamental principles of Pareto indifference and independence of irrelevant alternatives (d’Aspremont and Gevers, 1977). There has been a huge literature criticizing welfarism. On
the one hand, it has been argued that welfarism contains an unsatisfactory representation of individual advantage. On the other hand, it has been claimed that it is impossible to apply welfarism in practice. We may label these the pragmatic and the fundamental arguments against welfarism.

The underlying idea of the pragmatic argument is that we ‘must respect the constraints of simplicity and availability of information to which any practical policy conception [of justice] is subject (Rawls, 1993, p. 182). Welfarism implies that interpersonal comparisons should be based on comparisons of preference satisfaction, which in general is considered to be non-observable. Thus, the welfaristic framework does not provide a practicable public basis for considerations of justice.

The fundamental critique of welfarism is concerned with the substantive claims of this framework. Rawls (1971; 1993) argues that utility or well-being is not a relevant feature of states of affairs. Appropriate claims should refer to an idea of rational advantage that is independent of any particular comprehensive doctrine of the good, and for this purpose Rawls suggests a list of primary goods. Sen (1985; 1992a) defends the focus on well-being in social choices, but he argues against the idea of well-being implicit in welfarism. Sen introduces the framework of functionings and a capability set, where functionings are the various things that a person may value doing or being (for example, being adequately nourished, free from avoidable disease, and able to take part in the life of the community) and the capability set is the set of alternative functioning vectors available to her. The proposals of Rawls and Sen differ, but formally they are closely related; social alternatives are characterized by a vector of valuable elements assigned to each individual. However, this raises the fundamental question of how to trade off gains and losses in the various dimensions for each individual. On possibility, as first suggested by Rawls (1971), is to establish an objective index as the basis for interpersonal comparisons in a theory of justice. The problem with this approach, as observed by Gibbard (1979), is that this in general will violate the Pareto principle. Some people will have preferences that are in disagreement with how the index implicitly makes the trade-off, and thus we face what is commonly named the indexing impasse (Sen, 1996a; Plott, 1978; Blair, 1988; Arneson, 1990). Sen suggests that the indexing impasse follows from not taking note of the citizens’ preferences when constructing the index, and he argues in favour of an intersection approach which articulates only those judgements that are shared implications of all the preferences present in society. However, as shown by Fleurbaey and Trannoy (2000), Brun and Tungodden (2004), and Pattanaik and Xu (2007), this approach does not solve the problem. In any society where people have heterogenous preferences, the intersection approach runs into a conflict with the Pareto principle.

A related argument has been put forward by Kaplow and Shavell (2001; 2002). They argue that any notion of fairness or justice that implies a violation of the Pareto indifference principle will also imply a violation of the standard Pareto principle if we accept a minimal continuity condition. They apply this insight to argue against any notion of fairness or justice that does not rely on individual utilities. However, there are alternatives to welfarism that are consistent with the Pareto principle (Fleurbaey, Tungodden and Chang, 2003). In particular, there is a literature on fair allocation which exploits the fact that with a richer description of the social alternatives we may apply considerations that rely on the shape of the indifference curves of individuals when establishing a justice ranking (Fleurbaey, 2003; Fleurbaey, Suzumura and Tadenuma, 2005; Fleurbaey and Maniquet, 2006). This approach violates Arrow’s independence of irrelevant alternatives, and thus shows that this condition is far from innocent in an analysis of justice.
If we now turn to the question of how much weight to assign to the worse off, then the answer may depend on our assumptions about the informational framework (Bossert and Weymark, 2002). If we assume that there is a one-dimensional measure of individual benefits (which may be utility) and no constraints on interpersonal comparability, then there is a vast number of theories of justice satisfying the Pareto principle. Hence, we need to impose other ethical conditions on the justice ranking in order to choose among the set of possible theories. One possibility is to appeal to conditions that only cover two-person situations, that is, situations where only the benefits of two persons differ in a comparison of two social alternatives, and it turns out that these conditions are extremely powerful in an analysis of this kind (d’Aspremont, 1985). By way of illustration, the utilitarian and the leximin ranking follows almost directly from assuming two-person utilitarianism and two-person leximin within such a framework. Within this informational framework, one may also show that any aggregative theory faces what we may name the tyranny of aggregation (Tungodden, 2003), whereby the interests of the worse off may be outweighed by the interests of a sufficiently large number of better off, even though the gain of each of the better off is infinitesimal. Although the tyranny of aggregation is well-known in the context of utilitarianism, it is important to note that this applies to any aggregative approach to social choices, including any aggregative prioritarian rule. This raises the question of whether an aggregative approach can constitute the basis of a theory of justice.

**Justice and non-aggregation**

A core element in Rawls's theory of justice is precisely that each person possesses an inviolability that makes aggregation impermissible. This is expressed both in the absolute priority assigned to the fulfilment of basic liberties and in the difference principle. Rawls aimed at justifying a non-aggregative approach by a constructive theory whereby people choose fairness principles behind a veil of ignorance. An extensive literature has questioned this conclusion, and following Harsanyi (1955) it is commonly argued that the veil of ignorance approach implies some version of utilitarianism (Weymark, 1991; Broome, 1991; Mongin, 2001; Mongin and d’Aspremont, 2002).

However, there are other ways of justifying a non-aggregative approach to distributive justice. One possibility is to combine a concern for equality promotion with a concern for Pareto efficiency (Barry, 1989). Tungodden and Vallentyne (2005) have investigated this approach, where the basic idea is that distributive conflicts ought to be solved by choosing the more equal distribution. They show that any consistent theory of justice satisfying this approach has to assign strict priority to the worst off in society. This result is closely related to the formal results developed by Hammond (1975) on extreme inequality aversion, and questions the claim of some philosophers that the leximin principle is not consistent with a concern for equality (McKerlie, 1994).

Another interesting non-aggregative approach has been suggested by Nagel (1979) and Scanlon (1982; 1998). They both argue that justice requires pairwise comparisons of individual claims, where the just solution is to satisfy the individual with the most urgent claim. In other words, they reject the argument that the number of persons with a particular claim should count (Taurek, 1977). They do, however, defend the view that, in order to measure the urgency of a claim, one should take into account both gains and losses and the absolute circumstances of an individual. Hence, the aim is to outline a theory of
justice that lies in the middle ground between leximin and the standard aggregative perspective. It turns out, however, that it is impossible to establish such a middle ground within a framework satisfying some basic consistency conditions (Tungodden, 2003).

Frankfurt (1987) proposes the doctrine of sufficiency, which says that justice plays no role if everyone has enough. This may be interpreted as a non-aggregative approach, whereby absolute priority is assigned to those below the sufficiency threshold. There are two fundamental and interlinked issues within this framework. First, one needs to define what it means to have enough. Second, one needs to justify why justice is not an issue among those who have enough. Anderson (1999), who appeals to the notion of democratic equality, may be seen as one way of developing Frankfurt's proposal, where people have enough if they have what is sufficient to stand as an equal in society. Crisp (2003), on the other hand, relates the idea of sufficiency to the notion of compassion, where priority should be given to the worse off only when their circumstances warrant the compassion of an impartial spectator. Underlying both these proposals is the perspective that the role of justice is limited, which of course does not exclude the possibility that there are other reasons for caring about the circumstances of people above the sufficiency threshold.

The standard view within economics is to think of justice as unlimited, that is, as relevant independent of people's circumstances. However, it is commonly recognized that by far the most pressing problem of justice in the modern world is the presence of poverty, and this has caused a substantial literature on the definition and measurement of this concept (Sen and Foster, 1997). Given any definition of poverty, absolute or relative, there is then the further question of how to fit this into a more general theory of justice. One possibility is a non-aggregative approach, where strict priority is given to the alleviation of poverty but where this is combined with a concern for distributive justice among those who do not live in poverty. Interestingly, this scheme is formally closely related to the structure of the difference principle as suggested by Rawls (1971). Rawls proposed that a relative threshold should define the worst-off group, and that we should assign strict priority to the expectations of this group (and not only the worst-off individual). However, it turns out that a relative definition of the worst-off group does not make room for an interpretation of the difference principle that differs from the standard leximin interpretation (Tungodden, 1999). Hence, an absolute threshold is needed to build an alternative non-aggregative theory of justice to leximin.

Any non-aggregative theory of justices faces what we may call the tyranny of non-aggregation, that is, it sometimes justifies that minor improvements in the lives of some people should outweigh great losses for any number of better-off people. This may seem as a knock-down argument against a non-aggregative approach. However, it is important to have in mind that by rejecting a non-aggregative approach one accepts the tyranny of aggregation, since there does not exist any reasonable theory of justice that avoids both the tyranny of aggregation and the tyranny of non-aggregation.

**Libertarianism, rights, and consequentialism**

We have argued that a non-aggregative theory of justice has to assign absolute priority to the worse off, and thus such a theory provides a strong protection of the rights and liberties of this group. However, this may imply the violation of the rights of others. Libertarianism, on the other hand, holds that all agents are, initially at least (for example, prior to engaging in any commitments or unjust actions), full
self-owners, and that any violation of full self-ownership is unjust. The core idea of full self-ownership is that agents own themselves in just the same way that they can fully own inanimate objects.

The modern interest in libertarianism was initiated by the work of Nozick (1974), who not only defended full self-ownership but also the view that people should be free to appropriate parts of the external world as long as no one be left worse off with the appropriation than she would be if the thing were in common use. This view of just appropriation of the external world has recently been challenged by left-libertarians, who argue that people have joint ownership of natural resources (Moulin and Roemer, 1989; Steiner, 1994; Vallentyne and Steiner, 2000; Otsuka, 2003). If we accept the premise of joint ownership, then it follows that natural resources may be justly appropriated only with the permission of, or with a significant payment to, the other members of society.

The work of Nozick (1974) was partly motivated by Sen's liberal paradox (Sen, 1970b; Gibbard, 1974), where Sen shows that there is a conflict between respecting the Pareto principle and protecting a private sphere to each individual in society. This work has initiated a large literature, which has studied alternative formulations of individual rights. In particular, it has been argued that rights should be formulated as the admissibility of actions or strategies of individuals and not as the right to impose one's preferences on the ranking of a particular set of social alternatives (Gaertner, Pattanaik, and Suzumura, 1992). However, as pointed out by Sen (1992b; 1996a), even though this provides an interesting alternative formulation of rights, it does not in itself eliminate the tension between the Pareto principle and individual rights.

Libertarianism in its various forms provides one way of justifying individual rights, but the right-based perspective is certainly not exclusive to libertarianism (see, for example, Rawls, 1971; 1993; Kolm, 1996; van Hees and Dowding, 2003). Moreover, a rights-based perspective does not necessarily have to be non-consequentialistic in the sense that it imposes side constraints that cannot be overridden by other considerations of justice. It is possible to defend a consequentialistic rights-based approach, where the best overall outcome, as judged from an impersonal standpoint which gives equal weight to the interest of everyone, is to minimize the violations of some basic rights or liberties (Scheffler, 1988). In fact, it has also been argued that side constraints and agent relativity can be accommodated by consequential reasoning if we adopt a positional view of consequences (Sen, 1982; 1993). Finally, we should note that rights and liberties also may be justified on instrumental grounds, as a way of generating good consequences.

**Intergenerational justice and international justice**

The intergenerational perspective introduces several interesting challenges to a theory of justice (Parfit, 1984). First, we have to consider how to deal with the non-identity problem of future people, which questions whether people that are born as a result of a particular set of policies can be harmed by these policies, given that they would not have been born at all otherwise. Second, we have to consider how to avoid the repugnant conclusion, namely, that for any given affluent population there is a better world with more people, but where everyone has an arbitrarily low level of utility or well-being. This conclusion follows from two intuitively plausible conditions, namely, that we make the world better by bringing in people who have a life worth living and that we do not make the world worse by making it
more equal (at least as long as this does not reduce the total amount of utility in society). Blackorby, Bossert and Donaldson (1997; 2005) propose critical-level utilitarianism as the best possible solution to these problems, where critical-level utilitarianism disvalues only individuals whose utility level is below some fixed, low but positive threshold.

The literature on intergenerational justice has considered how to formulate a criterion of justice when there is an infinite number of generations. The basic problem was raised by Diamond (1965), who proved that within this framework it is impossible to construct a social welfare function that satisfies the Pareto principle, a principle of intergenerational equity and continuity. Basu and Mitra (2003) strengthen this result by proving that the continuity condition is superfluous. In other words, the fundamental conflict is between the Pareto principle an intergenerational equity. However, the literature also contains positive results, which show that a criterion for intergenerational justice can be formulated with an infinite horizon if one moves away from the framework of a social welfare function (Asheim, Buchholz and Tungodden, 2001; Asheim and Tungodden, 2004; Basu and Mitra, 2003; Basu and Mitra, 2007; Bossert, Sprumont and Suzumura, 2007; Fleurbaey and Michel, 2003).

Rawls (1971) limited his theory of justice to the circumstances of a nation, and recently this has been questioned by a number of philosophers (Pogge, 1989; 1992; 1994; 2001). They find any distinction between people based on territory arbitrary, and thus argue in favour of applying Rawls's principles of justice on the global scale. Consequently, they claim that the situation of the worst-off members of the global, rather than the domestic, society ought to be the starting point for considerations of justice. This view has been rejected by Rawls (1999), who argues that there is no basic structure in the international arena that can be the primary subject of social justice, and the difference principle cannot be a demand of justice in the international realm because, among other things, the justification of the difference principle has merit only between persons who cooperate in the way that this is done within the nation state.

Concluding remarks

The normative literature on justice has expanded enormously in recent years, with an extremely fruitful exchange of ideas between the disciplines of economics and philosophy. As a result, we now have a much richer understanding of how to think about the various possible conceptions of a just society. Still, there are many unresolved questions in the literature. Let me briefly mention three of them. First, there is a need further study of how to combine egalitarian ideas of responsibility with a concern for efficiency. Basic economic theory tells us that the efficient solution is to let individuals face the actual consequences of their choices, but this is clearly to hold individuals responsible for too much in many situations. How should we deal with this tension in a just society? Second, there is a need for further study of the metric of individual advantage. There are a number of suggestions present in the literature, including primary goods, basic needs, functionings and capabilities, but still need for more research on how to combine these approaches with a respect for individual preferences and choices. Finally, there is a need for further analysis of the prioritarian proposal. The core question within prioritarianism is how much more weight to attach to the worse off, and presently we lack a clear understanding of how to move forward on this issue.

justice

Amartya Sen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Traditionally, economists have treated justice as a component of social welfare maximization. Recently, philosophical treatments of justice have challenged the three principles underlying utilitarianism: welfarism, sum-ranking and consequentialism. Various theories of justice advance alternatives to utility (such as Rawls's notion of 'primary goods') as a basis for social judgements, counterpose distributional criteria (such as Sen's 'leximin' rule) to the aggregative approach of utilitarianism, and assert the moral priority of certain aspects of individual advantage (such as Nozick's idea of individual rights as entitlements) over consequences. This article attempts to distinguish and clarify these conceptions of justice.

Article

1. Justice and utilitarianism

The concept of justice is often invoked in economic discussions. Its relevance to economic evaluation is obvious enough. However, it is fair to say that in traditional welfare economics, when the notion of justice has been invoked, it has typically been seen only as a part of a bigger exercise, viz., that of social welfare maximization, rather than taking justice as an idea that commands attention on its own. For example, in utilitarian welfare economics (e.g. Pigou, 1952; Harsanyi, 1955) the problem of justice is not separated out from that of maximization of aggregate utility. This situation has been changing in recent years, partly as a result of developments in moral philosophy dealing explicitly with the notion of...
justice as a concept of independent importance (see especially Rawls, 1971, 1980).

In the utilitarian formulation the maximand in all choice exercises is taken to be the sum-total of individual utilities. The approach can be seen as an amalgam of three distinct principles: (1) welfarism, (2) sum-ranking, and (3) consequentialism. Welfarism asserts that the goodness of a state of affairs is to be judged entirely by the utility information related to that state, i.e., by information about individual utilities. All other information is either irrelevant, or only indirectly relevant as a causal influence on utilities (or as a surrogate for utility measures when such measurement cannot be directly done). The second principle is sum-ranking, which asserts that the goodness of a collection of utilities (or welfare indicators) of different individuals, taken together, is simply the sum of these utilities (or indicators). This eliminates the possibility of being concerned with inequalities in the distribution of utilities, and the overall goodness or ‘social welfare’ is seen simply as the aggregate of individual utilities. The third principle is consequentialism, which requires that all choice variables, such as actions, rules, institutions, etc., must be judged in terms of the goodness of their respective consequences. The overall effect of combining these three principles is to judge all choice variables by the sum-total of utilities generated by one alternative rather than another.

2 Sum-ranking and equality

A theory of justice can take issue with each of the principles underlying utilitarianism, and in fact in the literature that has developed in recent decades, each of these principles has been seriously challenged (see the papers included in Sen and Williams, 1982). Some critiques have been particularly concerned with assessing and questioning the axiom of sum-ranking, and have considered the claims of equality in the distribution of well-being (see, for example, Phelps, 1973; Sen, 1973, 1977, 1982; Kern, 1978). The summation formula can be defended either directly (e.g., in terms of attaching equal importance to everyone's ‘interest': see Hare, 1981, 1982), or indirectly through invoking some model of ‘impersonality’ or ‘fairness’ (e.g., involving a hypothetical choice in a situation of primordial uncertainty, in which each person has to assume that he or she has an as if equal probability of becoming anybody else: see Vickrey, 1945; Harsanyi, 1955). Other routes to deriving sum-ranking involve independence or separability requirements of various kinds (see d’Aspremont and Gevers, 1977; Deschamps and Gevers, 1978; Maskin, 1978; Gevers, 1979; Roberts, 1980; Myerson, 1981; Blackorby, Donaldson and Weymark, 1984; d’Aspremont, 1985).

Whether the defences obtainable from these approaches are convincing enough has been a matter of some dispute. There have also been some interpretative discussions as to whether giving equal importance to everyone's ‘interest’ does, as alleged, in fact yield the formula of summing individual utilities irrespective of distribution, and also whether the additive formula that is obtained on the basis of hypothetical primordial choice is, in fact, a justification for adding individual utilities as they might be substantively interpreted in welfare economic exercises (see Pattanaik, 1971; Smart and Williams, 1973; Sen, 1982, 1985a; Blackorby, Donaldson and Weymark, 1984; Williams, 1985). It is not obvious that this debate has been in any way definitively concluded one way or the other.

3 The difference principle and lexicin
Meanwhile, much attention has been paid to developing welfare-economic rules based on taking explicit note of inequalities in the distribution of utilities. A definitive departure on this came from Suppes (1966). Another major approach was developed in Rawls's (1971) *Theory of Justice*, even though Rawls himself was concerned not so much with the distribution of *utilities* but with that of the indices of primary goods (on which more later). The concern with the utility level of the worst-off individual has been formalized and reflected in various formulae suggested or derived in the rapidly growing welfare-economic literature on this theme. In particular, James Meade (1976) has provided an extensive treatment of this type of distributional issues, and it has also been penetratingly analysed by Kolm (1969), Phelps (1973, 1977), Atkinson (1975, 1983), Blackorby and Donaldson (1977), and others. In fact, the Rawlsian ‘Difference Principle’, which judges states of affairs by the advantage of the least well-off person or group, has often been axiomatized in welfare economics and in the social-choice literature by equating advantage with utility. In this form, the ‘lexicographic maximin’ rule (proposed in Sen, 1970) has been axiomatically derived in different ways. The rule judges states of affairs by the well-being of the worst-off individual. In case of ties of the worst-off individuals’ utilities, the states are ranked according to the utility levels of the second worst-off individuals respectively. In case of ties of the second worst-off positions as well, the third worst-off individuals’ utilities are examined. And so on. There is no necessity to interpret these axioms in terms of utilities only, and in fact the analytical results derived in this part of the social-choice literature can be easily applied without the ‘welfarist’ structure of identifying individual advantage with the respective utilities. Various axiomatic derivations of lexicographic maximin – ‘leximin’ for short – can be found in Hammond (1976), Strasnick (1976), Arrow (1977), d’Aspremont and Gevers (1977), Sen (1977), Deschamps and Gevers (1978), Suzumura (1983), Blackorby, Donaldson and Weymark (1984), d’Aspremont (1985), among others. These can be seen as exercises that incorporate concern for reducing inequality, related to recognizing the claims of justice.

While the Rawlsian approach rejects the aggregation procedure of utilitarianism (i.e., ranking by sums), a major aspect of the Rawlsian theory involves the rejection of utility as the basis of social judgements (i.e., welfarism). Rawls (1971) argues for the priority of the ‘principle of liberty’, demanding that ‘each person is to have an equal right to the most extensive basic liberty compatible with similar liberty for others’. Then, going beyond the principle of liberty, claims of efficiency as well as equity are both supported by Rawls's ‘second principle’ which *inter alia* incorporates his ‘Difference Principle’ in which priority is given to furthering the powers of the worst-off group. These powers are judged by indices of ‘primary social goods’ which each person wants (Rawls, 1971, pp. 60–65).

Primary goods are ‘things that every rational man is presumed to want’, including ‘rights, liberties and opportunities, income and wealth, and the social bases of self-respect’. The Difference Principle takes the form, in fact, of maximin, or lexicographic maximin, based on interpersonal comparisons of indices of primary goods. This rule can be axiomatized in much the same way as the other ‘lexicographic maximin’ rule based on utilities, and all that is needed is a reinterpretation of the content of the axioms (with the objects of value being indices of primary goods rather than utilities).

The Rawlsian approach to justice, therefore, involves rejection both of welfarism and of sum-ranking. Furthermore, consequentialism is disputed too, since the priority of liberty might possibly go against judging all choice variables by consequences only. At least, in the more standard forms, consequentialism does involve such a conflict, even though it is arguable that the problem can be, to a
great extent, resolved by a broader understanding of consequences, which takes into account the
fulfilment and violation of liberties and rights, and also the agent's special role in the actions performed
(Sen, 1985a).

4 Utilities, primary goods and capabilities

The claim of primary goods to represent the demands of justice better than utilities is based on the idea
that utilities do not reflect a person's advantage (in terms of well-being or powers) adequately. It is
arguable that in making interpersonal comparisons of advantage, the metric of utilities (either in the
form of happiness, or of desire fulfilment) may be biased against those who happen to be hopelessly
deprieved since the demands of unharrassed survival force people to take pleasure in small mercies and to
cut their desires to shape in the light of feasibilities (see Sen, 1985a, 1985b). The status of ‘preference’
may be disputed in view of the need for critical assessment (see Broome, 1978; McPherson, 1982;
Goodin, 1985, among others). Also, what types of pleasures should ‘count’ can itself be a matter for an
important moral judgement. As Rawls (1971) points out, in the utilitarian formulation, we have the
unplausible requirement that

if men take a certain pleasure in discriminating against one another, in subjecting others to
a lesser liberty as a means of enhancing their self-respect, then the satisfaction of these
desires must be weighed in our deliberations according to their intensity, or whatever,
along with other desires (pp. 30–31).

These and other types of difficulties have been dealt with by some utilitarians through moving to less
straight-forward versions of utilitarianism, for example Harsanyi's (1982) exclusion of ‘all antisocial
preferences, such as sadism, envy, resentment, and malice’ (p. 56); see also the refinements proposed by

Recently, it has been argued that primary goods themselves may be rather deceptive in judging people's
advantages, since the ability to convert primary goods into useful capabilities may vary from person to
person. For example, while the same level of income (included among ‘primary goods’) may give each
person the same command over calories and other nutrients, the nourishment of a person depends also
on other parameters such as body size, metabolic rates, sex (and if female, whether pregnant or
lactating), climatic conditions, etc. This indicates that a more plausible notion of justice may demand
that attention be directly paid to the distribution of basic capabilities of people (see Sen, 1982, 1985b).
The approach goes back to Smith's (1776) and Marx's (1875) focus on fulfilling needs.
The achievement of capabilities will, of course, be causally related to the command over primary goods,
and the capabilities, in their turn, will also influence the extent to which utilities are achieved, so that the
various alternative measures will not be independent of each other. However, the basic issue is the
variable that should be chosen to serve as the proper metric for judging advantages of people – the
equity and the distribution of which could form the foundations of a theory of justice. On this central
issue several alternative views continue to flourish in the literature.
5 Fairness and envy

A view of justice that is not altogether dissimilar from Rawls's concerned with primary goods is captured by the literature on ‘fairness’, inspired by a pioneering contribution of Foley (1967). In this approach a person's relative advantage is judged by the criterion as to whether he or she would have preferred to have had the commodity bundle enjoyed by another person. This has been seen as a criterion of ‘non-envy’. If no one ‘envies’ the bundle of anyone else, the state of affairs is described as being ‘equitable’. If a state is both equitable and Pareto efficient, it is described as being ‘fair’ (even though the term fairness is also sometimes used interchangeably with only ‘equitability’).

There has been an extensive literature on existence problems, in particular whether equitability can be combined with efficiency in all circumstances. (The answer seems to be no, especially when production is involved: Pazner and Schmeidler, 1974.) There has also been considerable exploration of the effects of varying the criterion of equitability and fairness to reflect better the common intuitions regarding the requirements of justice. Various results on these problems and related ones have been presented, among many others, by Foley (1967), Schmeidler and Vind (1972), Feldman and Kirman (1974), Varian (1974, 1975), Svensson (1980), and Suzumura (1983).

It should be remarked that the fairness criterion does not provide a complete ranking of alternative states. It identifies some requirements of justice, which makes the states fair. Varian (1974) has argued, with some force, that ‘social decision theory asks for too much out of the process in that it asks for an entire ordering of the various social states (allocations in this case)’, whereas ‘the original question asked only for a “good” allocation; there was no requirement to rank all allocations’ (pp. 64–5). While it is true that ‘the fairness criterion in fact limits itself to answering the original question’, the absence of further rankings may be particularly problematic if no feasible ‘fair’ allocation exists incorporating efficiency (as seems to be the case in many situations). Furthermore, while a ‘pass-fail’ criterion of justice may have attractive simplicity, it does not follow that two states, both passing this criterion, must be seen as being ‘equally just’. Various ‘finer’ aspects of justice have indeed been discussed in the literature (see particularly. Suppes, 1966; Kolm, 1969; Rawls, 1971; Meade, 1976; Atkinson, 1983).

It should also be noted that the ‘fairness’ literature deals with commodity allocations, or incomes, or some other part of the set of things that figures in Rawls's characterization of ‘primary goods’. The list is, in fact, much less extensive than that of primary goods as defined by Rawls (1971), and as such it leaves out many considerations that are regarded as important in the Rawlsian framework (e.g., the social bases of self-respect). On the other hand the criticisms – discussed earlier – of the Rawlsian focus on primary goods (based on recognizing inter-individual variations in the ability to convert primary goods into capabilities) would apply a fortiori to the fairness approach as well.

6 Liberty and entitlements

A different type of consideration altogether is raised by the place of liberty in a theory of justice. As was mentioned before, Rawls gives it priority. This priority has been questioned by pointing to the possibility that other things (e.g., having enough food) may sometimes be no less important than enjoying liberty without restriction by others. Rawls does, of course, attach importance to these other considerations, but in view of the priority of liberty, they may end up having too little impact on judgements regarding
justice in many circumstances, and this might not be acceptable (on this see Hart, 1973).

On the other hand, in some other theories of justice, the priority of liberty has been given even greater importance than in the Rawlsian structure. For example, in Nozick's (1974) theory of ‘entitlements’, rights are given complete priority, and since these rights are characterized quite extensively, it is not clear whether or not much remains to be supported over and above the recognition of rights. Nozick argues against any ‘patterning’ of outcomes, indicating that any outcome that is arrived at on the basis of people's legitimate exercise of their rights must be acceptable because of the moral force of rights as such. These rights, in Nozick's analysis, include not only personal liberty, but also ownership rights over property, including the freedom to use its fruits, to use it freely for exchange, and to donate or bequeath it to others (thereby asserting the legitimacy of inherited property).

This type of approach has been criticized partly on grounds of what has been seen as its ‘extremism’, since the constraints imposed by rights can override other important considerations, for example reducing misery and promoting the well-being of the deprived members of the society. In fact, it has been argued that a system of entitlements of the kind specified by Nozick might well co-exist with the emergence and sustaining of widespread starvation and famines, which are often the result of legally sanctioned exercises of property rights rather than of natural calamities (on this see Sen, 1981).

Although Nozick does refer to the possibility that in case of ‘catastrophic moral horrors’ rights may be compromised, it is not at all clear how his theory would accommodate such waiving of rights, in the absence of formulation of other, competing bases of moral judgements. On the other hand, there cannot be any doubt that Nozick's theory does capture some notions of justice that can be found in a less clear form in the literature. Nozick's analysis gives a well-formulated and illuminating account of an entitlement-based approach to justice.

7 Sources of difference

To conclude, theories of justice explicitly or implicitly invoked in the literature show a variety of ways in which the demands of justice can be interpreted. There are at least three different bases of variation. One source of variation concerns the metric in terms of which a person's advantage is to be judged in the context of assessing equity and justice. Various metrics have been considered in this context, including utility (as under utilitarianism and other welfarist theories of justice), primary goods index (as in the Rawlsian theory of justice), capabilities index (as in theories emphasizing what people can actually do or be, e.g., Sen, 1985b), incomes or commodity bundles (as in the literature on ‘fairness’, and on statistical measures of poverty, e.g., Foster, 1984), various notions of command over commodity bundles and resources (as in some notions of ‘equality’ developed in the literature, e.g., Archibald and Donaldson, 1973; Dworkin, 1981), and so on.

A second source of difference relates to the aggregating of diverse information regarding the advantages of different individuals. One approach, best represented by utilitarianism, sees nothing being needed to be ascertained other than the sum-total of the overall utilities of different people. Insofar as distributional considerations come into this exercise, they enter in the conversion of goods to be distributed into the appropriate metric of individual utilities. For example, inequality in the distribution of incomes may be disvalued in the approach of utilitarian justice because it may lead to a reduction in the sum-total of individual utilities, through (interpersonally comparable) ‘diminishing marginal utilities’. Other
approaches are more concerned with distributional properties related to the different individuals’ relative positions (vis-à-vis each other). The Rawlsian lexicographic maximin is one example of such a distributional concern, and there are others than can be considered, such as adding concave transformations of the individual utility indices (e.g., the additive formula used by Mirrlees, 1971, for his taxation assessment), and using various ‘equity’ axioms (e.g., Kolm, 1969, 1972; Sen, 1973; 1982; Atkinson, 1975, 1983; Hammond, 1976, 1979; d’Aspremont and Gevers, 1977; Roberts, 1980).

The third issue concerns the claimed priority of some particular aspect of a person's advantage (e.g., Rawls's insistence on the priority of liberty), or non-consequentialist priority of some processes over results (e.g., Nozick's, 1974, view of rights serving as unrelaxable constraints; or ideas of exploration based on counterfactual exercises of shared rights to social resources, e.g., Roemer, 1982).

Given the diversity of moral intuitions related to the complex notion of justice, which has been extensively used over centuries to arrive at normative assessment, it is not surprising that various theories of justice have been proposed in the economic and philosophical literature. The exercise of clearly understanding what the differences between distinct theories of justice consist of (and arise from) is, in some ways, the first task. This essay has been concerned with that task.

Article

Kahn was the favourite pupil and closest collaborator of John Maynard Keynes, at the time when the ‘Keynesian Revolution’ was under way (Keynes, 1936). For the whole of his academic career, he remained associated with King’s College, Cambridge (Keynes's College), where he lived, as a bachelor, from his undergraduate days.

Kahn was born in London on 10 August 1905, into a Jewish family of very strict religious observance. His father, Augustus Kahn, a schoolmaster, was a first-generation Englishman (his parents being German), who went back to Germany to marry Regina Schoyer, Richard's mother. They had three daughters besides Richard, their eldest son.

Richard won a scholarship to St Paul's School, London (curiously enough, Joan Robinson was educated in the girls’ section of the same school). Then he won a scholarship to King's College, Cambridge, where he studied mathematics and physics, and graduated in physics in 1927 (being placed in the second class of the Natural Science Tripos). The scholarship gave him the right to a fourth year and he took up economics, at a time of great effervescence in Cambridge intellectual circles.

He was taught economics (in 1927–8) at King's College by Keynes and Shove, and attended university lectures delivered by Pigou, Keynes, Shove, Dennis Robertson and, in the following academic year, by Piero Sraffa, the Italian economist who had just arrived at Cambridge. He obtained his university degree in economics in June 1928 (placing himself, after only one year, in the first class of the Economic Tripos Part II), and immediately, under strong encouragement from Sraffa and Keynes, started work on a Fellowship dissertation (under the title ‘The Economics of the Short Period’), which he wrote in a surprisingly short time, obtaining a Fellowship of King's College in March 1930.

‘The Economics of the Short Period’ (Kahn, 1929), which has remained unpublished (though a
translation appeared in Italian, in 1983), is one of the two substantial works (the other being Joan Robinson's *Economics of Imperfect Competition*, 1933) that were stimulated in Cambridge by the devastating critique of Marshall launched by Piero Sraffa in the late 1920s (Sraffa, 1926). Richard Kahn and Joan Robinson worked very much in collaboration, under the strong influence of Sraffa and Keynes. For Kahn and Joan Robinson this was the beginning of an intense intellectual partnership that lasted for life.

The most interesting part of Kahn's ‘Economics of the Short Period’ is perhaps his analysis of the extent to which – in periods of depressions – market imperfections affect the way in which output gets distributed among the various firms, the essential point being that market imperfections prevent the most efficient firms from reaching an optimum utilization of their productive capacities and instead cause *all* firms (efficient and inefficient alike) to reach equilibrium at a point at which there is under-utilization of productive capacity at less than full employment. This sets obvious relations between the microeconomic behaviour of the single firms and the situations of underutilization of productive capacity for the economic system as a whole.

The only part of the dissertation that reached publication in English is the treatment (part of Chapter 7) of duopoly, which Kahn re-elaborated in the form of an elegant article (Kahn, 1937) that has since become a standard reference in the economic literature on duopoly and oligopoly. But the whole of Kahn's dissertation deserves closer scrutiny. When it becomes more readily available, it may well contribute to piecing together the great analytical puzzle of the relations between Sraffa's critique of Marshall's theory of the firm and Keynes's macroeconomic theory, or, to put it in other terms, of the microfoundations of Keynes's *General Theory*. It will also contribute to clarify the role played by Kahn in Joan Robinson's *Economics of Imperfect Competition*, whose Preface, as is well known, contains heavy acknowledgements of Kahn's help.

There can be no doubt that on a strictly intellectual level these were the most productive years in Kahn's life. It was in the summer of 1930, in the process of criticizing a paper by Keynes and Henderson on public works, that he discovered the principle of the multiplier.

The multiplier is a relation between the *increase* in exogenous aggregate expenditure and the *increase* in net national product thereby generated (and thus also in employment, if employment is proportional to net national product and the economy is in a situation of unemployment due to lack of effective aggregate demand). If \( c \) is the fraction of any increase in income that consumers tend to spend, it can be shown that any increase of £1 of exogenous expenditure (or else of such an amount that generate 1 extra job) will finally generate \( 1/(1-c) \) of net national product (or else \( 1/(1-c) \) extra jobs). This is Kahn's multiplier. The author originally presented it in a short article with reference to employment (1931). It was then to be used by Keynes with reference to national income (and to the process of investments generating a corresponding amount of savings), as one of the major ingredients of Keynes's revolutionary work.

In 1930, Kahn started chairing and conducting the so-called ‘Cambridge Circus’, a group (or rather a closed club) of young Cambridge economists, among whom the most prominent members, besides Kahn, were Joan and Austin Robinson, Piero Sraffa and James Meade. The Cambridge Circus met regularly to discuss, criticize and propose changes to the subsequent drafts of what was later to become Keynes's *General Theory*.

The exact nature and extent of the part played by Kahn in Keynes's masterpiece will remain a matter of speculation. Schumpeter's view that Kahn’s ‘share in the historic achievement cannot have fallen very
far short of co-authorship' (Schumpeter, 1954, p. 1172) may well be exaggerated. Yet, from Keynes's acknowledgement of indebtedness to him, it can surely be argued that that part must have been very large.

But this was not all. Kahn's contributions to economic theory in those years also concern two other debated subjects in the 1930s: the development of the concept of elasticity of substitution among ‘factors of production’, as an analytical tool in the traditional theory of income distribution (Kahn, 1933), and the laying out of the foundations of welfare economics. Kahn's notes on ‘ideal output’ (1935), and his article on tariffs and the terms of trade (1947) were later to be basic to de Villiers Graaff's systematic (and rather pessimistic) theoretical work on welfare economics (Graaff, 1957).

Kahn was appointed a university lecturer in 1933 and became a member of the King's economics teaching staff in 1936. Except for an interruption due to the war, he was responsible for the teaching of economics at King's College from 1936 to 1951 (first with Shove and Keynes and later, from 1949, with Kaldor). From 1939 to 1944, during the Second World War, he worked for the British government on various schemes, mainly connected with war production and war rationing. He also became head of the General Division of the Board of Trade. At the end of the war he returned to economics teaching in King's College. He was appointed a professor of economics at the University of Cambridge in 1951, and retired from that professorship in 1972.

On many occasions, and for temporary periods, Kahn worked for various international organizations: in 1955 he was a member of the Research Unit of the Economic Commission for Europe; in 1959 he was a member of a Group of Experts of the OEEC to study the problem of rising prices; in the 1960s he served as a member of four Groups of Experts of UNCTAD. In this capacity, he contributed to numerous official publications, both of British and of international organizations (see, for example, Kahn et al., 1956; 1961). Of considerable importance has been his Memorandum of Evidence submitted to the Government-appointed Committee on the Working of the Monetary System (the Radcliffe Committee) (1960). This Memorandum, jointly with his theoretical work on the extension of the concept of liquidity preference (1954a), was among the substantial pieces behind the formation of what has become known as ‘the Radcliffe Committee view’ on the working of the monetary system. When in the 1970s the more traditional ‘monetarist’ views once again became fashionable, Kahn was consistent in reacting vehemently against them and in rallying to the defence of the Keynesian approach (1976a; 1976b). In 1965, Kahn was elevated to the House of Lords as a life peer (taking the title of Baron Kahn of Hampstead), in recognition of his services to the British government. Although a member of the Labour Party, he sat on the cross benches. For a number of years he was a reasonably active member of the House of Lords and made a number of speeches – almost exclusively on issues of government economic policy.

Kahn remained, for the whole of his life, a strong defender and faithful expositor of the original ideas contained in Keynes's major work. In a book reproducing his Mattioli Lectures and published in 1984, he gave his version – no doubt a version from the spot closest to the master – of how Keynes's historic work came into being. In one respect Kahn did go on to new ground to complete Keynes's views, and that was with reference to the inevitability of inflationary pressures in industrialized countries, once full employment is reached, unless some drastic changes are introduced into our institutions. On this subject he explored in considerable detail those institutional changes that he thought should be introduced into the process of wage negotiations (1976a; 1976b; 1977). He also took a major part in the shaping of the post-Keynesian theories of capital, growth and income distribution, as opposed to the neoclassical
theories (see, for example, Kahn, 1954b; 1959), as well as in the development of a post-Keynesian approach to planning (1958).

On the whole, Kahn was not a prolific writer. Apart from his Fellowship dissertation (still unpublished in its original version) and the publication of his Mattioli Lectures (Kahn, 1984), the only book that can be found in the library under his name is Kahn (1972), which is not in fact a proper book but the collection of his best articles, arranged together and published by two of his pupils on the occasion of his retirement from his Cambridge professorship. His most remarkable contribution to economic theory clearly remains the multiplier. But he will also be remembered as one of the crucial members of the post-Keynesian group of critics of neoclassical economics, although rarely did he come out in the battle forefront. By temperament, he constantly preferred to play the role of the meticulous scholar, never completely satisfied with any version of any work, of the relentless, sometimes even fastidious, critic, of the propounder of new alternatives and ideas to suggest to others to develop. In a few words, Kahn superbly played the role – rather congenial to him – of the éminence grise behind the scene. Precisely for these reasons, Kahn's association with Keynes in the late 1920s and the 1930s and his lifelong intellectual partnership with Joan Robinson will stimulate the imagination and curiosity of historians of economic thought for years to come.

Kahneman, Daniel (born 1934)

Matthew Rabin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A prominent figure in the new hedonic psychology, Daniel Kahneman has been influential in the emergence of behavioural economics. His research programme on heuristics and judgemental biases points to a range of important ways that economics has traditionally misunderstood human behaviour, and identifies how some common economic assumptions have been misleading. Especially in light of potential flaws in the way people manage their well-being, Kahneman and his colleagues have launched research that may help move economics towards a more realistic approach both to predicting behaviour and to welfare analysis.

Article

Daniel Kahneman was born in 1934, after his Jewish parents had emigrated from Lithuania to France. He grew up in France under German occupation, and then moved as an adolescent to what is now Israel. After studying in Israel, he entered the Ph.D. programme in psychology at the University of California in Berkeley in 1961. His intellectual journey continued from there, as he grew from a young psychologist specializing in vision research into a highly influential social and cognitive psychologist. Kahneman is a major figure in the field of psychology – his work with Amos Tversky on heuristics and biases was central to the ‘cognitive revolution’ in social psychology, and his later work on the psychology of happiness has made him a prominent figure in the new hedonic psychology. Kahneman’s contribution to economics, outside his own field, is more remarkable. He is one of the two psychologists (along with his
Kahneman, Daniel (born 1934) : The New Palgrave Dictionary of Economics

long-standing collaborator Tversky) to most influence the field of economics. Along with Tversky, Richard Thaler, and a few others, he is one of the primary founding figures in the emerging field of ‘behavioural economics’. In recognition of his contributions, in 2002 he was awarded the Nobel Memorial Prize in Economics.

Kahneman's research presents a menu of important ways that economics has traditionally misunderstood human behaviour, and hence plays the useful role of identifying ways in which common economic assumptions have been misleading. Yet Kahneman has not just been a thorn in the side of economics; his research provides the material to improve economics. Although he has not himself specialized in conventional economic analysis, a recent spate of behavioural economic research – which attempts to improve economic analysis by incorporating greater psychological realism into economics – has been built on different strands of Kahneman's research.

**Heuristics and biases**

Economics has traditionally assumed that, when making decisions under uncertainty, people form subjective probabilistic assessments about the state of the world derived correctly from to the laws of probability. Kahneman's influential early research, conducted jointly with Tversky, documents departures from rationality in probabilistic judgement and decision-making under uncertainty. As Tversky and Kahneman (1974, p. 1124) frame their agenda,

… people rely on a limited number of heuristic principles which reduce the complex tasks of assessing probabilities and predicting values to simpler judgmental operations. In general, these heuristics are quite useful, but sometimes they lead to severe and systematic errors. The subjective assessment of probability resembles the subjective assessment of physical quantities such as distance or size. These judgments are all based on data of limited validity, which are processed according to heuristic rules. For example, the apparent distance of an object is determined in part by its clarity. The more sharply the object is seen, the closer it appears to be. This rule has some validity, because in any given scene the more distant objects are seen less sharply than nearer objects. However, the reliance on this rule leads to systematic errors in the estimation of distance. Specifically, distances are often overestimated when visibility is poor because the contours of objects are blurred. On the other hand, distances are often underestimated when visibility is good because the objects are seen sharply. Thus, the reliance on clarity as an indication of distance leads to common biases. Such biases are also found in the intuitive judgment of probability.

Many other approaches to the study of cognition and judgement have been explored by psychologists. Yet, by dint of its study of systematic but limited departures from a normative Bayesian model, Kahneman and Tversky's research programme on judgemental biases has shown the most promise for integration into economics.

Probably the most important biases Kahneman and Tversky identified are an array of related phenomena collected under the rubric of ‘the representativeness heuristic’. Although Bayesian updating tells us that people ought use conditional probabilities as a clue to underlying states – somebody who has symptoms
of a disease is more likely to have the disease – Kahneman and Tversky and subsequent researchers demonstrate that people tend to overuse ‘representativeness’ in assessing probabilities. One implication of this is the tendency to underuse base rates: even if a certain symptom appears always among people with a rare disease, and only occasionally among people without the disease, given the rarity of the disease Bayesian reasoning tells us that most people who have the symptom do not have the disease. Yet people tend to exaggerate the likelihood of having the disease given the symptom.

The most striking manifestation of such base-rate neglect is the common violation of the conjunction rule, a fundamental axiom of probability theory: the probability that somebody belongs to both categories A and B is less than or equal to the probability that she belongs to category B alone. Kahneman and Tversky demonstrate what they call the conjunction effect: when a description is representative of a person in category A but not of a person in category B, people often judge it more likely that the description matches somebody who falls into both categories A and B than into category B alone. Tversky and Kahneman (1982b, p. 92) illustrate this effect by recounting an experiment in which subjects were provided with the following description:

Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.

Subjects were then asked to rate the relative likelihood that eight different statements about Linda were true. Two statements on the list were ‘Linda is a bank teller’ and ‘Linda is a bank teller and is active in the feminist movement’. Over 85 per cent of subjects judged it more likely that Linda was both a bank teller and a feminist than that she was a bank teller. This is because the description of Linda made her seem like a feminist, so that being a bank teller and a feminist seemed a more natural description, and thus more ‘representative’ of Linda, than simply being a bank teller.

Tversky and Kahneman (1971) argue that another manifestation of the representativeness heuristic is a bias they call ‘The Law of Small Numbers’: people exaggerate how often a small sample closely resembles the parent population or underlying probability distribution that generates the sample. We expect even small classes of students to contain very close to the typical distribution of smart ones and not-so-smart ones. Likewise, we underestimate how often a good financial analyst will be wrong a few times in a row, and how often a clueless analyst will be right a few times in a row. Such misunderstandings of variance in small samples have far-reaching implications for social and economic judgements.

Kahneman and Tversky identified and provided evidence for other heuristics and biases. Beyond the biases that Kahneman and Tversky have themselves documented, however, research on other biases (for example, the hindsight bias) that are likely to be quite important for economics has benefited from the more general research programme to which they have centrally contributed. Indeed, the early collection of papers edited by Kahneman, Slovic, and Tversky (1982c) serves as a sort of early bible of the programme, and the later collection edited by Gilovich, Griffin, and Kahneman (2002) presents much of the subsequent research indicating the insights of this research programme.

Loss aversion, prospect theory, and choice under uncertainty
One of the most important and widely cited papers in economics of recent decades is Kahneman and Tversky's (1979) ‘Prospect Theory: An Analysis of Decision Under Risk’ . (An ISI Web of Science search in April 2006 indicates that this is the second most widely cited article in *Econometrica*, and the only article among the top ten most cited that was not concerned with econometric theory.)

Humans are typically more sensitive to how an outcome contrasts with reference levels than to the absolute level of the outcome itself: Kahneman and Tversky (1979, p. 277) stress that the salience of changes from reference points is a basic aspect of human nature:

An essential feature of the present theory is that the carriers of value are changes in wealth or welfare, rather than final states. This assumption is compatible with basic principles of perception and judgment. Our perceptual apparatus is attuned to the evaluation of changes or differences rather than to the evaluation of absolute magnitudes. When we respond to attributes such as brightness, loudness, or temperature, the past and present context of experience defines an adaptation level, or reference point, and stimuli are perceived in relation to this reference point (Helson, 1964). Thus, an object at a given temperature may be experienced as hot or cold to the touch depending on the temperature to which one has adapted. The same principle applies to non-sensory attributes such as health, prestige, and wealth. The same level of wealth, for example, may imply abject poverty for one person and great riches for another – depending on their current assets.

In the context of utility theory, people often feel the effects of changes and contrasts more intensely than absolute levels. (While the role of reference levels in decision making is often inconsistent with fully rational behaviour, Tversky and Kahneman, 1991, and others have shown that many reference-level effects can be captured within the framework of utility theory.)

Kahneman and Tversky identify two pervasive ways in which reference levels influence preferences and choice. First, people are *loss averse*: in a wide variety of domains, people are more averse to losses relative to their reference level than they are attracted to same-sized gains. Second, people exhibit *diminishing sensitivity*: the marginal change in perceived well-being is greater for changes that are close to one's reference level than for changes that are further away. While these features of preferences have much broader implications, the most important and striking are in the context of choice involving monetary uncertainty. Loss aversion implies that people are significantly ‘risk averse’ for even small amounts of money. People dislike losing $10 more than they like gaining $11, and hence prefer their status quo to a 50–50 bet of losing $10 or gaining $11. While such ‘first-order’ risk aversion is widely observed, the standard concave-utility function implies that people are close to risk-neutral for small stakes. Diminishing sensitivity also has a provocative implication for risk preferences: while people are likely to be risk averse over gains, they are often risk *loving* over losses. For instance, Kahneman and Tversky (1979) find that 70 per cent of subjects report that they would prefer a 3/4 probability of losing nothing and 1/4 probability of losing $6,000 to a 1/2 probability of losing nothing and 1/4 probability each of losing $4,000 or $2,000. The preferred lottery here is a mean-preserving spread of the less-preferred lottery; hence, the responses of 70 per cent of the subjects are inconsistent with the standard concave utility-for-wealth assumption. Subsequent evidence has suggested more varied and context-specific features of risk attitudes in the loss domain, but it supports the finding that people more often have risk-seeking preferences over modest-scale losses than over modest-scale gains.
Another important phenomenon attributed by most researchers to loss aversion is the striking endowment effect identified by Thaler (1980; 1985), and subsequently fleshed out by Kahneman, Knetsch and Thaler (1990). Once a person comes to possess a good, she immediately values it more than before she possessed it. An experiment in the latter paper nicely illustrates this phenomenon. A decorated mug (worth about $5) was placed in front of each of one-third of a group of students. Prices at which the subjects were willing to sell their mugs were elicited in a way that made it optimal for subjects to be truthful. Other subjects were asked to give the minimal amount of money that they would prefer to receiving that mug. These two groups faced exactly the same choice, but differed in their reference level – for sellers, losing the mug was a loss, while for ‘choosers’ no loss was involved. The average selling price was about $7.00, and the average exchange value for choosers was about $3.50. The difference in these amounts reflects an instantaneous effect of owning on object on the valuation of that object. Such an endowment effect is usefully conceptualized as a case of loss aversion. Individuals treated the endowed mugs as part of their reference levels, and considered subsequently not having a mug to be a loss, whereas individuals without mugs considered not having a mug as remaining at their reference point. The inducement of a nearly instantaneous endowment effect suggests that reference points ubiquitously influence decision making – with potentially significant economic consequences.

Besides this value function, a second important element of Kahneman and Tversky's (1979) multifaceted prospect theory is the fact that people do not evaluate uncertain prospects in the linear-in-probabilities way conventionally assumed by economists. Kahneman and Tversky argue that people maximize with respect to a monotonic nonlinear function of probabilities with the following properties: they ignore very low probability events, but among events they don't ignore low probabilities are overweighted and moderate and high probabilities are underweighted, and the latter effect is more pronounced than the former. Tversky and Kahneman (1992, p. 297) conclude that decision weights and the value function combine to imply ‘a distinctive fourfold pattern of risk attitudes: risk aversion for gains and risk seeking for losses of high probability; risk seeking for gains and risk aversion for losses of low probability’.

Framing effects

Probably the most striking and problematic departure from rationality emphasized in Kahneman and Tversky's early research is what they call the framing effect: two logically equivalent statements of a problem lead decision-makers to choose different options. Examples of framing effects typically involve differing frames whose logical equivalence is neither totally transparent nor terribly obscure. Because losses resonate with people more than gains, for instance, a frame that highlights the losses associated with a choice makes that choice less attractive. Tversky and Kahneman (1986, p. S260) demonstrate framing effects in a public-health context, asking subjects the following hypothetical question:

Imagine that the U.S. is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:

If Program A is adopted, 200 people will be saved.
If Program B is adopted, there is a one-third probability that 600 people will be saved and a two-thirds probability that no people will be saved.

Seventy-two per cent of subjects said that they preferred Program A over B. But they also asked another group of subjects the same question with the two programs framed thusly:

If Program C is adopted, 400 people will die.

If Program D is adopted, there is a one-third probability that nobody will die and a two-thirds probability that 600 people will die.

In this second group, 78 per cent preferred Program D. Although A vs. B and C vs. D are precisely the same choices, framing the choice in terms of numbers of lives saved clearly evokes ‘risk aversion’ in gains – better to save 200 lives for sure than an uncertain number of lives averaging 200. Framing the choice in terms of number of victims dying evokes ‘risk-loving’ attitudes in losses – the chance of preventing any deaths is very attractive. (While these and other questions are hypothetical, Tversky and Kahneman found similar effects among experienced physicians judging cancer treatment, suggesting that similar patterns might play out in the real world. Moreover, similar framing effects were found in choices over lotteries with small monetary stakes.)

Perhaps the most fundamental example of a framing effect – whose centrality to understanding risk attitudes and other economic choices has only recently begun to be fully appreciated by researchers – is that people assess risky prospects in isolation, rather than by aggregating them. As an illustration of isolation errors, Tversky and Kahneman (1986, p. S255) ask subjects to ‘Imagine that you face the following pair of concurrent decisions. First examine both decisions, then indicate the options you prefer.’ To simplify, the choices were:

Choose between:

- A: $240 for sure
- and
- B: (.25+$1,000, .75 $0)

Choose between:

- C: – $750 for sure
- and
- D: (.75 – $1,000, .25 $0)

Eighty-four per cent of subjects chose A over B and 87 per cent chose D over C – in accordance with the principles of diminishing sensitivity. But, when subjects’ choices for both decisions were combined, 73 per cent chose the combination AD, 11 per cent chose AC, 14 per cent chose BD, and three per cent chose BC. The problem with these choices is that AD is in fact a 75 per cent chance of losing $760 and
25 per cent chance of no change, while BC is a 75 per cent chance of losing $750 and 25 per cent of no change. BC is clearly better than AD. The fact that most people made the choice AD when asked to choose separately clearly indicates that they did not integrate the decisions. (Indeed, in groups of other subjects asked to make just one of the A vs. B or C vs. D choices in isolation, 85 per cent chose A over B and 86 per cent chose D over C, virtually the same as those choosing for both choices.) Such examples were also observed for real (but smaller) monetary stakes by Tversky and Kahneman and subsequent researchers. In recent years, this notion that risk attitudes are fundamentally influenced by ‘narrow framing’ has become a major theme of research as researchers have begun to establish that loss aversion is not itself a sufficient explanation for modest-scale risk aversion without such narrow framing. (If people hated losses but integrated their losses and gains across different choices, they would become de facto risk neutral by cancelling out losses with gains.)

Fairness

Many economists have over the years discussed the existence and economic implications of preferences that depart from pure self-interest, as narrowly defined. But much of the credit for introducing the empirical study of the economic implications of fairness judgements into economics should go to Kahneman, Knetsch, and Thaler (1986). Their interest is positive, not normative: instead of studying normative standards of what we as policymakers (or philosophers) might consider fair allocations or appropriate social-welfare functions, they study with surveys what a typical economic actor might assess as fair or unfair behaviour. For instance, they asked subjects to assess the fairness of reducing the wages of current employees as opposed to hiring new employees at lower wages after normal turnover in response to market unemployment. They found that respondents are likely to consider lowering wages to current workers unfair, while they consider using market conditions to set new wages acceptable. Respondents also considered it unfair to raise the price of peanut butter already in stock in response to a rise in the wholesale price of peanut butter – much as people protest when gas stations immediately raise prices on petrol in stock in response to an increase in wholesale petrol prices. Kahneman, Knetsch, and Thaler identify some more general principles with their surveys: people generally find it acceptable for firms to raise prices or lower wages in response to concurrent shifts in their costs, but not in response to demand shifts or to shortages.

Decision utility, experienced utility, and happiness

The research on heuristics and biases discussed above indicates that people misjudge the probabilistic consequences of their decisions. But a spate of recent research suggests that, even when they correctly perceive the physical consequences of choices they make, people may systematically misperceive the hedonic consequences of those choices. As Kahneman (1994, pp. 20–1) argues,

… it may be rash to assume as a general rule that people will later enjoy what they want now. The relation between preferences and hedonic consequences is better studied than postulated. These considerations suggest an explicit distinction between two notions of utility. The experienced utility of an outcome is the measure of the hedonic experience of
that outcome. … The decision utility of an outcome, as in modern usage, is the weight assigned to that outcome in a decision.

Kahneman (2000) summarizes and provides a conceptual framework for understanding utility misprediction, and identifies several errors in this domain. He argues, for instance, that in forecasting future utility people tend to use the ‘transition rule: predictions of a person's initial reaction to a new situation, which may be quite accurate in itself, is incorrectly used as a proxy to forecast the long-term effects of that situation’ (2000, p. 703). The most important error resulting from this is the tendency to under-appreciate the hedonic effects of adaptation, leading people to exaggerate changes in utility caused by small and big changes in their lives. Kahneman and fellow researchers have also conducted a series of experiments demonstrating that another source of misprediction of future utility actually comes from a biased evaluation of past episodes: even when people might well recollect the momentary hedonic sensations from past experiences, they might be bad at ‘adding up’ these hedonic sensations from extended episodes. Through comparing moment-by-moment evaluation with retrospective evaluation of episodes (such as unpleasant medical procedures), they show that people are biased in sundry ways: retrospective evaluation tends to be over-influenced by such factors as extreme moments and final moments, and people are subject to ‘duration neglect’, with intensity of an episode looming much larger than its duration.

More generally, especially in light of potential flaws in how people manage their well-being, Kahneman and others have launched research that may help move economics towards a more realistic approach to welfare analysis. As an editor of and contributor to a recent volume (Kahneman, Diener and Schwarz, 1999), indeed, Kahneman is a leader in the exciting new focus in social science and public policy on the study of what makes people happy.

Conclusion

Daniel Kahneman, despite his accolades and influence in economics, is a psychologist and self-identifies as such. Although many of the examples and motivations in his research are quite directly inspired by economic concerns, his research rarely constitutes traditional economic analysis per se. But with the gradual rise of ‘behavioural economics’ as a field of research, and more recently as this research programme has moved into the mainstream, the insights established in his research has become ever more widely influential.

housing markets and policy; Kain, F. K.; residential segregation; school achievement; spatial mismatch hypothesis; urban economics; urban simulation models

Article

John Kain was an empirical economist who significantly changed analysis and modeling in urban economics. Modern urban economics was extensively developed during the 1960s, and Kain's contributions were particularly important in several key areas. His most famous line of inquiry revolved around the interactions of race and urban location and the importance of housing segregation for black welfare. He was also one of the early pioneers in developing general equilibrium urban simulation models that were capable of addressing interesting and important policy questions. His analyses of urban transportation policies have been influential in both developed and developing countries (Meyer, Kain and Wohl, 1966). A fourth significant endeavour, while having some of the same underpinnings, went to the issues of educational achievement.

His influential paper on the spatial mismatch hypothesis started a large line of inquiry (Kain, 1968; 1992). The innovative idea was that housing segregation kept blacks in areas that were increasingly farther from jobs (which were rapidly decentralizing from more central locations). As commuting to work became more costly, black employment suffered. Kain's connection of urban location, housing, and labour markets was a true innovation. A second important inquiry was the investigation of how segregation affected black housing costs and home ownership (Kain and Quigley, 1972). His early urban simulation models were developed to permit investigation of how multiple housing and job locations interact with a variety of housing policies and urban dynamics (for example, Ingram, Kain, and Ginn, 1972).

These urban studies derived from his intense interest in the intersection of geography, schools and race. In a different direction, he originated the use of large-scale administrative databases on school achievement to study the elements of human capital formation (Rivkin, Hanushek and Kain, 2005). But, again, he emphasized the fundamental influence of race on opportunities and outcomes (Hanushek, Kain
Ultimately, one of his most important and lasting influences was legitimizing the study of the economics of race through showing its fundamental importance to a range of social issues. Before his systematic work, few economists considered the economic influence of race and segregation. He received his Ph.D. from the University of California at Berkeley. Most of his career was spent in the Department of Economics at Harvard University, although he also taught at the US Air Force Academy and the University of Texas at Dallas. His last position at the University of Texas at Dallas led to his development of the extensive stacked panel databases on school performance.

Article
Nicholas Kaldor was born in Budapest. From 1927 to 1947 he studied and taught at the London School of Economics. Then, following two years at the Economic Commission for Europe in Geneva, he moved to Cambridge University, where he became a fellow of King's College and, in 1966, professor of economics. He was elevated to the peerage in 1974, as Baron Kaldor of Newnham. (For more biographical information, see Kaldor, 1960–89, vol. 1, pp. vii–xxxi, and Pasinetti, 1979.)

Kaldor was always passionately involved with practical problems of economic policy. As a (vigorously dissenting) member of a British Royal Commission in the early 1950s, he acquired international renown in the field of taxation. But he also constantly addressed the major domestic and international economic issues of the day – in books and journal articles, in letters to newspapers, in lectures and speeches, and through personal contacts. He was special advisor to the British Chancellor of the Exchequer in 1964–8 and 1974–6, and also gave advice to the governments of many other countries, and to various international organizations. Though a defender of the private enterprise market system, he consistently advocated government intervention to make capitalist economies more productive and equitable, and has devised many policies and instruments for this purpose.

Yet Kaldor's main intellectual interest, and the main basis of his fame as an economist, was always theory – simplified analytical description of how economies function. Driven from within by logic,
creativity and curiosity, he nonetheless became a committed advocate and exponent of the inductive method – that to be fruitful, theory must spring from (and constantly be tested against) direct observation of reality. His involvement in practical matters contributed to, as well as benefited from, his theoretical work; and he was a steady and perceptive consumer of statistics and the empirical work of other economists.

Range and evolution of Kaldor's thought

Kaldor's theoretical contributions cover an astonishing range. And on many topics, his views changed over time – sometimes evolving linearly, sometimes being rejected and replaced with contrary views. His nine volumes of *Collected Economic Essays*, with illuminating retrospective introductions, amply document the scope and chronological progress of his theorizing – important aspects of which are concealed in many of the ostensibly non-theoretical essays. Studies of his work include Nell and Semmler (1991), Targetti (1992) and Turner (1993).

During the 1930s, with Hicks, Hayek, Robbins and Scitovsky among his friends and colleagues, Kaldor made several notable contributions to mainstream neoclassical theory. He named the cobweb theorem, introduced the idea of compensation tests into welfare economics, and clarified the relationship between tariffs and the terms of trade. He also entered into the prevailing controversy on the theory of capital, defending the Austrian view against the criticisms of Knight (though he later came to accept that the concept of roundaboutness could not solve the problem of measuring capital in homogeneous units, and indeed to reject the whole idea of interpreting the rate of profit or interest as the marginal product of capital).

But much of his theoretical work during this period revolved around the firm and imperfect competition. Like others, he saw the supply curve as a weak link in competitive theory, arguing that diminishing returns to scale do not convincingly explain firm size, and hence that perfect competition is not compatible with equilibrium. He accordingly welcomed the emphasis that Joan Robinson and Chamberlin gave to demand-side limitations on firm size in imperfectly competitive markets, being particularly impressed by Chamberlin's reconciliation of imperfect competition with free entry. At the same time, however, he criticized them for assuming that firms in imperfectly competitive markets generally face conventional demand curves. More commonly, Kaldor contended, such firms must take direct account of the reactions of a relatively small group of rivals to their price and output decisions. Though Kaldor never lost sight of the importance of microeconomic foundations, the publication of Keynes's *General Theory* greatly stimulated his interest in macroeconomics, as well as setting him on the path to becoming a committed critic of mainstream neoclassical theory. The first fruits of this change were two essays closely related to Keynes's own theorizing. One was on speculation and economic stability, focusing on the relationships between changes in demand and supply flows and changes in speculative stocks, and between price stability and income stability. Among other things, this essay argues that the long-term interest rate cannot adjust sufficiently to equate current saving and investment because it is constrained by the bond market's concept of a normal interest rate, which is simply the expected future average of short-term rates (themselves determined by the prevailing balance between the transactions demand for, and the supply of, money). The second essay – of equal analytical power, though less influential – concerned own-rates of interest.

There then followed some prominent contributions to trade cycle theory. Kaldor criticized simple
multiplier–accelerator models for having to be either unrealistically stable or unrealistically unstable. He argued that a convincing theory of purely endogenous cycles would need to be based on nonlinearities in the investment function, but also that in reality cycles are not purely endogenous. In particular, he suggested that entrepreneurial dynamism could cause cumulative upswings of investment that periodically crashed against exogenous barriers such as full employment or bottlenecks in the supply of capital goods. This approach, and perhaps also the sustained prosperity of the 1950s, gradually led him to become less interested in cycles as such, and much more interested in long-term economic growth.

The first main phase of his work on growth, which lasted until the mid-1960s, found expression in a series of formal steady-state models. Though similar to other such models in some respects, including the assumptions that full employment generally prevails and that long-term growth of output is governed by supply rather than demand, Kaldor's models have two important distinctive features. One is an original theory of distribution, whereby the share of profits in national income is determined by the share of investment, which in turn depends on the aggregate capital–output ratio and on the (independently given) aggregate growth rate. Another way of expressing this theory is to say that the aggregate profit rate on capital is determined by the aggregate growth rate – an approach further developed by Pasinetti (1962), and in Kaldor's subsequent neo-Pasinetti theorem.

The reason for this linkage between profits and investment is that the proportion of profits saved (by enterprises, not by rentiers) is much higher than the proportion of wages saved. As a result, an economy can achieve the aggregate saving rate needed to sustain any given growth rate through adjustment of the share of profits in its national income. This Kaldor regarded as a long-term generalization of a Keynesian principle – that investment determines savings, rather than the other way round. He opposed it to the neoclassical principle that ‘availability of capital’ constrains growth and governs the rate of profit.

The other distinctive feature of Kaldor's formal growth models is his technical progress function. He rejected the neoclassical concept of a production function that is shifted over time by autonomous technical progress, and indeed the whole notion that productivity gains due to capital accumulation are separable from those due to technical advance. Instead, he argued that the knowledge needed to increase productivity is acquired through a process of learning that is inseparable from the process of investment, and hence that the pace of applied technical progress depends on the rate of investment (which in turn depends on entrepreneurial expectations of profitability and risk). This principle was eventually formalized, in an ingenious vintage model developed with Mirrlees, as a relationship between the rate of change of gross investment per worker and the rate of increase in labour productivity on newly installed equipment.

During the 1960s, however, Kaldor's own empirical research and practical experience caused him to become deeply dissatisfied with formal macroeconomic growth models. Their microeconomic underpinnings seemed inadequate. They were excessively aggregated, and did not capture the different characteristics of (and critical relationships between) the various broad economic sectors. Their assumptions of full employment and of growth governed solely by supply appeared increasingly implausible. And they failed to come to grips with international economic linkages and the spatial pattern of development.

These concerns launched the second main phase of Kaldor's work on growth, in which several fundamentally new ideas displaced or modified some – but by no means all – of the principles of the first phase, and in which some of his earlier theoretical insights were reintroduced. This work was not,
however, embodied in formal models. Nor, more generally, did Kaldor ever attempt a comprehensive theoretical treatise, showing how his ideas in different areas fitted together, and how new ideas in particular areas affected his thinking in other areas. For this reason, the rest of the present article will try to summarize the latest versions of Kaldor's theories in several areas, and to assemble them into a relatively complete Kaldorian view of how the world works. A number of questions can be raised about this view, some calling for theoretical amplification, others for more empirical research. But all theories have shortcomings; and economists choose among alternative theories ultimately on the basis of their strong points, not their weak points. It is thus on the strengths and insights of the Kaldorian view that this article will concentrate.

The process of economic growth

Kaldor's account of growth provides the context for most of his theorizing in other areas. Like Ricardo, he drew a sharp distinction between industry and primary production.

Increasing returns

In industry, especially in manufacturing, growth of output per worker arises principally from static and dynamic economies of scale, whose realization depends on (but also contributes to) expansion of markets for industrial products. Increasing returns, noted by Smith but subsequently emphasized by only a few economists such as Marx, Marshall and Allyn Young (who taught Kaldor at LSE), are a multifaceted and pervasive feature of industrial production. They often exist at plant and firm level. They are to be found also at the industry level, where larger scale permits greater internal specialization of production among different firms (many of which may in fact be small). Finally, increasing returns operate at the 'macroeconomic' level, partly because different industries stimulate each others' development through demand and supply linkages, partly because all of them benefit from a common labour market large enough to justify the development of many highly specialized skills.

Increasing returns and technical progress are intimately related. This is because the construction and operation of larger-scale plants, the finer subdivision of production processes, and the emergence of more specialized skills, all require the development and application of new knowledge. Each pathbreaking stage of realization of scale economies is initially painful and problematic; but effort and experience gradually eliminate the problems and realize the full potential of this technical stage, making it possible to plan and implement the next step forward. (Increasing returns are thus not simply a static function of the scale of production, but also of the cumulative amount of production over time.)

Scientific advances, and better technical and general education, facilitate industrial growth, but do not drive it.

Much the same is true, in Kaldor's view, of the accumulation of physical capital. Sustained growth of labour productivity in industry requires investment, mainly because a finer division of labour can generally only be realized through increased mechanization – more capital per worker. This explains why the secular growth of modern industry has entailed continuing increases in both output per worker and the capital-labour ratio, but much less change in capital-output ratios (and why there are large differences in capital-labour ratios, but no systematic differences in capital-output ratios, between rich and poor countries). It also explains why rapid industrial growth is associated with high ratios of...
investment to output. But it is not the investment that is generating the growth; rather, it is the growth that is generating the investment.

Increasing returns cause a strong statistical correlation, for example across countries, between growth of industrial labour productivity and growth of total industrial output. (This is known as Verdoorn's Law, after the economist who first noticed the correlation.) On average across industries, and over periods of a decade or more, industrial labour productivity nonetheless generally grows slower than total industrial output. This means that relatively rapid industrial labour productivity growth tends to involve relatively rapid growth of industrial employment.

**Sectoral complementarities**

Agriculture and mining are subject not to increasing but to decreasing returns. Over time, the productivity of most land is increased through accretion of technical knowledge; but in Kaldor's view, technical progress in primary production is more exogenous – less responsive to the need for it – than in industry, which means that there is a relatively inflexible upper limit on the rate of growth of primary production. Nor are the primary sectors subject to Verdoorn's Law – labour productivity growth is generally independent of output growth.

In a closed system, this technically determined upper limit on the rate of primary production growth is the main long-term constraint on the growth rate of industrial production, and hence on the growth of the whole economy. One reason for this is that expansion of industrial production requires increased amounts of food for industrial workers and of raw materials for processing. Relatedly, growth of primary production and incomes is a vital source of growth in demand for the products of industry. For industrial expansion cannot be self-sustaining, simply because a significant part of the incomes generated in industry is spent on non-industrial goods such as primary products.

To offset this leakage of industrial demand into other sectors, there must clearly be demand for industrial products from the incomes generated in other sectors. But Kaldor's position is stronger and more specific, namely, that growth of demand from the primary sectors in a closed economy actually determines the long-term growth rate of industrial production. This is because there is no enduring limit to growth within industry itself: the supply of industrial capital, labour, knowledge and skills will generally respond to whatever happens to be the rate of growth of overall demand for industrial products. It is also because expansion of demand for industrial products from within the industrial sector is in the long term passively determined by expansion of industrial production. (Kaldor regarded all this as a long-run generalization, albeit confined to industry, of the Keynesian principle that output is determined by effective demand, combined with Harrod's concept of the foreign trade multiplier and Hicks's concept of the supermultiplier.)

For primary production to constrain the growth of a closed economy, decreasing returns (and comparatively unresponsive technical advance) in agriculture and mining are essential, since otherwise primary output could be profitably increased to any required level simply by a larger allocation of capital, skilled labour and research expenditure. It is likewise important that the primary-industry terms of trade not be completely flexible, since otherwise any primary sector output constraint on industrial growth might be overcome by an increase in the prices of agricultural and mining products relative to industrial products, which could make a larger volume of primary output profitable, increase the purchasing power of primary producers over industrial goods, and switch some industrial purchasing
power from primary to industrial products. This does not happen, in Kaldor's view, because industrial wages – and hence industrial prices – are inflexible downwards in terms of their purchasing power over primary products, especially food. The primary-industry terms of trade thus cannot improve enough to prevent primary sector production from constraining the long-term pace of industrial growth.

A substantial share of output and employment in all economies of course derives from neither the primary nor the industrial sector, but from services. However, Kaldor argued that service sector expansion is not generally an active ingredient of economic growth, but rather a consequence and complement of expansion in other sectors, particularly industry. He also argued that in high-income countries the service sector acts as an industrial employment reservoir, since (for reasons discussed below) it usually contains a considerable proportion of underemployed workers, who are paid less than workers in industry and are thus willing and able to fill industrial vacancies as they arise. In low-income countries, by contrast, agriculture is the main reservoir of industrial labour. But in both sorts of countries the existence of these reservoirs is one of Kaldor's main reasons for arguing that expansion of industrial output is not normally constrained by availability of labour.

Cyclical interruptions

Economic growth is not mechanical or smooth. Even though its long-run path is governed by certain basic constraints and linkages, entrepreneurial dynamism – expectations of future growth – is what keeps the process going. Shocks and disturbances of many kinds are constantly disrupting the process in an upward or downward direction. But the resilience of entrepreneurial expectations normally tends to damp rather than to amplify these disturbances, and gives the long-term growth path a momentum sufficient to transcend temporary shocks. The momentum can be broken, however, in deep and sustained recessions, which may cause an enduring downward shift of business expectations and hence the actual growth rate for long periods to fall below the maximum imposed by technical advance in the primary sectors.

Kaldor regarded the volatility of primary product prices as an important source of economic instability, especially when expectations of normal prices for these products are weak (and hence movements in speculative stocks reinforce rather than offset price changes arising from demand or supply fluctuations). A large fall in primary product prices tends to retard industrial growth by slashing the purchasing power of primary producers over industrial products. But a large rise in primary product prices does not have symmetrical benefits for industry, since it tends to push up industrial wages and prices, and provokes governments to deflate. (For reasons of this kind, Kaldor strongly advocated international buffer stock schemes to stabilize the general level of primary product prices, ideally in the form of a commodity-backed world currency).

The resilience of entrepreneurial expectations in the face of temporary disturbances causes increasing returns to be a short-term as well as a long-term feature of industrial production. This is partly because firms deliberately expand capacity somewhat ahead of demand, partly because they base their employment decisions on medium-term prospects rather than immediate needs. As a consequence, and because increases and decreases in aggregate demand tend to be spread across efficient and inefficient firms alike, industrial labour productivity normally rises in booms and falls in slumps. Only in a severe recession, when business expectations are badly dented and financial reserves are exhausted, do the least efficient firms close down – thus checking the fall in productivity and causing the industrial sector to
display some signs of decreasing returns.

**Spatial patterns and relationships**

The ‘closed economy’ to which the growth model sketched above applies most directly is the world as a whole. But Kaldor also offered a theoretical explanation for the differing development paths of the various geographical subdivisions of the world economy, and a complementary account of the determinants and consequences of trade among these subdivisions. The spatial pattern of primary production and trade is more or less self-explanatory, being determined mainly by the unalterable location of natural resources. Kaldor thus focused mainly on industrial development, and especially on the reasons for its tremendous spatial unevenness – its long-term tendency to become concentrated in particular cities, regions, and countries.

**Cumulative causation**

The root cause of the unevenness of industrial development is increasing returns, which mean that success tends to breed further success, and that failure also tends to be self-perpetuating. For example, within a particular country or region, any locality that somehow becomes a substantial centre of industry will thereby achieve higher labour productivity than other smaller industrial centres, which, with fairly uniform wages, will mean lower unit labour costs. The firms in the larger locality will thus be able to charge lower prices or to spend more on marketing and product development, which will cause their sales to increase at the expense of their competitors in the smaller industrial centres. They will thus be able to expand production, further increasing their labour productivity and competitive advantage, and so on, with migration of workers from the declining smaller centres overcoming any labour shortages in the expanding larger centre.

Even within a single country, and even without deliberate government intervention, the eventual outcome will not necessarily be the concentration of all industry in a single place. This is because increasing returns, possibly in conjunction with diseconomies of urban agglomeration, may cause different large centres to specialize in different industrial products. There are also forces which retard the disequalizing process. One is the automatic redistributive effects of a unitary fiscal system. Another is that the smaller centres usually derive some offsetting benefits from expansion of the larger centres, including a bigger market for some of their products. But their growing competitive disadvantage is ultimately more important, and hence they tend to fall further and further behind.

Kaldor also emphasized a subtly different version of cumulative causation, based on the Verdoorn relationship between growth of industrial output and growth of industrial labour productivity, coupled with the assumption that the relative growth rates of exports from different localities depend on relative growth rates – rather than relative levels – of unit costs. This makes differences in industrial growth rates self-perpetuating. For, just as in a closed economy the long-term rate of industrial growth is governed by growth of demand from primary producers, so for a particular locality the necessary ‘external’ determinant of industrial growth is its growth rate of industrial exports. A locality whose industrial output happens to be growing relatively fast thereby has relatively rapid growth of labour productivity. In so far as wages are uniform across localities, it therefore has relatively slow growth of unit labour costs, and can thus achieve relatively rapid growth of exports. This causes the locality to
sustain relatively rapid output growth, and so on. Kaldor regarded cumulative causation as important also in explaining the differing industrial development paths of different countries. Rapid industrial output growth, rapid labour productivity growth, and rapid export growth constitute a virtuous circle for some countries, with a corresponding vicious circle of low growth for others. But the underlying mechanism cannot be exactly the same as for different localities within a single country, because restrictions on international migration mean that wages are not uniform across countries. Moreover, empirical observation confirms what Kaldor's own theory of distribution implies, namely, that variation in the level and growth of real wages across countries is closely related to variation in the level and growth of average labour productivity. This clearly reduces the competitive advantage in international markets that countries with higher or faster-growing productivity would otherwise possess.

Indeed, Kaldor himself for many years argued that real wage rate changes brought about by regular exchange rate adjustments (with dual exchange rates for developing countries) could prevent cumulative causation at the international level. Experience with floating exchange rates after 1971, however, led him to the conclusion that neither exchange rate adjustments nor linkages between productivity and real wages are in practice sufficient to neutralize cumulative causation. There are various possible reasons for this. One is that the demand for industrial products is much more sensitive to quality than to price: increasing returns may thus involve feedback from faster output growth to faster product quality improvement, which increases international competitiveness and hence makes for faster export growth, faster output growth and so on.

Development and trade policy

Cumulative causation explains why places which acquire an initial advantage in industrial production tend to consolidate and increase this advantage at the expense of other places. Yet why do some places, rather than others, get ahead initially? Kaldor argued that this cannot usually be explained by the location of natural resources, nor by endowments of industrial capital or skills (which are for the most part generated by industrial growth itself). More important are transport facilities and general education, as well as social and institutional circumstances, which affect the willingness of individuals (or government organizations) to become entrepreneurs, and their ability to obtain bridging finance and to recruit a factory labour force. But what starts the process going is some stimulus to local industrial production, typically provided by deliberate protection against (or extraneous interruption of) imports. Kaldor therefore advocated protection or subsidies (of one sort or another) for infant industries, which can enable backward places to get the virtuous circle of industrialization started. He also argued that protection may be needed to prevent decline in an industrialized place (such as the UK) that has somehow begun to slip behind. At the same time, he emphasized that high or indiscriminate protection may be harmful. This is partly because it causes production to be spread thinly over many industries, none of which benefits sufficiently from increasing returns. It is also because protection discourages industrial exports, whose growth is in Kaldor's view essential – to pay for the increasing imports required by industrial expansion, to realize scale economies in particular industries, and to provide a dynamic external source of demand to propel the whole industrial sector. In this and other senses, Kaldor's emphasis on increasing returns caused him to have very mixed feelings about trade. On the one hand, trade can have destructive or disqualifying effects. On the other hand,
trade is essential to the expansion of markets needed for the realization of increasing returns and hence for economic growth. The world as a whole therefore benefits from faster growth of trade, and most advanced (and some developing) countries from increased industrial specialization and exchange. The problem for policy – which Kaldor himself regarded as largely unsolved – is how to secure these collective benefits without aggravating the difficulties of industrially weak or backward places.

**Markets, prices and wages**

Kaldor's macroeconomic view of growth both stems from and contributes to his microeconomic view of how markets function. For primary products, his account of price formation is basically conventional – demand and supply under perfect competition – though modified to allow for the important influence of changes in stocks held by dealers and speculators.

**Imperfect competition**

Industrial and service enterprises, by contrast, are generally neither atomistic, passive price-takers nor static monopolies preoccupied with marginal adjustments in the face of given demand and technology. Instead the main task of most enterprises is to seek and develop both markets and technological opportunities, under competitive pressure from other enterprises. Enterprises generally do not have a well-defined optimum size, and they usually operate with excess capacity (either involuntarily or in order to be able to take advantage of unexpected sales opportunities), so that their actual size at any moment is determined by the demand for their products. Over time, by attracting more demand, many enterprises grow. Indeed, with increasing returns, industrial enterprises must grow in order to remain competitive.

Kaldor emphasized the force of competition in most markets for industrial goods and services, but also that it is imperfect, since firms have some discretion in setting their prices, and since non-price competition is important. He distinguished two main types of imperfect competition. One is polypoly, in which numerous firms – which can freely enter or leave the market – supply more or less imperfectly substitutable products. The number of competitors is too great for each firm to take direct account of the possible reactions of other firms in setting its price, which it accordingly does with a markup based on its perception of the elasticity of demand for its own product. But although prices are thus set above marginal costs, free entry ensures that the rate of profit on capital is not more than normal, by obliging firms to operate with excess capacity – underutilization of indivisible overhead inputs. (In services such as commerce, where polypoly often prevails, labour is usually treated as an overhead cost, which explains why these sectors act as reservoirs of underutilized labour, even in advanced countries.)

The other form of imperfect competition is oligopoly, where a smaller number of sellers (often the result of increasing returns) must consider each other's reactions in price setting and similar decisions. Kaldor regarded price leadership as the most common type of behaviour in this situation, with most firms tailoring their own market strategies to that adopted by one of the largest and most efficient firms. All firms tend to set their prices on the basis of markups over costs at normal capacity use, and not to vary their prices in the face of temporary fluctuations in demand. Nonetheless, the need to remain competitive with the leader greatly influences the size of the markups chosen by individual firms, and in particular means that less efficient firms must accept smaller margins of profit.
It is clearly important in this model of oligopoly to explain how the leading firm sets its own profit markup. Kaldor argued that this involves striking a balance between two opposing pressures, both arising from a desire to make the firm expand as fast as possible (which in Kaldor’s view serves the interests not just of managers but also – in an uncertain world of increasing returns – of shareholders). One is the need to compete demand away from other firms, by lower prices or higher marketing and product development expenditure, which requires a low profit margin. The other is the need to finance investment in capacity expansion, which requires a high profit margin. This is because borrowing and new share issues are necessarily limited in relation to existing equity capital, and hence enterprises must rely heavily on retained profits as a source of finance.

Though Kaldor regarded this account of profit margin determination as relevant mainly to the leading firm in each market, it could apply more generally, especially when price is only one of a number of dimensions of market strategy. This is because each follower firm presumably also wants to grow, and also faces an inverse trade-off between its profit margin and expansion of its share of market demand, as well as needing to finance much of its capacity expansion internally – even though its maximum attainable growth rate will normally be less than that of the market leader. In any event, such an account of behaviour on the part of the average or representative firm (as in Wood, 1975) fits well with Kaldor’s macroeconomic theory of profits, discussed earlier.

**Real, relative and money wages**

This theory of profits ties real wages to average productivity, except in low-income countries, where they may be governed by a subsistence minimum. Actually, Kaldor distinguished two such subsistence minima, one applicable to traditional agriculture, the other to industry, where higher food intake requirements (because of more intensive work) and other expenses of factory employment necessitate higher wages. Even at higher income levels, industrial real wages – especially in terms of primary commodities such as food, and especially where unions are powerful – tend to be inflexible downwards from whatever level they happen previously to have been raised to by productivity growth. Although relative wage rates within the industrial sector tend to be rather rigid, and although labour market pressures may tend to equalize wages within agriculture and within services, wages are not normally uniform across these broad sectors. The initially large wage gap between agriculture and industry tends to diminish in the course of development, as more and more labour is sucked out of agriculture into other employment. But a similar wage gap between the industrial and service sectors tends to persist, fluctuating cyclically as workers released from industry in periods of recession crowd into service jobs, with a reverse flow in booms. Only perhaps at a very mature level of development would wages tend to equality across all broad sectors.

The average level of money wages, which is the main determinant of the absolute level of prices, has a life of its own, and tends to rise spontaneously in economies where collective wage bargaining is widespread, even in the face of substantial unemployment. Kaldor was inclined to believe that no simple general model can explain why money wages have risen at different rates in different places and at different times. But he identified some key elements, including efforts by unions in fast-growing industries to capture some of the profits created by productivity growth, imitative transmission of wage increases from one industry to another, and generalized resistance to real wage reductions. He has also consistently advocated the control of inflation through incomes policy (with restraint of dividends as
well as wages), despite the many practical problems involved.

**Fiscal and monetary policy**

Though well aware of the political obstacles to effective tax reform, Kaldor regarded taxation as the best available instrument for improving the distribution of income (as well as for altering the composition of production and expenditure). His extensive writings on tax policy covered many issues, theoretical and practical. But one consistent theme was equity as between different sources of income, and specifically the need to ensure that income from property bears a fair (but not penal) share of the tax burden. This motivated, among other things, his well-known pioneering proposal to change the basis of progressive personal taxation from income to expenditure, which better covers capital gains and other windfalls. In macroeconomic management, Kaldor subscribed to the Keynesian view that effective demand is crucial and can be powerfully influenced through the budget. He also believed, however, that full employment and sustained growth in an open industrial economy cannot be secured simply through fiscal deficits, because these tend to be reflected in (ultimately unsustainable) foreign trade deficits. Instead, employment and growth objectives must be approached, for theoretical reasons discussed above, by operating on the foreign trade multiplier – especially on the rate of increase of exports, but also on the propensity to import. Yet this, Kaldor thought, is in practice not at all easy, since exchange rate adjustments are not very effective, even if coupled with an incomes policy to prevent offsetting money wage adjustments. Measures aimed at the basic determinants of international competitiveness, such as faster replacement of equipment and increased expenditure on training and product development, can make a significant contribution; but subsidies and protective tariffs or their equivalent may also be necessary.

Kaldor attached much less importance to monetary policy. The financial system is vital to modern capitalism, especially because it enables investment to be relatively independent of the current level of income. But the demand for money is not a stable function of income. Nor can the authorities effectively control the money supply, which in a credit money economy is largely endogenously determined by the needs of enterprises and households. On these grounds, Kaldor always rejected the view that regulation of the money supply is an important ingredient of macroeconomic policy, even though interest rates can be directly manipulated to influence some components of domestic demand and international capital flows.

**Conclusion**

No second-hand account of Kaldor's economic theorizing can capture the force and vitality of the original, which greatly influenced many other economists, especially those fortunate enough to have been his students or colleagues in Cambridge. Nor can one adequately convey in a few pages the tremendous scope and depth of Kaldor's theoretical work. Finally, a survey like this is liable to give a misleadingly settled impression. Kaldor's thinking evolved constantly, and in its latest form – as at earlier stages – contained gaps, loose ends, inner tensions and unanswered empirical questions, which will provoke further progress. But it is an analytical framework of great range, power, and practical relevance, which constitutes a major contribution to our understanding of the way in which economies work.

Kalecki, Michal (1899–1970)

Malcolm Sawyer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article gives an outline of the life and work of Michał Kalecki, in particular his contributions on macroeconomics in capitalist economics, including his discoveries of the role of effective demand, the significance of investment, the interplay between profits and investment and the degree of monopoly. His writings on socialism and on development are also outlined.

V.; socialism; state capitalism; unemployment; wage determination; workers’ councils

Article

Michal Kalecki was born on 22 June 1899 in Lodz, Poland, and died in Warsaw on 17 April 1970. His academic training was in engineering, and he was self-taught in economics, influenced by writers such as Marx and Rosa Luxemburg. He obtained his first quasi-academic employment in 1929 at the Research Institute of Business Cycles and Prices in Warsaw, where his work involved the study of business cycles and the preparation of reports on specific industries. A Rockefeller Foundation Fellowship allowed him in 1936 to study abroad in Sweden and then England, where he remained for the next ten years; during the Second World War he was employed at the Oxford University Institute of Statistics. After work for the International Labour Office in Montreal, Canada, in 1945 and 1946, Kalecki was appointed at the end of 1946 as deputy director of a section of the economics department of
the United Nations secretariat in New York. In that job, a major task was the preparation of the World Economic Reports. When a board of directors was appointed to exercise control over that Report, which he and others viewed as McCarthyite American involvement in the work of the UN, he resigned in protest. Kalecki returned to Poland in 1955. He served as a consultant on economic planning with the government and then with the Planning Commission (1955 to 1964), and was heavily involved in the debates over the role of decentralization and of workers’ councils, the speed of industrialization and the relative size of consumption and investment. He undertook research and teaching at the Polish Academy of Sciences between 1955 and 1961. The centre of his activities after 1961 was the Central School of Planning and Statistics.

In his analysis of capitalist economies, Kalecki discovered a range of ideas on the importance of effective demand and the role of investment similar to those discovered by Keynes, but Kalecki can claim priority of publication (Kalecki, 1933; Keynes, 1936). While there are similarities there are also differences, for example over the determinants of investment, the perception of the economy as competitive or oligopolistic (on the relationship between Kalecki and Keynes, see Sawyer, 1985, ch. 9).

A central element in Kalecki’s work was the idea that the level of economic activity would be determined by the level of aggregate demand, and that investment decisions were a particularly significant element in the determination of the level of demand. Any decision to increase investment expenditure can come to fruition only if the finance is available, and the provision of additional finance comes through the banking system. Actual investment expenditure generates a corresponding amount of savings. Kalecki argued that savings were undertaken predominantly out of profits, and he often assumed as a first approximation that workers did not save, and hence investment expenditure in aggregate determined the volume of profits. As Kalecki wrote, ‘capitalists as a class gain exactly as much as they invest or consume, and if – in a closed system – they ceased to construct and consume they could not make any money at all’ (Kalecki, 1990–97, vol. 1, p. 79). If $s_p$ is the propensity to save out of profits, and if there are no savings out of wages, then in a closed economy $s_p P = I$ where $P$ is profits and $I$ investment, with the direction of causation here running from investment to profits. The assumption that wages are spent and the view that capitalists’ expenditure determines their income was reflected in the aphorism that was ascribed by Joan Robinson to Kalecki – ‘the workers spend what they get, and capitalists get what they spend’ (Robinson, 1966, p. 341) – though it cannot be found in the writings of Kalecki. There is also a reverse direction of causation at the level of the enterprise, whereby the profitability of the enterprise will influence its investment decisions. Profits provide internal finance for investment, and the present level of profits influences expectation on future profits.

Kalecki saw capitalism as oligopolistic and monopolistic and dismissed the notion of perfect competition as a ‘dangerous myth’. His approach to pricing put forward the idea of the ‘degree of monopoly’ which expresses the notion that the market power which an enterprise possess will strongly influence the markup of its price over its (production) costs. The extent of market power depends on factors such as the dominance of the enterprise in its market, the barriers to entry into the industry and so forth. The degree of monopoly leads to a theory of the distribution of income and of the determination of real wages. At the level of the enterprise, the degree of monopoly sets the price–cost ratio; from this the ratio of profits to sales can be derived.
Then the share of profits is \( \frac{(\lambda - 1)(1+j)}{1 + (\lambda - 1)(1+j)} \) and the share of wages \( \frac{1}{1 + (\lambda - 1)(1+j)} \), where \( j = M/W \).

The real product wage can be calculated as \( \frac{W}{P} = \frac{1}{\lambda} - \frac{m}{P} \).

Further derivation and then aggregation indicates that the share of profits in national income depends on the average degree of monopoly and on the cost of imports. Since wages are a major component of costs, the degree of monopoly impacts the real product wage. Kalecki thus advanced a distinctive theory of the distribution of income between wages and profits, and the view that firms’ pricing behaviour, rather than events in the labour market, set the real wage.

Kalecki’s approach could be summarized by saying that the volume of profits depends on the level of investment, while the share of profits in national income depends on the degree of monopoly, that is, the market power possessed by firms.

The phenomenon of the business cycle was central to Kalecki’s economic analysis of capitalism, and his discovery of the importance of aggregate demand for the level of economic activity was undertaken in the context of cyclical fluctuations. Kalecki viewed ‘the determination of investment decisions by, broadly speaking, the level and the rate of change of economic activity’ as the *pièce de résistance* of economics (Kalecki, 1968, p. 263). The central feature of Kalecki’s explanation of the business cycle is the influence of investment on economic activity, and hence the determinants of investment. He distinguished between on the one hand the decision to invest and the placing of orders for investment, and, on the other hand, the actual investment taking place (for example, because it takes time to build the factory, there is a lag between investment orders and actual investment). Investment orders depend on profits, and profits are generated by actual investment (as noted above). He also postulated that investment is negatively influenced by the size of the capital stock. Combining these elements, Kalecki arrived at a mixed differential-difference equation (see, for example, Kalecki, 1990, vol. 1, pp. 82–3), for which there may be many solutions. Kalecki sought to establish that there is one solution for which the amplitude remains constant. ‘This case is especially important because it corresponds roughly to the real course of the business cycle’ (Kalecki, 1990, p. 90). He then argued that, with that condition satisfied, the other parameters of the model are such that a regular cycle of around ten years would be generated, which conforms with the general pattern of the time of a cycle of the order of eight to twelve years in length. The mixed differential-difference equation was the basis of Kalecki’s attempt to generate a self-perpetuating cycle, which was later to be resolved through the notion of limit cycles.

The central feature of Kalecki’s explanation of the business cycle is the influence of investment on economic activity, and hence the determinants of investment. Steindl (1981) identified three versions by Kalecki of the trade cycle, each with a different view of the determinants of investment, and he observed that there are differences in the ways through which profits influence investment and the impact of the size of the existing capital stock on investment (see also Sawyer, 1996).

Kalecki argued that ‘the long-run trend is but a slowly changing component of a chain of short-period situations; it has no independent entity’ (Kalecki, 1968, p. 263). This can be interpreted as undermining the predominant equilibrium approach to economic analysis whereby there is a long-period equilibrium
around which the economy fluctuates or towards which the economy tends and which is unaffected by the short-period movements of the economy. The expansion of investment (and other forms of spending) has to be financed, and that comes predominantly through the creation of bank credit. In one of his earliest papers (1933), Kalecki acknowledged the link between the cycle and money creation. He asked:

how can capitalists invest more than remains from their current profits after spending part of them for personal consumption? This is made possible by the banking system in various forms of credit inflation. Hence … without credit inflation there would be no fluctuations in investment activity. Business fluctuations are strictly connected with credit inflation…. A similar type of inflation is the financing of investments from bank deposits, a process usually not classified as inflation but one which perhaps has the greatest importance in the inflationary financing of investments during an upswing in the business cycle. (1990, vol. 1, pp. 148 and 149; emphasis in original)

Kalecki presented a number of ideas which now appear in the structuralist Post Keynesian analysis of endogenous money and in the circuitist approach, and he developed a substantial analysis of the workings of the monetary system (see Sawyer, 2001). Kalecki viewed the rate of interest as essentially a monetary phenomenon, and specifically not as a mechanism for bringing about the equality between savings and investment. He wrote that ‘the rate of interest cannot be determined by the demand for and supply of capital because investment automatically brings into existence an equal amount of savings. Thus, investment “finances itself” whatever the level of the rate of interest. The rate of interest is, therefore, the result of the interplay of other factors’ (Kalecki, 1997, vol. 7, p. 262).

The cost of borrowing is influenced by the ‘principle of increasing risk’ (Kalecki, 1937). Simply put, this principle is the idea that the greater the volume of borrowing a company wishes to undertake, relative to its own size and profits, the greater is the risk that the company will be unable to repay the borrowing. Any investment venture is subject to risk and uncertainty and to the vagaries of the business cycle. There is then some chance that a business will not be able to meet its loan commitments when its profits turn down. The lender would charge a risk premium on the loan, which makes the loan more expensive and increases the chances that the loan repayments cannot be met. The ‘principle of increasing risk’ then forms an upper limit on a business’s ability to borrow and then to expand and grow.

The discoveries of Keynes and Kalecki in the 1930s on the principle of effective demand and the associated idea that governments could (and should) manipulate their budget stance to generate high levels of employment (rather than aim for a balanced budget) appeared to open up the way for the achievement of permanent full employment in capitalist economies. Kalecki (1943) raised many doubts on the possibilities of achieving prolonged full employment in a laissez-faire capitalist economy. Kalecki introduced an idea which was later interpreted in terms of the political business cycle. Economic activity and employment could be stimulated prior to elections to aid the chances of the governing party being re-elected. But the resulting high level of employment would not last, and at best full employment would be achieved only at the top of the cycle. There were a number of routes through which effective demand could be stimulated. Kalecki argued that the promotion of investment expenditure would be subject to important limits, namely that as investment rose, there would be a tendency for the output to capital ratio to fall (as investment adds to the capital stock) and for the rate of profit to fall. Instead,

Kalecki favoured a redistribution of income towards the working class which would stimulate spending, and the acceptance, if necessary, of a budget deficit by the government.

Socialism

Almost all Kalecki’s writings on the economics of socialism were undertaken after his return to Poland in December 1954. While much of his writing was of a theoretical nature, the questions tackled and the approach adopted were much influenced by his perceptions of the Polish situation. He was directly involved in many of the debates of the mid-1950s on the development and organization of the Polish economy. His general approach can be summarized by saying that, while he sought a departure from the system of bureaucratic centralism, he thought that the main parameters of development in an economy should be centrally planned, with the market mechanism used in a subordinate role. He advocated a substantial increase in self-management by workers under a system of workers’ councils, though he acknowledged that there would be tensions between them and central planning.

Soviet economic planning from the 1920s onwards and eastern European planning in the post-war period placed great weight on rapid industrialization and a heavy industry investment programme. The tendency towards overambitious plans often led to the sacrifice of consumption in favour of investment, when the overall plan could not be implemented but investment was safeguarded. Kalecki’s criticisms of heavy industrialization and the sacrifice of consumption to investment brought him into conflict with the prevailing orthodoxy in Poland at the theoretical and at the practical levels.

Kalecki’s approach to growth under socialism can be illustrated by reference to the basic relationship in which the growth of output is equal to the impact on productive potential of new investment minus the loss of the production through depreciation plus the change in the utilization of productive capacity. Much of Kalecki’s theoretical work stemmed from this equation for the growth of output, with modifications for foreign trade, limited labour supply and technical progress. The emphasis was on the identification, and then pushing back, of the effective constraints on economic growth.

Kalecki viewed the market as involving the inefficient allocation of resources and the cause of insufficient aggregate demand. The socialist system was seen in terms of its ability to solve the problem of effective demand and to involve price–wage flexibility. Although he was critical of the decisions made under central planning, he was opposed to the market socialist alternative.

Development

Kalecki was heavily involved with teaching and research in the area of development planning from the late 1950s to the late 1960s. It is convenient to summarize his writings on development in terms of four themes. The first is that unemployment is seen to arise from a shortage of capital equipment, rather than from a deficiency of effective demand as in industrialized capitalist economies, so that constraints on employment and the pace of development arise more from the supply side than from the demand side. This led Kalecki to an identification of the binding constraints in any concrete situation: difficulties of expanding agricultural production, problems of achieving the desired rate of investment, and shortages of foreign exchange. These essentially economic constraints were generally compounded by the political resistance of powerful groups whose interests would be harmed by economic development. The second theme is the need for the expansion of agricultural production as a part of the development
process, since development and increased incomes leads to an increased demand for food. If that increased demand for food is not satisfied, then the price of food is likely to rise, thereby reducing real wages. But the agricultural sector is likely to suffer from low productivity and outdated techniques. Since there are often powerful obstacles to the development of agriculture, such as feudal or semi-feudal relations in land tenure and the domination of the peasants by merchants and moneylenders, substantial institutional changes would be required to sustain agricultural and economic development.

The third theme is that market mechanisms, left to themselves, are unlikely to produce outcomes that Kalecki would have regarded as acceptable or desirable. He saw a strong need for planning and direct government intervention, particularly in investment and foreign trade.

The fourth theme is the distributional aspects of growth and development, and in particular a concern that the process of development should benefit the poor. This was combined with an awareness that prospective distributional consequences may block development.

In his work on developing countries, Kalecki developed the concept of an ‘intermediate regime’. Countries with intermediate regimes had generally achieved political independence after the Second World War and could not be considered as either socialist or laissez-faire capitalist economies though they sought economic development with government involvement. Kalecki argued that the governments of these intermediate regimes represented the interests of the lower-middle class, rich peasants and managers in the state sector. The poorest strata of society were still unorganized and lacked any political power. He further argued that in order to keep power these representatives of the middle class would have to achieve political and economic emancipation, carry out land reform and assure continuous economic growth. State capitalism develops at the expense of socialism in the economies of intermediate regimes because it helps the middle class to retain power by, for example, aiding faster growth and economic emancipation.

The Kalman and Particle filters are algorithms that recursively update an estimate of the state and find the innovations driving a stochastic process given a sequence of observations. The Kalman filter accomplishes this goal by linear projections, while the Particle filter does so by a sequential Monte Carlo method. With the state estimates, we can forecast and smooth the stochastic process. With the innovations, we can estimate the parameters of the model. The article discusses how to set a dynamic model in a state-space form, derives the Kalman and Particle filters, and explains how to use them for estimation.

Article

The Kalman and Particle filters are algorithms that recursively update an estimate of the state and find the innovations driving a stochastic process given a sequence of observations. The Kalman filter accomplishes this goal by linear projections, while the Particle filter does so by a sequential Monte Carlo method. Since both filters start with a state-space representation of the stochastic processes of interest, Section 1 presents the state-space form of a dynamic model. Section 2 introduces the Kalman filter and Section 3 develops the Particle filter. For extended expositions of this material, see Doucet, de Freitas, and Gordon (2001), Durbin and Koopman (2001), and Ljungqvist and Sargent (2004).

1. The state-space representation of a dynamic model

A large class of dynamic models can be represented by a state-space form:

\[ X_{t+1} = \phi(X_t, W_{t+1}, \gamma) \]

(1)

\[ \gamma_t = g(X_t, V_t, \gamma). \]

(2)
This representation handles a stochastic process by finding three objects: a vector that describes the position of the system (a state, $X_t \in \mathbb{X} \subseteq \mathbb{R}$) and two functions, one mapping the state today into the state tomorrow (the transition equation, (1)) and one mapping the state into observables, $Y_t$ (the measurement equation, (2)). An iterative application of the two functions on an initial state $X_0$ generates a fully specified stochastic process. The variables $W_{t+1}$ and $V_t$ are independent $i. i. d.$ shocks. A realization of $T$ periods of observables is denoted by $\{y_t\}_{t=1}^T$ with $\mathbf{0}$. Finally, $Y$, which belongs to the set $\mathbb{Y} \subseteq \mathbb{R}^p$, is a vector of parameters. To avoid stochastic singularity, we assume that $\dim(W_t) = \dim(V_t) = \dim(Y_t)$ for all $t$.

This framework can accommodate cases in which the dimensionality of the shocks is zero, where the shocks have involved structures, or where some or all of the states are observed. Also, at the cost of heavier notation, we could deal with more general problems. For example, the state could be a function or a correspondence, and the transition equation a functional operator. The basic ideas are, however, identical.

The transition and measurement equations may come from a statistical description of the process or from the equilibrium dynamics of an economic model. For example, dynamic stochastic general equilibrium models can be easily written in state-space form with the transition and measurement equations formed by the policy functions that characterize the optimal behaviour of the agents of the model. This observation tightly links modern dynamic macroeconomics with the filtering tools presented in this article. It is important to note that there are alternative timing conventions for the state-space representation of a dynamic model and that, even while the timing convention is kept constant, the same model can be written in different state-space forms. All of those representations are equivalent, and the researcher should select the form that best fits her needs.

2 The Kalman filter

The Kalman filter deals with state-space representations where the transition and measurement equations are linear and where the shocks to the system are Gaussian. The procedure was developed by Kalman (1960) to transform ('filter') some original observables $y_t$ into Wold innovations $u_t$ and estimates of the state $x_t$. With the innovations, we can build the likelihood function of the dynamic model. With the estimates of the states, we can forecast and smooth the stochastic process.

We begin with the state-space system defined by the transition equation:

$$X_{t+1} = AX_t + GW_{t+1}, W_{t+1} \sim N(0, Q)$$

and the measurement equation:

$$Y_t = CX_t + v_t, v_t \sim N(0, R)$$

where $A$, $G$, $C$, $Q$, and $R$ are known matrices.

There are different ways to derive and interpret the Kalman filter, including an explicitly Bayesian one. We follow a simple approach based on linear least-square projections. The reader will enhance her understanding with the more general expositions in Durbin and Koopman (2001) and Ljungqvist and Sargent (2004).

Let $x_{gt-1} = E(x_t|y^{t-1})$ be the best linear predictor of $x_t$ given the history of observables until $t-1$, i.e., $y^{t-1}$. Let $v_{gt-1} = E(y_t|y^{t-1}) = Cx_{st-1}$ be the best linear predictor of $y_t$ given $y^{t-1}$. Let $x_{gt} = E(x_t|y^t)$ be the best linear predictor of $x_t$ given the history of observables until $t$, i.e., $y^t$. Let $\Sigma_{gt-1} = E((x_t - x_{gt-1})(x_t - x_{gt-1})')|y^{t-1}$ be the predicting error variance-covariance matrix of $x_t$ given $y^{t-1}$. Finally, let $\Sigma_{gt} = E((x_t - x_{gt})(x_t - x_{gt})'|y^t)$ be the predicting error variance-covariance matrix of $x_t$ given $y^t$.

How does the Kalman filter work? Let’s assume we have $x_{gt-1}$ and $y_{gt-1}$, that is, an estimate of the state and a forecast of the observable given $y^{t-1}$. Then, we observe $y_t$. Thus, we want to revise our linear predictor of the state and obtain an estimate, $x_{gt}$, that incorporates the new information. Note that $x_{gt+1} = AX_{gt} + GW_{t+1}, Y_{t+1} = CX_{gt} + V_{t+1}$, so we can go back to the first step and wait for the
Therefore, the key of the Kalman filter is to obtain $x_{t+1}$ from $x_{t-1}$ and $y_t$. We do so with the formula:

$$x_{t+1} = x_{t-1} + K_t (y_t - x_{t-1}) = x_{t-1} + K_t (y_t - C x_{t-1}),$$

that is, our new value $x_{t+1}$ is equal to $x_{t-1}$ plus the difference between the actual $y_t$ and the forecasted $x_{t-1}$, times a matrix $K_t$, called the Kalman gain. Durbin and Koopman (2001) derive this formula from probabilistic foundations. Ljungqvist and Sargent (2004) find it through an application of a Gram–Schmidt orthogonalization procedure.

Then, if we choose $K_t$ to minimize $\sum_{t-1}$, we get $K_t = \Sigma_{t-1}^{-1} C' (\Sigma_{t-1}^{-1} C' + R)^{-1}$. This expression shows the determinants of $K_t$. If we made a big mistake forecasting $x_{t-1}$ using past information ($\Sigma_{t-1}$ large), we give a lot of weight to the new information ($K_t$ large). Also, if the new information is noisy ($R$ large), we give a lot of weight to the old prediction ($K_t$ small).

Now, note that $\Sigma_{t-1} = E((x_t - x_{t-1})(x_t - x_{t-1})') = \Sigma_{t-1} - K_t C \Sigma_{t-1}$. Therefore, from $x_{t-1}, \Sigma_{t-1}$, and $y_t$, we compute $x_{t+1}$ and $\Sigma_{t+1}$.

We collect all the previous steps. We start with some estimates of the state $x_{t-1}$, the observables $y_{t-1}$, and the variance-covariance matrix $\Sigma_{t-1}$. Then we observe $y_t$ and compute $x_{t+1}$, $y_{t+1}$, and $\Sigma_{t+1}$.

Thus, the Kalman filter can be recursively written as follows:

- $y_{t-1} = C x_{t-1}$
- $K_t = \Sigma_{t-1}^{-1} C' (\Sigma_{t-1}^{-1} C' + R)^{-1}$
- $\Sigma_{t-1} = \Sigma_{t-1} - K_t C \Sigma_{t-1}$
- $x_{t+1} = x_{t-1} + K_t (y_t - C x_{t-1})$
- $\Sigma_{t+1} = \Sigma_{t-1} - K_t C \Sigma_{t-1}$
- $x_{t+1} = A x_{t} + G Q G'$
- $\Sigma_{t} = \Sigma_{t} - K_t C \Sigma_{t}$

The differences between the observable and its forecast, $a_t = y_t - y_{t-1} = y_t - C x_{t-1}$, are, by construction, Wold innovations. Moreover, since the system is linear and Gaussian, $a_t$ is normally distributed with zero mean and variance $C \Sigma_{t-1} C' + R$. That is why the Kalman filter is a whitening filter: it takes as an input a correlated sequence $y_T$ and it produces a sequence of white noise innovations $a_t$.

With this last result, we write the likelihood function of $y_T = \{y_t\}_{t=1}^T$ as:

$$\log L\left(y_T | A, C, Q, R\right) = \sum_{t=1}^T \log L\left(y_t | y_{t-1}^{-1} A, C, Q, R\right) = -\sum_{t=1}^T \left[ N \log 2 \pi + \frac{1}{2} \log |C \Sigma_{t-1} C' + R| + \frac{1}{2} \sum_{t=1}^T a_t' \left(C \Sigma_{t-1} C' + R\right)^{-1} a_t\right].$$

This likelihood is one of the most important results of the Kalman filter. With it, we can undertake statistical inference in the dynamic model, both with maximum likelihood and with Bayesian approaches.

An important step in the Kalman filter is to set the initial conditions $x_{1|0}$ and $\Sigma_{1|0}$. If we consider stationary stochastic processes, the standard approach is to set $x_{1|0} = x^*$ and $\Sigma_{1|0} = \Sigma^*$ such that $x^* = A x^*$ and $\Sigma = \Sigma A' A + G Q G'$, where

$$\Sigma^* = A \Sigma^* A' + G Q G' = (I - A \otimes A)^{-1} \text{vec}(G Q G').$$
Non-stationary time series require non-informative prior conditions for $x_{1|0}$. This approach, called the diffuse initialization of the filter, begins by postulating that $x_{1|0}$ is equal to:

$$x_{1|0} = \tau + \Phi \delta + C \omega_0, \quad \omega_0 \sim N(0, Q) \text{ and } \delta \sim N(0, \kappa_0)$$

where $\tau$ is given and $\Phi$ and $C$ are formed by columns of the identity matrix such that $\Phi C' = 0$. This structure allows for some elements of $x_{1|0}$ to have a known joint distribution, while, by letting $\kappa \to \infty$, to formalize ignorance with respect to other elements. Clearly, $x_{1|0} = E(x_{1|0}) = \tau$. To determine the initial variance, we expand $\Sigma_{1|0} = \kappa \Phi \Phi' + CGC'$ as a power series of $\kappa^{-1}$ and take $\kappa \to \infty$ to find the dominant term of the expansion. Durbin and Koopman (2001) provide details.

The Kalman filter can also be applied for smoothing, that is, to obtain $x_{t|T}$, an estimate of $x_t$ given the whole history of observables, that is, $y_{1:T}$. Smoothing is of interest when the state $x_t$ has a structural interpretation of its own. Since smoothing uses more information than filtering, the predicting error variance covariance matrix of $x_t$ given $y_{1:T}$ will be smaller than $\Sigma_{t|t-1}$. Finally, we note that the Kalman filtering problem is the dual of the optimal linear regulator problem.

### 3 The Particle filter

The Kalman filter relies on the linearity and normality assumptions. However, many models in which economists are interested are nonlinear and/or non-Gaussian. How can we undertake the forecast, smoothing, and estimation of dynamic models when any of those two assumptions are relaxed?

Sequential Monte Carlo methods, in particular the Particle filter, reproduce the work of the Kalman filter in those nonlinear and/or non-Gaussian environments. The key difference is that, instead of deriving analytic equations as the Kalman filter does, the Particle filter uses simulation methods to generate estimates of the state and the innovations. If we apply the Particle filter to a linear and Gaussian model, we will obtain the same likelihood (as the number of simulations grows) that we would if we used the Kalman filter. Since it avoids simulations, the Kalman filter is more efficient in this linear and Gaussian case.

We present here only the basic Particle filter. Doucet, de Freitas and Gordon (2001) discuss improvements upon the basic filter. Fernández-Villaverde and Rubio-Ramírez (2007) show how this Particle filter can be implemented to estimate dynamic stochastic general equilibrium models. Our goal is to evaluate the likelihood function of a sequence of realizations of the observable $y_{1:T}$ implied by a stochastic process at a parameter value $\gamma$:

$$L\left(y_{1:T} ; \gamma \right) = p\left(y_{1:T} ; \gamma \right).$$

Our first step is to factor the likelihood function as:

$$p\left(y_{1:T} ; \gamma \right) = \prod_{t=1}^{T} p\left(y_t \mid y_{1:t-1}, \gamma \right) = \prod_{t=1}^{T} \int p\left(y_t \mid w_t, x_0, y_{1:t-1}, \gamma \right) \times p\left(w_t, x_0 \mid y_{1:t-1}, \gamma \right) dw_t dx_0,$$

where $X_0$ is the initial state of the model and the $p$'s represent the relevant densities. In general, the likelihood function ((4)) cannot be computed analytically. The Particle filter uses simulation methods to estimate it.

Before introducing the filter, we assume that, for all $\gamma$, $x_0$, $w_t$, and $t$, the following system of equations:
Kalman and particle filtering: The New Palgrave Dictionary of Economics

has a unique solution, \((v^t, x^t)\), and we can evaluate \(p(v^t; \gamma)\). This assumption implies that we can evaluate the conditional densities \(p(v^t | w^t, x_0^t, y^{t-1}, \gamma)\) for all \(\gamma, x_0, w^t, \) and \(t\). Then, we have:

\[
p(v^t | w^t, x_0^t, y^{t-1}, \gamma) = |\partial_y(v_0^t) \partial p(v_0^t)|
\]

for all \(\gamma, x_0, w^t, \) and \(t\), where \(|dy(v^t; \gamma)|\) stands for the determinant of the Jacobian of \(y^t\) with respect to \(V^t\), evaluated at \(v^t\).

Conditional on having \(N\) draws of \(\{v^t_{i-1,t}^t, w^t_{i-1,t}^t\}_{i=1}^N\) from the sequence of densities \(\{p(W^t, x_0|y^{t-1}; \gamma)\}_{t=1}^T\), the law of large numbers implies that the likelihood function ((4)) can be approximated by:

\[
p(y^T; \gamma) = \prod_{t=1}^T \frac{1}{N} \sum_{i=1}^N p(v^t_{i-1,t}^t, x_0_{i-1,t}^t, y_{i-1,t}^t, \gamma).
\]

This observation shows that the problem of evaluating the likelihood ((4)) is equivalent to the problem of drawing from \(\{p(W^t, x_0|y^{t-1}; \gamma)\}_{t=1}^T\). Since the algorithm does not require any assumption about the distribution of the shocks except the ability to evaluate \(p(v^t | w^t, x_0^t, y^{t-1}, \gamma)\), either analytically or by simulation, we can deal with models with a rich specification of non-Gaussian innovations. But, how do we sample from \(\{p(W^t, x_0|y^{t-1}; \gamma)\}_{t=1}^T\)?

Let \(\{v^t_{i-1,t}^t, w^t_{i-1,t}^t\}_{i=1}^N\) be a sequence of \(N\) draws from \(p(W^t_{i-1,t}^t, x_0_{i-1,t}^t|y^{t-1}; \gamma)\). Let \(\{x_0_{i,t}^{t-1}, w^t_{i-1,t}^t\}_{i=1}^N\) be a sequence of \(N\) draws from \(p(W^t_{i-1,t}^t, x_0_{i-1,t}^t|y^{t-1}; \gamma)\). We call each draw \((x_0_{i,t}^{t-1}, w^t_{i-1,t}^t)\) a particle and the sequence \(\{x_0_{i,t}^{t-1}, w^t_{i-1,t}^t\}_{i=1}^N\) a swarm of particles. Also, define the weights:

\[
q_t^i = \frac{p(v^t_{i-1,t}^t, x_0_{i-1,t}^t, y_{i-1,t}^t; \gamma)}{\sum_{i=1}^N p(v^t_{i-1,t}^t, x_0_{i-1,t}^t, y_{i-1,t}^t; \gamma)}.
\]

The next proposition shows how to use \(p(W^t, x_0|y^{t-1}; \gamma)\), the weights \(\{q_t^i\}_{i=1}^N\), and importance sampling to draw from \(p(W^t, x_0|y^{t-1}; \gamma)\):
Proposition 1: Let \( \{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N \) be a draw from \( p(W^t, X_0|y^{t-1}, \gamma) \). Let the sequence \( \{\hat{x}_0^i, \hat{w}^i\}_{i=1}^N \) be a draw with replacement from \( \{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N \) where \( q^i_t \) is the probability of \( (x_0^{t-1,i}, w^{t-1,i}) \) being drawn \( \forall i \). Then \( \{\hat{x}_0^i, \hat{w}^i\}_{i=1}^N \) is a draw from \( p(W^t, X_0|y^{t}, \gamma) \). Then, with a draw \( \{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N \) from \( p(W^t, X_0|y^{t-1}, \gamma) \), we get a draw \( \{x_0^i, w^i\}_{i=1}^N \) from \( p(W^t, X_0|y^{t}, \gamma) \) and we generate a sequence of particles \( \{\{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N\}_{t=1}^T \) from the sequence \( \{p(W^t, X_0|y^{t-1}, \gamma)\}_{t=1}^T \). Given some initial conditions, we can recursively apply the idea of the previous proposition as summarized by the algorithm:

- **Step 0, Initialization:** Set \( t \leftarrow 1 \). Initialize \( p(W^{t-1}, X_0|y^{t-1}, \gamma) = p(X_0; \gamma) \).

- **Step 1, Prediction:** Sample \( N \) values \( \{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N \) from the conditional density \( p(W^t, X_0|y^{t-1}, \gamma) = p(W_0; \gamma) p(W^t|X_0,y^{t-1}, \gamma) \).

- **Step 2, Filtering:** Assign to each draw \( (x_0^{t-1,i}, w^{t-1,i}) \) the weight \( q^i_t \) as defined in (5).

- **Step 3, Sampling:** Sample \( N \) times with replacement from \( \{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N \) with probabilities \( \{q^i_t\}_{i=1}^N \). Call each draw \( (x_0^i, w^i) \). If \( t < T \) set \( t \leftarrow t + 1 \) and go to Step 1. Otherwise stop.

With the algorithm's output \( \{\{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N\}_{t=1}^T \), we obtain the estimate of the states in each period and compute the likelihood:

\[
p(Y^T; \gamma) = \frac{1}{N} \left( \prod_{t=1}^T \frac{1}{N} \sum_{i=1}^N p(Y_t|w^{t-1,i}, x_0^{t-1,i}, y^{t-1}, \gamma) \right).
\]

The sampling step is the heart of the algorithm. If we skip it and weight each draw in \( \{x_0^{t-1,i}, w^{t-1,i}\}_{i=1}^N \) by \( \{N q^i_t\}_{i=1}^N \), we have a sequential importance sampling. The problem with this approach is that it diverges as \( t \) grows. The reason is that, as \( t \to \infty \), all the sequences become arbitrarily far away from the true sequence of states (the true sequence being a zero measure set), and the sequence that happens to be closer dominates all the remaining sequences in weight. In practice, after a few steps only one sequence has a non-zero weight. Through resampling, we eliminate this problem as we keep (and multiply) those sequences that do not diverge from the true one.

The algorithm outlined above is not the only procedure to evaluate the likelihood of nonlinear and/or non-Gaussian dynamic models. However, the alternatives, such as the extended Kalman filter, the Gaussian sum approximations, or grid-based filters, are of limited use, and many, such as the extended Kalman filter, fail asymptotically. Consequently, the Particle filter is the most efficient and robust procedure to undertake inference for nonlinear and/or non-Gaussian models, and we will witness many applications of this filter in economics in future years.

Article

Kantorovich made valuable contributions to the theory of welfare and was the founder of the theory of optimal planning of socialist economics. As a professional mathematician, he also made a valuable contribution to a number of sections of modern mathematics. He is regarded (together with G. Dantzig) as the founder of linear programming, the mathematical discipline which has many applications in economics.

L.V. Kantorovich was born on 19 January 1912. He graduated from the department of mathematics of Leningrad University in 1930 at the age of 18. Four years later he became professor of mathematics at Leningrad University. In 1939, through the publishing house of Leningrad University, he published a small booklet, ‘Mathematical Methods of Organization and Planning of Production Process’. This may be considered a historic document, containing the facts about discovery of the linear programming. The mathematical formulation of production problems of optimal planning was presented here for the first time and the effective methods of their solution and economic analysis were proposed. Thus the idea of optimality in economics was founded scientifically. This booklet and a number of subsequent articles establish Kantorovich together with F.P. Ramsey and J. von Neumann as the founders of the optimization approach to the analysis of economic problems.

His fundamental work, The Best Uses of Economic Resources, written in 1942 but published for the first time only in 1959, is a brilliant example of the consistent application of the optimization principle to the analysis of a wide variety of economic problems: the planning of production from the level of enterprise to the level of the national economy as a whole; a theory of price formation, which includes the principles of price formation not only for goods and services but also for the factors of production, the time factor, the space factor, natural conditions, the conditions of labour application, and so on; a theory of economic and social-economic efficiency of economic enterprises.
In fact, Kantorovich developed a powerful tool for the analysis of economic problems from the unified position of global optimum and indeed it is not necessary to find this optimum, it is enough to postulate its existence. In a number of his subsequent articles Kantorovich demonstrated the power of his method for the analysis and improvement of the mechanism of economic management of the socialist economy as a whole and its components. He proposed methods for calculating wholesale price levels for the branches of the national economy; the value of the norm of effectiveness of capital investments; the norm of depreciation allowances, and the value of transport tariffs, rent payments, and so on.

For a number of years Kantorovich showed great interest in the problems of economic dynamics. He proposed, analysed and used in practice a dynamic model of optimal planning. On the basis of this model and its different modifications Kantorovich proposed an original theory of economic evaluation of technical ventures. The essence of this theory is that the economic effect of the introduction of a scientific-technical innovation includes three components: a producer effect; a consumer effect; and an effect which is the result of the increase in general scientific-technical economic potential derived from the innovation. The third component is ignored in usual economic practice which leads to a distorted calculation of the real efficiency of innovations.

Kantorovich was also a world-famous mathematician. He made great contributions to a number of different branches of mathematics, among them the descriptive theory of functions and of sets; the constructive theory of functions; a decision method of solving a wide range of problems concerning the best approximation of functions by polynomials; calculus of variations; functional analysis, where he introduced and studied the class of semi-ordered spaces (K-spaces); approximate calculation methods; and developed several effective algorithms as well as a number of other branches of mathematics. This demonstrates his mathematical genius and the vast range of his interests and knowledge.

The author of about 300 scientific works, Kantorovich was awarded the Nobel Prize in economics in 1975.

Katona, George (1901–1981)

James N. Morgan
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

consumer confidence; Cowles Commission; inflation; Katona, G.; psychological economics

Article

Katona developed the theory and substance of psychological economics, with particular attention to the effects of national events on the confidence, expectations, plans and ultimately behaviour of masses of individuals. From a background in Gestalt psychology, he noted that there can be major restructuring of the way people interpret their world and its future, leading to sometimes dramatic shifts in behaviour. And he had a firm belief in people's capacity to learn and to adjust their goals, so that behaviour was more than a simple response to stimuli. Like most great ideas, these were at the same time simple and profound, obvious (that attitudes would affect behaviour) but not accepted, particularly by economists who preferred to keep attitudes and expectations endogenous so they need not be measured or dealt with directly.

The theory argued that the importance of mass psychology was growing as consumers became more affluent, used credit and had to make long-term commitments to levels of investment in housing and cars, and to repayment schedules. Furthermore, he argued, the world was becoming increasingly volatile and unpredictable, so that it was necessary for people to interpret the chaos. The repeated measures of consumer confidence were useful for short-run prediction, but the long-run goal was, and is, to understand mass changes in consumer attitudes and behaviour.

Katona was born in 1901 in Budapest, and was a law student at the University of Budapest when a communist putsch under Bela Kun closed the University. Instead he studied psychology under Mueller at the University of Göttingen. His Ph.D. was on the psychology of perception. While at the University of Frankfurt, he wrote a prize-winning monograph on the psychology of comparison, with an empirical orientation. Hyperinflation drove him to work for a Frankfurt bank and he wrote a widely quoted article on the mass psychological aspects of inflation. There followed a period in Berlin studying Gestalt psychology with his friend Max Wertheimer and writing for Gustav Stolper's Der Deutsche Volkswirt. When Hitler closed down the paper, Katona emigrated to New York. An attack of tuberculosis ended his
career as an investment counsellor and he turned again to writing. His path-breaking book Organizing and Memorizing (1940), showed how organizing material in gestalts made it easier to remember and apply to other situations, and could lead to changes in expectations. Concern with the economic effects of the war led him to write War without Inflation: The Psychological Approach to the Problems of a War Economy (1942). After tours at the Cowles Commission for Research in Economics at the University of Chicago, and the Division of Program Surveys of the US Department of Agriculture, he moved with that programme to the University of Michigan to help form the Survey Research Center. There he began the continuing series of surveys measuring mass changes in consumer confidence, building a body of knowledge about how people respond to events and interpret them for their own lives. A series of books starting in 1951 and continuing through 1978 summarized the research. He died in West Germany on 18 June 1981, the day after receiving an honorary degree from the Free University of Berlin.

Kautsky was born in Prague on 16 October 1854 and died in Amsterdam on 17 October 1938. Marxist thinker and writer, leading theoretician of the German Social Democratic Party (SPD) and the Second International, he studied law and arts in Vienna. Fascinated by the theories of Marx and Engels (both of whom he met and befriended in London in 1881), Kautsky must be credited with the spread and development of their ideas in all his embodiments – as a prodigal and versatile columnist; as founder and editor (1883–1917) of the SPD theoretical journal Die Neue Zeit, which soon became the chief Marxist forum in Europe; as editor of Marx’s books and unfinished manuscripts (Kautsky edited them in three volumes called Theorien über den Mehrwert, which appeared in 1905–10); and also as socialist thinker. Kautsky presented his ideas systematically in Die materialistische Geschichtsauffassung (1927), expounding a theory of social development which combined Marx's and Engels's historical materialism with Darwin's naturalism.

Kautsky's first major popular book designed to spread Marxian theories was Karl Marx’ ökonomische Lehren (1887), which expounds the substance of the first volume of Das Kapital. It went into numerous editions in German and other languages, and in some countries (as in Russia) its effect on the spread of Marxism was significant.

His original contribution to Marxian theory was his Agrarfrage (1899), described by Lenin as the most outstanding work since the third volume of Das Kapital had appeared in print. In it, Kautsky analyses trends of development in agricultural production against the backdrop of Marx's theory of capitalism, of capitalist development's own specific features and, in particular, of the then much-discussed question of persistence of small peasant holdings. Kautsky studied the causes of small private farms’ relative viability, a phenomenon which at that time was often cited as evidence that Marx's concentration theory
was wrong. He attributed the survival of small peasant holdings to the undernourishment and excessive toil of peasant families, to the demand for seasonal labour by large landed estates and to their interest in preserving local labour reserves. Kautsky also pointed out that, in agriculture, concentration of production does not necessarily go along with increases of crop area but may result from more intensive cultivation. Generally, though, he believed that the conquest of agriculture by capitalism was just a question of time. Kautsky's motive for studying the agrarian question was pragmatic; he wanted to answer the question of whether or not the SPD needed an agricultural policy of its own. In particular, it was unclear whether the SPD ought to defend peasants on their own holdings against the adverse effects of capitalism. Kautsky came to believe that such a move would only hamper what was an inexorable social process, namely, the emergence of large capitalist farms relying on hired labour, and hence would hamper the ascent of socialism. Without compromising its own tenets and aspirations, Kautsky said, the SPD could demand the abolition of all vestiges of feudalism in the countryside and defend peasants as working people, as semi-proletarians. But he thought the idea of defending peasants as smallholders a reactionary utopia. He used the same logic to interpret the role of the capitalist metropolitan countries in subjugating colonies.

Kautsky wrote the *Agrarfrage*, as well as his studies concerning crises, as polemics against ‘revisionists’, who argued that the spread of cartels and trusts, along with the expansion of bank activities, eliminated the anarchy in capitalist production and hence was likely to allay or forestall crises in the future. Kautsky opposed these theories in a series of articles (1901–2) in *Die Neue Zeit* which he wrote in reaction to a German translation of Mikhail Tugan-Baranovsky's *Studien zur Theorie und Geschichte der Handelskrisen in England* (1901). Tugan-Baranovsky reinterpreted Marx's reproduction models in terms of Say's Law and attributed the causes of crises to the disproportions of capitalist development. The spread of cartels, Tugan-Baranovsky argued, eliminated those disproportions and hence also forestalled crises. Kautsky defended the theory of underconsumption as the basis of business cycles and argued that cartels and other similar organizations of capitalists, keen as they were on maximizing profits, were unable to keep control of production and demand on a national scale, to say nothing of the world economy. He countered the optimistic picture presented by the ‘revisionists’ with his own hypothesis of capitalism's inexorable drift toward ‘a chronic depression’. That was one of the first-ever theories of stagnation. Later (1910), Kautsky was inclined to attribute the principal cause of ‘recent’ crises to the circumstance that agricultural growth was slower than and lagging behind industrial growth. He also cited this particular disproportion in his concept of imperialism as the expansion of advanced industrial countries into agrarian markets. During the First World War Kautsky formulated his well-known hypothesis portraying ultra-imperialism as an alliance of previously rival imperialist powers for a joint exploitation of world resources.

In many studies Kautsky returned to the political and economic problems of the transition to socialism and to the organization and operation of the socialist economy. At first, those problems were overshadowed by the dominant question of political revolution to seize power and of proletarian dictatorship, and Kautsky's casual remarks indicate he regarded a socialist economy simply as the negative of a market-dominated capitalist economy. But from the war onwards, especially in the 1920s, he interpreted socialism and the socialist economy as a continuation and further development of capitalist accomplishments not only in economics but also in terms of social advancement and political
His writings are pervaded by a concern for freedom and democracy. Accordingly, he views the transition period as a long process of socialization of production during which those accomplishments would be preserved and economic efficiency would be maintained.

Kautsky was one of the first socialist writers to dispute the idea of a natural, that is money-free, socialist economy. Already at the turn of the century (1902) he argued that money and market were indispensable if freedom of choice in consumption and jobs was to be preserved. Two decades later, when the wave of revolution in Germany, but especially in the Soviet Union, made the construction of socialism a topical question, Kautsky considered the question in a systematic manner (1922). Apart from reaffirming the advantages of money and prices, Kautsky acknowledged the importance of money as a measure of value which permitted the quantitative assessment of production by means of accounting techniques and as a device for identifying benefits that may be gained from trade transactions. However, he failed to furnish a clear picture of how he interpreted economic choice in the allocation of resources. He was probably not quite consistent on this point. On the one hand, he wrote in the spirit of ‘market socialism’ that socialist society would be governed by the law of value. On the other hand, he overrated the benefits of economies of scale, that is, the supremacy of large-scale over small-scale production, and he was adamant in his faith in vertical and horizontal integration. If his beliefs came true, the integration was bound to lead to ubiquitous monopolistic practices on the part of socialist industrial giants.

He also believed that full socialization of production and of the bank credit system would render the latter superfluous. He accepted that interest rates might be charged by the socialized banks, but solely in order not to deprive them of their competitive edge in relations with capitalist banks and only in the transition period. His idea of economic planning also seems incompatible with ‘market socialism’. In his view, economic planning would amount to the entire community of consumers negotiating output volumes and prices with the branch producers. Since this implied that a lot of time would be needed to build an efficient system of statistical records, Kautsky believed full economic planning was a remote prospect. But what would a fulfilment of those plans actually guarantee? Kautsky failed to realize how complex a question that was, although some of his remarks, such as his comments about the important part that talented production organizers, who are as rare as talented artists, might play in socialism, sound quite up-to-date.

Opposed as he was to total state control. Kautsky was an advocate of a plurality of ownership forms in socialism. Apart from a certain scope for state ownership of production (which would not be managed by state-employed functionaries), he saw in socialism room for production cooperatives, for municipal enterprises, and for union-sponsored autonomous enterprises similar in character to those advocated by Guild Socialists. He regarded the general idea of guild socialism as excellent and inspiring, but he thought that this school focused its attention too much on producers to the detriment of consumers, and he resisted in particular attempts to present guild socialism as the only feasible production organization model for socialism.

kernel estimators in econometrics

Aman Ullah
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The kernel estimation method is a nonparametric procedure for analysing economic models. It is a data-based procedure which avoids the a priori parametric specification of the economic model, and it has become popular because of its wide applicability and well-developed theory. A substantial literature has developed where the local polynomial kernel estimator has been proposed to analyse various economic models, which include regression models, single-index models, dynamic time series models and panel data models. The frontier of this subject is expected to develop further in both theory and applications, especially with advances in computer technology.

Keywords

bootstrap; convergence; cross-section econometrics; curse of dimensionality; kernel estimators in econometrics; linear models; local modelling; nonlinear models; nonlinear time-series analysis; nonparametric regression; time-series econometrics

Article

For empirical research, we draw from economic theory the types of variables which can be used in the economic relationship (model) under consideration. But theory usually does not provide the functional form of the economic model. Empirical and theoretical work in econometrics is, therefore, often carried out by assuming linear or nonlinear parametric functional forms of the economic models (see Gallant, 1987, for work on nonlinear models by econometricians sparked by the work of statisticians Hartley, 1961, and Jennrich, 1969). However, these parametric models may often be mis-specified and hence they may provide biased and misleading conclusions. With this in view, econometrics moved in the direction of local modelling (local averaging), which is a data-based approach, for studying the economic relationships of unknown forms. In the regression framework this approach is also called ‘nonparametric regression’ or ‘nonparametric smoothing’. Here our focus is on nonparametric kernel...
kernel estimators in econometrics: The New Palgrave Dictionary of Economics

Nonparametric kernel regression methods are becoming increasingly popular for applied data analysis; they are best suited to situations involving large data-sets for which the number of variables involved is manageable. A kernel is simply a weighting function. The kernel estimation procedure was developed in the seminal published work of Rosenblatt (1956) on the density function, and later in the context of the regression function, by Nadaraya (1964) and Watson (1964). A detailed development on this subject in statistics was first presented by Prakasa Rao (1983), and then Härdle (1990) and Fan and Gijbels (1996), followed by the work of Pagan and Ullah (1999) in econometrics. There are other ways to do local modelling – for example, spline methods, series methods, differencing methods, and neural network methods (see Pagan and Ullah, 1999) – but the kernel smoothing procedure has become popular because of its vast applicability, simplicity, and well-developed theoretical underpinnings for both time-series and cross-section data. Nonparametric kernel methods essentially involve local averaging in a regression context: we can obtain a consistent estimate of the conditional mean by locally averaging those values of the dependent variable which are ‘close’ in terms of the values taken on by the regressors. The amount of local information used to construct the average is determined by a window width, also known as a ‘bandwidth’ or a ‘smoothing parameter’.

Suppose one wished to estimate the function $m$ in the regression equation:

$$y_i = m(x_i) + u_i, \quad i = 1, \ldots, n$$

(1)

where $y_i$ is the dependent variable, $x_i$ is a vector of $q$ regressors, and $u_i$ is an additive error. A parametric approach intends to fit the data to a parametric model $m(x_i) = m(x_i; \theta)$, often a linear model with $m(x_i; \theta) = \alpha + x_i\beta$, where $\theta$ is a parameter set of the model. But from the perspective of economic theory many economic models tend to be nonlinear. This makes the linear model specification inappropriate for understanding economic relationships. A way to capture the nonlinearity in data is to model the regression function locally, that is, to obtain the regression function $m(x)$ at a given point $x$ by applying the linear regression technique to the data in a window width of size $h$ using the linear model

$$y_i = \alpha(x) + (x_i - x)\beta(x) + u_i, \quad \text{for } x_i \text{ in } x \pm \frac{h}{2}$$

(2)

This local linear regression method leads to the following locally weighted minimization problem:
where \( K(\cdot) \), a non-negative weight (kernel) function, is a decreasing function of distances of \( x_i \) from the point \( x \), and \( h \) is a window width that determines how rapidly the weights decrease as the distance of \( x_i \) from \( x \) increases. Let \( \hat{\alpha}(x) \) and \( \hat{\beta}(x) \) be the estimated local linear least squares estimators, which are the solutions of (3). Then the estimated regression function at the point \( x_i = x \) is \( \hat{m}(x) = \hat{\alpha}(x) \) and \( \hat{\beta}(x) \) is the estimator of \( \beta(x) = \frac{\partial m(x)}{\partial x} \), which is the local slope. If \( \beta(x) = 0 \) in (2) and (3), then the resulting estimator of \( m(x) = \alpha(x) \) is the Nadaraya (1964) and Watson (1964) kernel regressor estimator. The local linear regression approach in (2) amounts to considering a linear Taylor series expansion of \( m(x_i) \) around \( x \) in model (1). This approach can be extended to a local polynomial regression by taking a polynomial expansion of order \( p \), of \( m(x_i) \) around \( x \). This provides the local polynomial least squares estimator of \( m(x) \) (Stone, 1977). The local linear estimators (\( p = 1 \)) perform better than the Nadaraya–Watson estimator (\( p = 0 \)) with respect to bias reduction, absence of boundary effects, and the adaptation to various design situations; for \( p \geq 1 \) the local polynomial estimators may suffer singularity problems in applied settings.

The principle of local regression estimators can be generalized to other parametric regression settings such as local logit and probit, local proportional hazards, local quantile, robust regression, and nonlinear time-series models. For example, if we let \( m(x_i, \theta) \) be a parametric model and \( L_i(y_i, x_i, m(x_i, \theta)) \) be the loss or the log-likelihood of the i-th observation, then we can minimize (if a loss) or maximize (if a likelihood) the objective function given by

\[
L(\theta) = \sum_{i=1}^{n} L_i(y_i, x_i, m(x_i, \theta)) K\left(\frac{x_i - x}{h}\right)
\]

(4)

The \( m(x_i, \theta) \) is now locally estimated by \( m(x_i, \hat{\theta}(x)) \), for example, when \( m(x_i, \theta) = \alpha + x_i \beta \) then \( m(x_i, \theta(x)) = \alpha(x) + \beta(x) x_i \) and \( L_i(y_i, x_i, m(x_i, \theta(x))) = (y_i - \alpha(x) - (x_i - x) \beta(x))^2 \), or \( L(\theta) \) is maximized with \( L_i \) written presuming normality of errors. Similarly, in a single index econometric model \( L_i(y_i, x_i, m(x_i, \theta)) = \log [F(x_i \beta)^{y_i}(1 - F(x_i \beta))^{1-y_i}] \) where \( y_i = 1 \) or \( 0 \) and \( F(\cdot) \) is a cumulative distribution function, and in the case of a local linear \( k \)-th quantile regression \( L_i = u_i(k - I(u_i < 0)) \) where \( u_i = y_i - \alpha(x) - (x_i - x) \beta(x) \), \( 0 < k < 1 \), and \( I(\cdot) \) is the usual indicator function.

The selection of window width \( h \) is by far the most important issue of nonparametric kernel estimation.
When $h$ is arbitrarily small, the bias of the estimator is small but the variance is large. Conversely, when $h$ is large, the estimator has a lower variance and a higher bias. Much of the literature on the methods of window width selection can really be viewed as attempts to balance this classic bias–variance trade-off. Overall, the selection rules fall into roughly three broad categories: (a) reference rules that would be optimal from a reference data generating process, (b) plug-in, penalizing, and cross-validation methods, and (c) bootstrap methods (see Pagan and Ullah, 1999, and Marron, 1992).

The asymptotic properties of the local polynomial estimators are well established (see Fan and Gijbels, 1996, for cross-section data and Masry, 1996, for the time-series case). The implication of these results is that the rate of convergence of the pointwise estimator of the $r$–th derivative of $m(x)$ is the inverse of $(nh^{q+2r})^{\frac{1}{2}}$, $r \geq 0$, which is slower than the parametric rate of $\sqrt{n}$. In fact, as the dimensions of the regressors $q$ for a given $r$ increase, the rates become worse, which is the well-known ‘curse of dimensionality’ problem. However, the rate of convergence of the average of the pointwise estimators (global estimators) of these derivatives is widely known to have $\sqrt{n}$ rate of convergence. One of the most popular ways to deal with the ‘curse of dimensionality’ is to consider the nonparametric additive regression model which can be written as $y_i = \beta_0 + \sum_{j=1}^{q} m(x_{ij}) + u_i$. Imposing this additivity provides an estimator having a one-dimensional nonparametric rate of convergence. In recent years the kernel regression estimation methods have progressed in various directions. These include testing for the significance of a regressor or group of regressors, consistent testing for the correct parametric functional form, estimation of the so-called ‘structural relationship’ among endogenous (dependent) variables, and the estimation of various types of semiparametric models consisting of a combination of parametric and nonparametric models (see Pagan and Ullah, 1999). Extensive work on the empirical applications of the kernel regression estimation have begun to appear in both cross-section econometrics and time-series econometrics, especially in labour economics and empirical finance. Although some related work is being done, several challenging research issues remain to be worked out. The first is the development of a unified approach towards a data-driven window width, and the development of software that permits fast computation of kernel-based estimators and test statistics for large data-sets in a desktop environment. The second is the development of kernel-based estimation of time-series models for non-stationary data. Third is the systematic development of the work on kernel estimation of panel-data models with heterogeneity parameters, especially when the time-series component of the data is large. Finally, the development of the theory of kernel estimation of various econometric models with both continuous and discrete variables is important, especially for the empirical applications of the kernel regression methods (see Racine and Li, 2004).

The nonparametric kernel regression method is a dynamic area, and there are rapid ongoing theoretical advances. With advances in computer technology, applications of the kernel regression approach continue to increase. The developments described above provide the dimensions in which the kernel-estimation procedures have been explored in econometrics and statistics. In a broad sense, the frontier of this research area has moved on, and is expected to continue with further developments in both its theory and applications.

Keynes, John Maynard (1883– 1946)

Don Patinkin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

J. M. Keynes was the greatest political economist of the first half of the 20th century. This article traces the development of his thinking about economic theory and policy. It focuses largely on the inter-war trilogy, the Tract on Monetary Reform (1923), the Treatise on Money (1930), and the General Theory of Employment, Interest and Money (1936), in which Keynes's monetary thought evolved from the quantity-theory tradition he had inherited, changed the face of monetary theory, laid the foundation for its development into macroeconomic theory, and defined the analytical framework and research programme of this theory for decades to come.

Article

John Maynard Keynes was one of the great intellectual innovators of the first half of our century, and certainly its greatest political economist. He was born in Cambridge on 5 June 1883, and died at Tilton (in Sussex) on 21 April 1946. His father was John Neville Keynes, also an economist, author of The Scope and Method of Political Economy (1891), and later registrary of Cambridge University.

With the help of a scholarship, Keynes was educated at Eton. He then went on to King's College, Cambridge, where he took a degree in mathematics in 1905. Afterward he spent an additional year at Cambridge studying economics under the then-doyen of British economics, Alfred Marshall, as well as under the latter's student and successor-to-be as Professor of Political Economy at Cambridge, Arthur Pigou. Keynes then entered the Civil Service, where he worked for over two years in the India Office, though he never actually visited India. Out of this work grew his first book in economics, Indian Currency and Finance (1913), which was largely descriptive in nature, and whose main concern was not the Indian monetary system as such – and a fortiori not the Indian economy – but with this system as an example of the workings of a gold-exchange standard. This work also led to Keynes's first major participation in public life as a member of the Royal Commission on Indian Finance and Currency (1913–14).

In 1908 Keynes returned to Cambridge as a Lecturer in Economics (some of Keynes's notes for his lectures during this period have survived and are reproduced in JMK XII, pp. 689–783). During that year he continued his work on A Treatise on Probability, which he successfully submitted to King's College as a fellowship dissertation in 1909. This dissertation was published in a revised form in 1921 and continues to be recognized as a pioneering work in the field. Shortly after the outbreak of World War I, Keynes took a leave of absence from Cambridge to enter the Treasury. Here his exceptional ability and capacity for work led to his rapid advancement, and by 1919 he was principal Treasury representative at the Peace Conference at Versailles. His passionate disagreement with what he considered to be the harsh
In his profession, Keynes is known primarily for his fundamental contributions to monetary economics. The *Tract on Monetary Reform* (1923; henceforth *Tract*), the *Treatise on Money* (1930; henceforth *Treatise or TM*), and the *General Theory of Employment, Interest and Money* (1936; henceforth *GT*): this is the inter-war trilogy that marks the development of Keynes's monetary thought from the quantity-theory tradition that he had inherited from his teachers at Cambridge; to his subsequent systematic attempt to dynamize and elaborate upon this theory and its applications; and, finally, to the revolutionary work (as Klein, 1947, so rightly termed it) which he wrote under the constant stimulus and criticism of his colleagues and students - and with which he changed the face of monetary theory, laid the foundation for its development into macroeconomic theory, and defined the analytical framework and research programme of this theory for decades to come.

(The following discussion draws freely on the material in Patinkin 1976a, 1977 and 1982, to which the reader is referred for further details; all references to Keynes's writings are to the form in which they appear in the relevant volumes (most of which were edited by Donald Moggridge) of the Royal Economic Society's edition of his *Collected Writings*, referred to henceforth as, e.g., *JMK IX, JMK XIII*, and so forth. Though it has its faults (see Patinkin, 1975, section I; 1980. pp. 2–3 (especially n.2 and n.6), p. 8 (n.14), and pp. 14–15 (n.22 and n.23); see also Schefold, 1980, and section 3 below), this edition – to paraphrase one of the famous passages of the *Treatise* – is verily a widow's cruse from which students of the development of Keynes's thought will continue to draw materials for years to come, without diminution in the profits to scholarship.)

Though I have referred to Keynes's three books on monetary theory as a trilogy, they differ from each other greatly not only in substance (a difference that has, of course, been a major theme of all studies of the development of Keynes's thought) but also in form and purpose. Thus the *Tract* is not really a book, but in large part a revision and elaboration of the series of article on postwar economic policy that Keynes first published in 1922 in the 'Reconstruction Supplements' (which he edited) of the *Manchester Guardian Commercial*, with the addition of material that is not always integrated with that from the series.

Thus chapters 1 and 3:2 of the *Tract* are based on these articles and deal with the pressing problems of inflation, deflation, and the resulting exchange rate disequilibrium that then beset Europe. Keynes analysed this disequilibrium in terms of the purchasing-power-parity theory, which he expounded in detail and tested with contemporary data from the countries involved. In the new material presented in chapter 4, he then provided a lucid analysis of the basic dilemma between the 'alternative aims' of stability of the internal price level and stability of the exchange rate – and strongly argued the view that he was to reaffirm in the *Treatise* of giving precedence to the aim of internal price stability. Similarly, the brief, formal presentation of monetary theory that appears in chapter 3:1 of the *Tract* – and which, as Keynes tells us (*Tract*, p. 63, n.1) 'follows the general lines of Professor Pigou ... and of Dr Marshall' – is part of the material that Keynes added to these articles in making up the book.

In this context, Keynes presents the 'famous quantity theory of money' in the following terms:

> Let us assume that the public, including the business world, find it convenient to keep the equivalent of \( k \) consumption units in cash and a further \( k' \) available at their banks against cheques, and that the banks keep in cash a proportion \( r \) of their potential liabilities (\( k' \)) to the public. Our equation then becomes

\[
n = p(k + r k')
\]

[where \( n \) is the quantity of money and \( p \) the price level]. So long as \( k, k' \) and \( r \) remain unchanged, we have the same result as before, namely, that \( n \) and \( p \) rise and fall together (*Tract*, p. 63).

This equation is nothing but a minor variation on the famous 'Cambridge equation' that Pigou had first presented in print in his classic 1917 article (p. 166), to which Keynes at this point refers.

Similarly, when he goes on to explain the determinants of \( k \) and \( k' \), Keynes states that the matter cannot be summed up better than in the words of Dr Marshall:

> 'In every state of society there is some fraction of their income which people find it worth while to keep in the form of currency; it may be a fifth, or a tenth, or a
twentieth. A large command of resources in the form of currency renders their business easy and smooth, and puts them at an advantage in bargaining; but on the other hand it locks up in a barren form resources that might yield an income of gratification if invested, say, in extra furniture; or a money income, if invested in extra machinery or cattle.' A man fixes the appropriate fraction ‘after balancing one against another the advantages of a further ready command, and the disadvantages of putting more of his resources into a form in which they yield him no direct income or other benefit.’ ‘Let us suppose that the inhabitants of a country, taken one with another (and including therefore all varieties of character and of occupation), find it just worth their while to keep by them on the average ready purchasing power to the extent of a tenth part of their annual income, together with a fiftieth part of their property; then the aggregate value of the currency of the country will tend to be equal to the sum of these amounts’ (Tract, p. 64).

The words are from Marshall's Money, Credit and Commerce (1923), pp. 44–5. In this source, however, Marshall indicates that in large part they go back to his testimony before the Indian Currency Committee in 1899 (reproduced in Marshall's Official Papers [1926], esp. pp. 267–9).

Just as this theoretical material was (by Keynes's 'revealed preference') not necessary for an understanding of the original articles in the Manchester Guardian, so is it not really necessary for the book: its deletion would interfere very little with an understanding of the argument of the Tract at other points, as indeed Keynes indicated (Tract, p. 61n).

Conversely (and this is one of the clearest manifestations of the failure of the Tract to be an integrated whole) this added theoretical material in chapter 3:1 barely reflects the penetrating and elegant analysis of inflation as a tax on real money balances (including the notion of an optimum rate of inflation!) that Keynes reproduces from the aforementioned articles in chapter 2:1 of the Tract—and that can be read with both profit and pleasure even today.

Nor does the Tract incorporate the dynamic analysis of the way in which an influx of gold operates through the banking system—and thence on prices—that Keynes (basing himself on Marshall) had summarized in his long 1911 review of Irving Fisher's Purchasing Power of Money (1911), a review that I would essentially consider to be Keynes's first published work on monetary theory. Thus the Tract—as a theoretical work—is not only not integrated within itself, but even fails to reflect some major aspects of Keynes's thinking about monetary problems at the time it was published.

2. On both of these scores the Treatise (on which Keynes began working less than a year after the appearance of the Tract) is the exact opposite. It is as specifically designed for a professional audience whose major concern was with the latest developments in monetary theory as the Tract was designed for a general audience whose major concern was with current policy. Indeed, from the viewpoint of traditional scholarship, the Treatise is Keynes's most ambitious and weighty work: the two-volume work—on ‘The Pure Theory of Money’ and ‘The Applied Theory of Money’—designed to endow him with an academic reputation that would match the public one he had already achieved. At its core (in Books III–IV of Volume I) is a formal, rigorous presentation of a theory of money that deals in detail with both the static and dynamic aspects of the problem. And in the slow, stately, and systematic manner in which an academic treatise customarily proceeds— but in which Keynes of the interwar period so rarely proceeded—it leads up to this core, first, by defining the nature of money and describing its historical origins (Book I); and then (in Book II) describing at length the various index numbers that can be used to measure the value of money, which (to use one of Keynes's favourite terms) is the quaesitum of monetary theory. And afterwards comes Volume II, which begins with a lengthy description of the respective empirical magnitudes of the critical theoretical variables described in the preceding volume—as well as the institutional features of the financial sectors which bear upon these variables (Books V–VI). Only when all this is completed does Keynes finally proceed (in Book VII) to a systematic presentation of the monetary policy, both domestic and international, that he derives from his theory.

The basic problem that Keynes set out to analyse in the Treatise was that of the ‘credit cycle’ and the fluctuations in employment and output which characterize it. His analysis was essentially a simple one: profits—by which Keynes means profits above those representing a normal return on capital—are the motive force of the economy (TM I, pp. 126, 163). The existence of profits causes firms to expand their respective outputs and hence their demands for the inputs of productive services—and conversely for losses. Now (in the Marshallian terms that Keynes used: Principles, Book III, ch. III and Book IV, ch. I), profits are the difference between the ‘demand price’ (i.e. market price; cf. TM I, pp. 186, 189) of a unit of output and its ‘supply price’ (i.e. cost of production). Hence the study of cyclical movements of output reduces to a study of the causes of the differential movements of prices and costs. It is these movements that Keynes then tries to analyse rigorously by means of his ‘fundamental equations’. These are derived (in Chapter 10 of the Treatise) after first distinguishing between ‘consumption goods’ and ‘investment goods’ and then defining the following basic variables of the analysis, where all variables refer to total or aggregate quantities. (For simplicity, and since my main concern is to compare the Treatise with the General Theory, I disregard the variables relating to foreign investment, which actually plays an important role in the Treatise):

\[ E = \text{current money income} = \text{factor earnings (including normal return on capital)} = \text{costs of production}; \]
\[ O = \text{the same, at base-period prices}; \]
\[ I = \text{that part of } E \text{ earned in the investment-goods sector} = \text{current money costs of producing investment goods}; \]
\[ C = \text{the same, at base-period prices}; \]
\[ I = \text{the same, at current market prices, i.e. the current market value of investment goods produced;} \]

\[ E - I' \text{ is that part of } E \text{ earned in the consumption-goods sector; current money costs of producing consumption goods; and } \]
\[ R \text{ is the same, at base-period prices.} \]

Keynes then proceeds to define the price variables

\[ P \text{ = current price level of consumption goods;} \]
\[ P' \text{ = the same, for investment goods; and} \]
\[ \Pi \text{ = the same; for output as a whole = the weighted average of } P \text{ and } P' \text{ = the general price level.} \]

Keynes implicitly (and sometimes explicitly) assumes that the base period is one of the equilibrium – defined as a situation in which per-unit price = per-unit costs in both the consumption-goods and investment-goods sectors. Hence there is no difference between evaluating current output at base-period prices and evaluating it at base-period costs of production. He then defines what are effectively (1) an index of the money wages per unit of labour, \( W \) (where labour represents factors-of-production-in-general) and (2) an index of output per worker, \( e \) (or the ‘coefficient of efficiency’); and he implicitly assumes that both of these indexes change in exactly the same way in both sectors. From these definitions it then follows that the change in the cost of production with respect to the base period in both the consumption and investment sectors is

\[
\frac{E}{O} = \frac{W}{e} = W_1,
\]

where \( W_1 \) (which Keynes calls ‘the rate of efficiency earnings’) is accordingly an index of costs of production per unit of output.

From all this, Keynes then derives his two fundamental equations in the following alternative forms:

\[
P = \frac{E}{O} + \frac{Q_1}{R} = \frac{W}{e} + \frac{Q_1}{R} = W_1 + \frac{Q_1}{R} \tag{i}
\]

\[
\Pi = \frac{E}{O} + \frac{Q}{O} = \frac{W}{e} + \frac{Q}{O} = W_1 + \frac{Q}{O} \tag{ii}
\]

where \( Q_1 \) and \( Q \) represent profits in the consumption sector and in the economy as a whole, respectively. Thus all that fundamental equation (i) consists of is the quite obvious statement that the change (with respect to the base period) in the price of consumption goods equals the change in the per-unit costs of production of these goods (the first term of equation (i)) plus the change in the per-unit (abnormal) profits, assumed zero in the base period (the second term); and equation (ii) makes a correspondingly obvious statement for output as a whole.

The deeper meaning that Keynes attributed to these equations stemmed from his demonstration that profits \( Q_1 \) and \( Q \) were related to savings and investment. In particular, he first defined current savings \( S \) as the difference between income (defined, it will be recalled, as exclusive of abnormal profits) and consumption, or

\[
S = E - PR,
\]
where all variables are defined in current money terms. From this definition and those listed above, it follows that (abnormal) profits in the consumption sector are

\[ Q_1 = PR - (E - I) = I' - S, \]

whereas total (abnormal) profits in the economy are

\[ Q = (PR + I) - E = I - S. \]

Thus one of the distinguishing features of the *Treatise* is that as a result of its special definition of income, savings and investment need not be equal even ex post. The fundamental equations can then be written as

\[ P = E / O + (I' - S) / R \]

and

\[ \Pi = E / O + (I - S) / C \]

– and this, indeed, is their primary form in the *Treatise* (I, pp, 122–3). In this way a change in the general price level – which for Keynes of the *Treatise* (like other monetary economists of that time and earlier, such as Knut Wicksell, Irving Fisher, A.C. Pigou) was the central concern of monetary theory – was directly related to the excess of investment over savings. When \( I' = I = S \), the second terms of (i) and (ii) respectively, disappear, so that price = cost of production (including normal return on capital), and the economy is in equilibrium.

It must be emphasized that though the relation between savings and investment plays a central role in the *Treatise*, this relation served there (in sharp contrast with the subsequent *General Theory*) to analyse in the first instance not changes in output, but changes in prices. Correspondingly, though as indicated, Keynes does discuss changes in output in the *Treatise*, he considers these to be derivative from the changes in prices.

Keynes recognized that his equations were identities, and indeed said so; but he also claimed that they were identities that were useful for classifying causal relationships (*TM* I, p. 125; see also p. 120). In particular, the causal relationship to which he assigned a crucial role in his theory was that connected with the rate of interest. Thus, if we start from a position of equilibrium, a (say) decrease in this rate would cause investment to increase and savings to decrease, thus generate an excess of the former over the latter, thus generate profits, and thus – as indicated by the second term of the second fundamental equation – cause prices to rise. In this way, says Keynes, a decrease in the rate of interest would ‘in itself’ cause a price rise – and not only (as in the traditional quantity theory) as the result of its first generating an increase in the quantity of money (*TM* I, pp. 167–76, esp. p. 171). Conversely, an increase in the rate of interest would directly cause prices to fall. Explicitly following Wicksell, Keynes denotes the rate of interest that would equate savings and investment (and thus generate equilibrium in the system) ‘the natural rate of interest’; and the rate which actually prevails, ‘the market rate’ (*TM* I, p. 139).

Keynes made use of the causal interrelationship of interest and prices to provide a dynamic analysis of the change in the price level generated by a change in the quantity of money –
by which Keynes meant currency plus total bank deposits, which because of the relative unimportance of the former in a modern economy can be conveniently approximated by these deposits alone (TM I, p. 27). For this purpose he first decomposes total deposits into ‘the industrial circulation’ (roughly, demand deposits) and ‘the financial circulation’ (roughly, savings or time deposits) (TM I, chs 15 and 17). These in turn roughly correspond to what were to become the transactions and precautionary-speculative balances of the General Theory (pp. 167 n.1, 194–6).

Similarly, the Treatise contains some of the major features of what was to become the liquidity-preference theory of the General Theory. The presentation in the Treatise is less precise in that it does not adequately analyse the nature of the ‘liquidity premium’ and explicitly present the corresponding functional relationship between the demand for money and the rate of interest. On the other hand, it is more precise with respect to the distinction between stocks and flows: between the stock of wealth on whose asset composition the individual must decide; and the flow of income, with respect to which the individual decides on how much to consume and how much to save, i.e. to add to his wealth (TM I, p. 127). (The emphasis on the distinction between stocks and flows and the specification of a functional relationship are the two major features which distinguish the liquidity-preference theory of the Treatise and General Theory from the Cambridge cash-balance theory which Keynes espoused in his Tract; cf. Patinkin, 1974.) In any event, Keynes explains that the volume of savings deposits (i.e. the financial circulation) is determined by the decision of individuals as to what proportion of their wealth to hold in the form of such deposits as compared with the alternative of holding securities, a decision that depends (inter alia) on the rate of interest (TM I, ch. 10, s.3). Insofar as the industrial circulation is concerned, this is determined by the basic relationship $M_1V_1 = E$, where $M_1$ is the volume of demand deposits, $V_1$ their velocity of circulation, and $E$ the level of aggregate money income=aggregate money costs of production (or $W_1O$). In the real world, $V_1$ is largely determined by institutional factors and hence remains more or less constant in the short run.

Let us now start from an initial position of equilibrium in which, by definition, the market rate of interest equals the natural rate, so that $l′ = l = 5$. Assume that this equilibrium is disturbed by an increase in the quantity of money. Initially, only part of this increase will be absorbed in the industrial circulation; part will be used to bid up the price of securities, which they lend. As a result, entrepreneurs will increase their borrowings in order to finance the undertaking of new projects, so that investments will begin to exceed savings, thus disturbing by an increase in the quantity of money. Initially, only part of this increase will be absorbed in the industrial circulation; part will be used to bid up the price of securities, which they lend. As a result, entrepreneurs will increase their borrowings in order to finance the undertaking of new projects, so that investments will begin to exceed savings, thus increasing money wages and thereby in the per-unit cost of production. That is, $E=W_1O$ will increase, and with it the need for the industrial circulation. This process will continue until money wages have risen sufficiently to eliminate excess profits and until all of the new money has been absorbed in the increased demand for the industrial circulation generated by the increase in $W_1$ and hence in $E$. In Keynes’s words:

This [process] must continue until $(M_1V_1) / O$ has settled down at a higher figure, which is in equilibrium with the new total quantity of money and also with values of $P$ and $P′$ which are enhanced relatively to their old values in a degree corresponding to the amount by which $(M_1V_1) / O$ has been increased (TM I, p. 241).

This conclusion has the unmistakable ring of the quantity theory. And indeed Keynes explains that his second fundamental equation can be rewritten as

$$\Pi = (M_1V_1) / O + (l - 5) / O$$

which in equilibrium (i.e. when $l = 5$) reduces to the Fisherine

$$M_1V_1 = \Pi O.$$

Thus (emphasizes Keynes) for the purpose of comparing equilibrium positions (i.e. for purposes of comparative statics), the traditional quantity theory does indeed remain valid. The purpose of the Treatise in this context, however, is, first, to extend this theory to an economy with a developed banking system, and then to analyse the dynamics of the movement from one equilibrium position to another in such an economy. And this is the role of the interest-rate savings-investment mechanism as it manifests itself in the fundamental equations (TM I, pp. 120, 131–3, 137–8). Indeed, at the beginning of Volume II of the Treatise, Keynes summarizes the dynamic workings of his second fundamental equation by first writing
the quantity equation in the form \( M_1 V' = \Pi C \) and then stating that the purpose of his new theory is to explain how ‘during the transition from one position of equilibrium to another’ the overall velocity of circulation \( V' \) deviates upwards or downwards from its normally constant level, \( V_1 \), in accordance with whether \( l - S > 0 \) or \( l - S < 0 \), respectively (TM II, pp. 4–5; Patinkin 1976a, p. 46, n.2). Thus Keynes regarded his Treatise not as a refutation of the quantity theory, but as an extension of it.

The general policy proposal of the Treatise follows directly from its theoretical analysis: if the ‘credit cycle’ is generated by the alteration of prices with respect to costs, thus generating profits (losses) and hence increases (decreases) in output and employment, then, claimed Keynes (as had Wicksell, Fisher and Pigou before him – and the Chicago School of the 1930s afterwards: Patinkin, 1969), the way to stabilize the economy was to stabilize the price level. And, continued Keynes, the major policy variable for achieving this objective is the Bank Rate as fixed by the central bank, which should be raised when prices tend to rise and lowered when they tend to fall.

At the same time, Keynes recognized that in the gold-standard world which then existed, an undue lowering of the rate of interest in one country relative to others might generate a capital outflow and consequently dangerous loss of gold reserves; hence such ‘international complications’ might prevent the central bank from lowering the rate of interest sufficiently to deal with a depression. And Britain – which was a major centre of international trade and finance – was particularly vulnerable in this respect. For this reason, in the Treatise (II, pp. 337–38), as in the ‘private evidence’ that he gave before the Macmillan Committee when he was in the final stages (February–March 1930) of preparing this book (JMK XX, pp. 71, 125–32), and as in his earlier political pamphlet Can Lloyd George Do It?: An Examination of the Liberal Pledge (1929; JMK IX, pp. 118–19, 123–4) – Keynes’s policy advice for Britain at that time was to combat the depression that beset it not by further reductions in the rate of interest, but by an increase in government expenditures on public works. On the other hand, the United States – which was in much less danger of loss of gold reserves due to international capital movements – should indeed combat its depression by means of a central-bank policy of lowering the rate of interest. This policy difference between Britain and the United States was repeatedly and most explicitly stressed by Keynes in his contributions to the round-table discussions at the 1931 Harris Foundation lectures in Chicago (1931b, pp. 84, 92, 303; see Patinkin, 1979a, pp. 292–3). Accordingly, when in September 1931 Britain abandoned the gold standard, Keynes immediately advocated that it reduce the rate of interest, thus laying the basis for the well-known ‘cheap-money’ policy of subsequent years (Moggridge and Howson, 1974; Howson and Winch, 1977, pp. 57–8; Patinkin, 1979b).

3. Keynes had great hopes for the Treatise. Thus shortly after its publication, in his June 1931 Harris Foundation lecture on ‘An Economic Analysis of Unemployment’, he explicitly made use of the analysis of this book and proclaimed, ‘That is my secret, the clue to scientific explanation of booms and slumps (and of much else, as I should claim) which I offer you’ (JMK XIII, p. 354). But these hopes were not to be fulfilled. For it rapidly became clear that the theoretical part of the book was not a success and was indeed subjected to severe criticism. To a certain extent this was due to the fact (which Keynes had only in part and somewhat grudgingly recognized (see TM I, pp. 176–8, especially p. 177, n.3, and p. 178, n.2) that this theory, as well as the corresponding policy proposal, had been largely adumbrated at the turn of the century by Wicksell (1898, 1906, 1907) – which brought on Gunnar Myrdal’s (1933, pp. 8–9) chiding remark about ‘the attractive Anglo-Saxon kind of unnecessary originality, which has its roots in certain systematic gaps in the knowledge of the German language on the part of the majority of English economists’. (In point of fact, Keynes – at least before World War I – knew German well enough to review in the Economic Journal several books written in that language (see the reviews reprinted in JMK XI, pp. 400–403, 562–74); it is, however, not difficult to believe that in the course of fifteen years, Keynes might have lost a good deal of his proficiency in that language). But the most telling criticism of the Treatise was that, on the one hand, its ‘fundamental equations’ were actually tautologies, and, on the other, that the book had explained the forces that caused output to expand or contract, but had not explained what determines its actual level during any period. (See the end of section 8 below for a discussion of circumstances connected with the writing of the Treatise that also contributed to its lack of success.)

As a result of this criticism, Keynes began within a relatively short time after the appearance of the Treatise to work on a new book which ultimately developed into the General Theory (1936). The chronology of this development can in part be traced by means of the materials (including correspondence, fragments of earlier drafts, and galleys of successive proofs) that Moggridge has reproduced and annotated in JMK XIII–XIV and XXIX. There can, however, be legitimate differences of opinion about the dating of some of these fragments (cf. Patinkin, 1976a, p. 71, n.7; 1980, pp. 14–15, n.22 and n.23, and pp. 18–19); so we are extremely fortunate to be able to supplement them with the precisely dated materials in the unique ‘archaeological’ record of the successive ‘strata’ of Keynes’s thought provided by Robert Bryce’s notes on Keynes’s weekly lectures during the autumn terms of the years 1932, 1933, 1934 and Lorie Tarshis’s notes for these years as well as 1935 (reproduced in Ryms (ed.), 1988). The first year after the publication of the Treatise (viz., 1930–31) was devoted to a criticism of this book, greatly aided by the detailed comments of Ralph Hawtrey and the extensive discussions that took place in the so-called ‘Cambridge Circus’ (in the sense of ‘circle’) – or what today would probably be called the ‘Cambridge Colloquium’. The major participants of this legendary ‘Circus’ were Keynes’s younger colleagues, Richard Kahn, James Meade, Austin Robinson, Joan Robinson and Piero Sraffa, with his former student Kahn serving as the channel of communication between Keynes and the group (JMK XIII, pp. 337–43; Kahn, 1984, pp. 105–11: Keynes at that time was in his late forties, whereas the members of the ‘Circus’ were mostly in their mid-twenties). The aforementioned lecture notes, however, show that the central message of the Treatise (explicated below) was not fully developed until some time in 1933, well after the activities of the ‘Circus’ as such had come to an end (Patinkin, 1976a, chs 7–8; 1977; 1982, ch. 1). However, from some of the younger members of the ‘Circus’ (especially Kahn and Joan Robinson) – as well as from his contemporaries, Ralph Hawtrey and Dennis Robertson – Keynes continued to seek out and benefit from criticisms throughout the process of working through and revising the successive drafts of the General Theory (cf. JMK XIII, ch. 5; JMK XXIX, ch. 3; Patinkin and Leith (eds), 1977, passim).

Like the Treatise, the General Theory is – in Keynes words of his preface – ‘chiefly addressed to … fellow economists’. It differs from the Treatise in being almost exclusively concerned with theory. Indeed, this is the whole purpose of the book, as indicated by its very title. Thus General Theory practicably contains no description of institutional details.
And for a work that is credited with having initiated a revolution in fiscal policy, it contains surprisingly few explicit discussions of the policy implications of its analysis. Indeed, the major new policy conclusion of the *General Theory* as compared with the *Treatise* – namely, that monetary policy directed at lowering the interest rate, though an essential component of a full-employment policy, might not be enough even in the absence of ‘international complications’ to achieve this goal, so that an effective policy for this purpose may well require direct government spending – this conclusion is never developed systematically and in detail. Indeed, it is only referred to on one or two occasions in passing (e.g. *GT*, p. 164) and in brief ‘Concluding Notes’ of a general nature (*GT*, pp. 372–84). Thus, the advocacy per se of public-works expenditure was not the purpose of the *General Theory*; rather it was to provide a theory which would, among other things, rationalize such a policy – with the actual advocacy of the policy being left for Keynes’s public activities of the period (see section 11 below).

Similarly, the problem of the relation between internal price levels and exchange rates – and indeed the whole problem of the international monetary system and its relation to domestic policies, which were a major concern of Keynes in the *Treatise*, as they had been in the *Tract*, and were again to be at Bretton Woods toward the end of World War II – are not discussed in the *General Theory*. The explanation for this fact too probably lies in the situation that prevailed in the Western world during the period that the *General Theory* was being written. In particular, this was the new world ushered in by England’s abandonment of the gold standard: a world of flexible exchange rates and/or severe restrictions on the flow of international trade, in which the aforementioned problems had accordingly largely lost their relevance. Correspondingly, the analysis of the *General Theory* is carried out almost entirely on the implicit assumption of a closed economy.

I should, however, emphasize that if from these viewpoints the *General Theory of Employment, Interest and Money* was more narrowly conceived than the *Treatise on Money*, from another viewpoint it is – as its title indicates – much broader. For ‘monetary theory’ in the *Treatise* means, first and foremost, a theory that explains the determination of the price level. Accordingly, if the argument of the *Treatise* revolves about Keynes’s ‘fundamental equations’, these are (as the title of its chapter 10 makes clear) ‘The Fundamental Equations for the Value of Money’ (*TM*, p. 151, italics added). Again, Keynes prefaces Book VI of the *Treatise*, ‘The Rate of Investment and Its Fluctuations’, with the statement that it is ‘in the nature of digression, which is doubtfully in place in a treatise on money’ (*TM*, II, p. 85). In conformity with this view – and in sharp contrast with the systematic attempt of the *General Theory* to base its analysis on the marginal concepts of value theory and thus integrate monetary and value theory (*GT*, pp. 292–3) – the term ‘marginal productivity’ (of labour or of capital) does not appear in the *Treatise*. Thus, though as noted above, Keynes attributes the term ‘natural rate of interest’ to Wicksell, he does not follow the latter in associating this term with the marginal productivity of capital (Wicksell, 1898, pp. 102–4, 171; 1906, pp. 192–3; 1907, pp. 214–19). Finally, and as a corollary of the primary concern of the *Treatise* with prices, whereas that book deals with output only as derivative from changes in price and in this context indicates only the direction of change of output and employment, the *General Theory* presents a theory of the determination of the equilibrium levels of these variables.

A more precise specification of the basic contention of the *General Theory* can be obtained by letting Keynes speak for himself, as he did in a letter to Roy Harrod in August 1936, commenting on a draft of the latter’s review article of the *General Theory* – a letter whose first and most important point largely repeats what Keynes had written to Abba Lerner two months earlier on his review (see JMK XXIX, pp. 214–16):

You don’t mention effective demand or, more precisely, the demand schedule for output as a whole, except in so far as it is implicit in the multiplier. To me the most extraordinary thing, regarded historically, is the complete disappearance of the theory of demand and supply for output as a whole, i.e., the theory of employment, after it had been a quarter of a century the most discussed thing in economics [presumably, the quarter-century between the beginning of the Ricardo–Malthus debate on the possibility of a ‘general glut in the market’ in 1820 and the appearance of J.S. Mill’s *Principles of Political Economy* in 1848; see also the reference to this period in the *General Theory* (pp. 32–4)]. One of the most important transitions for me, after my *Treatise on Money* had been published, was suddenly realizing this. It only came after I had enunciated to myself the psychological law that, when income increase, the gap between income and consumption will increase, – a conclusion of vast importance to my own thinking but not apparently, expressed just like that, to anyone else’s. Then, appreciably later, came the notion of interest being the measure of liquidity preference, which became quite clear in my mind the moment I thought of it. And last of all, after an immense amount of muddling and many drafts, the proper definition of the marginal efficiency of capital linked up one thing with another (cited from the ‘Editorial Introduction’ to the *General Theory* JMK VII, p. xx, italics in original; there are significant errors of transcription in this passage in the full text of this letter as reproduced in *JMK* XIV, pp. 83–6: see Patinkin, 1976a, p. 66, n.3).

Now, in the *General Theory* (p. 141) Keynes himself had attributed priority for the notion of the marginal efficiency of capital to Irving Fisher. Insofar as the theory of liquidity preference is concerned, this is clearly a contribution of Keynes, but (as noted above) it is one whose basic features had already been presented in the *Treatise*. This leaves the theory of effective demand as the distinctive analytical contribution of the *General Theory* and its central message (on the meaning and significance of this last term, see Patinkin 1982, chs 1 and 4).

That this is its central message is also clear from the *General Theory* itself. Thus Keynes tells us in its preface that, in contrast with his earlier *Treatise*, his new work is ‘primarily a study of the forces which determine changes in the scale of output and employment as a whole’; gives chapter 3 of ‘Book I: Introduction’ the title ‘The Principle of Effective Demand’, and presents in it a ‘summary of the theory of employment’ that he will develop in the book (*GT*, p. 27); and devotes most of the remaining chapters of the *General Theory* to this development.
Figure 1 reproduces the familiar diagram which has served to transmit the central message of the *General Theory* to generations of economics students. I wish, however, to refine the usual analysis which accompanies this diagram in one respect. In particular, what I mean by the theory of effective demand is not only that the intersection of the aggregate-demand curve $E = F(Y)$ with the 45° line determines equilibrium real output $Y_0$ at a level that may be below that of full employment $Y_F$ not only (as Leijonhufvud (1968) has also emphasized) that disequilibrium between aggregate demand and supply causes a change in output and not price; but also (and this is the distinctively novel feature) that the change in output (and hence income) itself acts as an equilibrating force. That is, if the economy is in a state of excess aggregate supply at (say) the level of output $Y_1$, then the resulting decline in output, and hence income, will depress supply more than demand and thus eventually bring the economy to equilibrium at $Y_0$. Or, in terms of the equivalent savings=investment equilibrium condition, the decline in income will decrease savings and thus eventually eliminate the excess of savings over investment that exists at $Y_1$. In Keynes's words,

The novelty in my treatment of saving and investment consists, not in my maintaining their necessary aggregate equality, but in the proposition that it is, not the rate of interest, but the level of incomes which (in conjunction with certain other factors) ensures this equality (1937, p. 211; cf. also *GT*, p. 31, lines 16–23; p. 179, lines 2–6).

In more formal terms (which Keynes himself did not use), the theory of effective demand is concerned not only with the mathematical solution of the equilibrium equation $F(Y) = Y$, but with demonstrating the stability of this equilibrium as determined by the dynamic adjustment equation $dY/\,dt = G[F(Y) - Y]$, where $G' > 0$. 

Figure 1
Correspondingly, as Keynes emphasizes in his letter to Harrod and elsewhere, a crucial assumption of his (Keynes’s) analysis is that the marginal propensity to consume is less than unity, which in turn implies that the marginal propensity to save is greater than zero. For, if the marginal propensity to consume were equal to unity, no equilibrating mechanism would be activated by the decline in output. Specifically, as income (output) decreased, spending would decrease by exactly the same amount, so that any initial difference between aggregate demand and supply would remain unchanged. Alternatively, as income decreased, the initial excess of desired saving over investment would remain unchanged. Thus the system would be unstable. This is the major novel feature of the *General Theory* and its central message: the theory of effective demand as a theory which depends on the equilibrating effect of the decline in output itself to explain why ‘the economic system may find itself in stable equilibrium with \( N \) [employment] at a level below full employment, namely at the level given by the intersection of the aggregate demand function with the aggregate supply function’ (*GT*, p. 30).

Since most economists today probably learned the theory of effective demand as just another chapter in their introductory course in economics, it may be difficult for them to conceive of the intellectual shock wave that this theory created when Keynes first presented it. Testimony to this impact has, however, been given by many elders of our profession who (in Samuelson’s words) were ‘born as economists prior to 1936’ (1946, p. 315). And though my ‘birthyear’ was about a decade after this date, I began my studies before the theory of effective demand had percolated down to the introductory course in the field. So I, too, can still remember how strange and even difficult it was during my later graduate studies to have to learn to think in terms of a demand for aggregate output as a whole – a demand that was in some way conceptually different from actual aggregate income, as if national income expended could somehow differ from national income received!

Similarly, under the influence of Marshall’s *Principles* (which was then still being used as a textbook), it had been thoroughly ingrained into us that the demand function for a good could be defined only under the assumption of ‘ceteris paribus’. Indeed, in order to insure that this assumption was fulfilled in practice, the more punctilious economists of those days were only willing to speak of the demand function for a good the total expenditure on which was small, so that variations in these expenditures as price varied would not significantly affect the ‘marginal utility of money’ (i.e. the marginal utility of money expenditures: see ibid., Bk. III, chs iii and vi). How then could one validly speak of a demand function for the aggregate of all goods? How was it possible for ‘other things to be held constant’ in such a case?

(The foregoing diagram does not appear in the *General Theory* – a fact which has in recent years led certain circles to contend that it does not represent Keynes's theory. This,
however, is an invalid inference: for with one exception, Keynes did not use analytical diagrams in any of his writings. And that one exception is the diagram which appears on p. 180 of the General Theory – a diagram which in the accompanying footnote, Keynes attributes to Harrod. Furthermore, in his later ‘How to Pay for the War’ (1940; JMK IX, pp. 416–17), Keynes analysed the expected inflationary gap in Britain by means of the C+I=Y rubric, which is of course the arithmetical counterpart of the 45° diagram. See also section 5 below for a conjecture about why Keynes presented his theory of effective demand in terms of the level of employment, and not of national income, as in the diagram.)

Needless to say, there are other interpretations of the novelty and central message of the General Theory. The preceding and following discussions implicitly (and sometimes explicitly) explain why I do not accept some of the leading ones: namely, the interpretations which contend that this message is the analysis of an economy caught in the ‘liquidity trap’ (Hicks, 1937) and/or one in which money wages are completely inflexible downwards (Modigliani, 1944); that it is the proposition that unemployment is caused by the inadequacy of aggregate demand; that it is the analysis of the way expectations are formed and influence behaviour in an uncertain world whose uncertainty is not subject to the probability calculus (Shackle, 1967, ch. 11; Davidson, 1972); that it is the multiplier; that it is the crucial role of fluctuating investment in generating business cycles; that it is the theory of effective demand (and particularly of the aggregate supply function) as a determinant of the wage and price levels (Weintraub, 1961); and that it is the advocacy of public works as a means of combating unemployment (the implicit interpretation of various writers who have regarded such advocacy as an anticipation of the General Theory; cf. e.g., Garvy, 1975 and Backhaus, 1985). Insofar as Leijonhufvud (1968) is concerned, he himself has subsequently admitted that his book was about ‘theoretical problems that were current problems in the early or mid-sixties … . What Keynes might have meant etc. was not one of the problems. Doctrine history was not what the book was about’ (Leijonhufvud, 1978).

(For further details, see Patinkin, 1976a, pp. 141–2; 1982, pp. 5–7, 84 fn.8, 153–8; 1984, pp. 101–2.) To bring out the central message of the General Theory more sharply, let me contrast Keynes’s discussion in this book with the corresponding one of the Treatise. In the General Theory, a decrease in consumption – or, equivalently, an increase in savings – is represented by a downward shift of the aggregate-demand curve in Figure 1 to $E’$; the resulting decline in output will then cause a corresponding decline in the amount consumed – and hence in the amount saved – until a new equilibrium is necessarily reached at $Y_2$ (cf. GT, pp. 82–5, 183–4). Contrast this with Keynes’s ‘parable’ in the Treatise of a simple ‘banana plantation’ economy in an initial position of full-employment equilibrium which is disturbed because (in Keynes’s words) ‘into this Eden there enters a thrift campaign’. Making use of the analytical framework of the Treatise, Keynes explains that the resulting increased savings, unmatched by increased investment, will cause entrepreneurs to suffer losses (i.e. $Q = I - S < 0$) and they will seek to protect themselves by throwing their employees out of work or reducing their wages. But even this will not improve their position, since the spending power of the public will be reduced by just as much as the aggregate costs of production. By however much entrepreneurs reduce wages and however many of their employees they throw out of work, they will continue to make losses so long as the community continues to save in excess of new investment. Thus there will be no position of equilibrium until either (a) all production ceases and the entire population starves to death, or (b) the thrift campaign is called off or peters out as a result of the growing poverty; or (c) investment is stimulated by some means or other so that its cost no longer lags behind the rate of saving (TM I, pp. 159–60).

In brief, it seems to me that – to make anachronistic use of a concept of the General Theory – Keynes is implicitly assuming here that the marginal propensity to spend is unity, so that a decline in output cannot reduce the excess of saving over investment and thus cannot act as an equilibrating force. Instead, the decline in output continues indefinitely; or alternatively, the decline might end as the result of some exogenous force that closes the gap between saving and investment – ‘the thrift campaign is called off’, or ‘investment is stimulated by some means or another’. In brief, none of these alternatives indicates that Keynes of the Treatise understood that the decline in output itself acts directly as a systematic endogenous equilibrating force.

4. The foregoing is the essence of the theory of effective demand as presented in ‘Book I: Introduction’ of the General Theory under the explicit simplifying assumptions of a constant level of investment (which presupposes a constant rate of interest) and a constant money wage-rate (GT, pp. 27–9). (For deficiencies in this presentation – and particularly in that of the aggregate supply function – stemming primarily from Keynes’s failure to apply the marginal concept correctly, see Patinkin, 1982, pp. 142–57. In this connection it should be noted that according to Joan Robinson’s own testimony (1969, p. xi), ‘Keynes was not much interested in the theory of imperfect competition’ that she was developing in the early 1930s, and in which marginal analysis played a central role (J. Robinson, 1933a). See also the similar statement by Austin Robinson in Patinkin and Leith, 1977, p. 79.) After a ‘digression’ from the ‘main theme’ (GT, p. 37) in ‘Book II: Definitions and Ideas’ for the purpose of clarifying various concepts, Keynes then devotes most of the remainder of the book to an elaboration of the theory of effective demand which (inter alia) is free of these restrictive assumptions.

In ‘Book III: The Propensity to Consume’ he elaborates upon the determinants of the consumption component of aggregate demand and also discusses the related multiplier (GT, pp. 114–15), referring in this context to the 1931 article of his former student, Kahn. (This article was actually the successful outcome of Kahn’s efforts – with his mentor’s encouragement – to provide a precise formula for measuring the ‘indirect effects’ of an increase in government expenditures, effects which Keynes in his 1929 election pamphlet Can Lloyd George Do It?, had described as of ‘immense importance’, but impossible of measurement ‘with any sort of precision’ (JMK IX, pp. 106–7; cf. Howson and Winch, 1977, pp. 48–9; Patinkin, 1978)).

In ‘Book IV: The Inducement to Invest’, Keynes drops the assumption of a constant level of investment and explains how this level is determined by the marginal-efficiency-of-
capital schedule in conjunction with the rate of interest, which rate is determined in turn by the liquidity-preference schedule in conjunction with the quantity of money. I might note that Keynes's liquidity-preference function \( N = n_1 (Y) + n_2 (\gamma) \), where \( M \) and \( Y \) respectively represent nominal money and nominal income (GT, p. 199) – actually (though in all probability, inadvertently) reflects money illusion (see Patinkin 1956 and 1965, chapter XI:1 and Supplementary Note K:2).

Chapter 12 (‘The State of Long-Term Expectations’) elaborates upon the argument of Book II, chapter 5 (‘Expectations as Determining Output and Employment’). The crucial influence of uncertainties on both the aforementioned schedules – and hence the necessity to make decisions with respect to them on the basis of expectations – is emphasized. As Samuelson (1946, p. 320) has however noted, Keynes’s discussion ‘paves the way for a theory of expectations, but it hardly provides one’ (see also the detailed critique by Hart, 1947). In any event, Keynes emphasizes that the uncertainties in question are not subject to a probability calculus, so that long-run investment decisions in particular may instead be the result of ‘animal spirits’ (GT, p. 161; see also Keynes's 1937 JQJE article as reproduced in JMK XIV, p. 114). (The distinction between risk, which is subject to such a calculus, and uncertainty which is not, was the major point of Knight's classic 1921 work on Risk, Uncertainty, and Profit; there may also be a hint of this distinction in chapter 6 of Keynes's Treatise on Probability, published the same year, to which Keynes refers (GT, p. 148, n.1); see also Lawson and Pesaran, 1985.) These uncertainties are a major source of the effectively low interest-elasticity of the first of these schedules, as well as the source of the speculative demand for money, and hence the effectively high (though not infinite) interest-elasticity of the second of them. (Keynes does not always distinguish between a movement along a demand curve and a shift of the curve itself, and it is the combined result of these two changes that I denote by ‘effective elasticity’).

Thus the many interpretations to the contrary notwithstanding, Keynes did not base his theory on the so-called ‘liquidity trap’. In his words, ‘whilst this limiting case might become practically important in future, I know of no example of its hitherto’ (GT, p. 207. See also Keynes's brief description of the way in which, after Britain abandoned the gold standard in 1931 (see concluding paragraph of section 2 above), the monetary authorities had succeeded in gradually driving down the rate of interest. But see Patinkin, 1976a, pp. 111–13 for some indications of ambivalence in the General Theory about the relevance of the ‘liquidity trap’.) It is because of these elasticities that monetary policy may well be inadequate to the task of eliminating unemployment: for an increase in the quantity of money will not significantly reduce the rate of interest; and to the extent that there is such a reduction, it will not generate a significant increase in investment and hence in aggregate demand (cf. GT, pp. 164, 168–70). Book IV also includes chapter 17 on ‘The Essential Properties of Interest and Money’, with all of its confusions and obscurities (see Lerner, 1952; see also Hart, 1947, p. 416 and Hansen, 1953, p. 159).

Keynes concludes Book IV with a summary chapter (18) entitled ‘The General Theory of Employment Re-Stated’. In substance, though not in form, and certainly not with intent (see section 9 below and Patinken, 1976a, pp. 98–100), this chapter (like the diagram on p. 180 of chapter 14) provides a general equilibrium analysis of the determination (as of a given money-wage rate and nominal quantity of money) of the equilibrium level of national income by the interactions between the commodity (consumption- and investment-goods) and money markets (GT, pp. 246–7). Thus a basic contribution of the General Theory is that it is in effect the first practical application of the Walrasian theory of general equilibrium: ‘practical’, not in the sense of empirical (though the General Theory did provide a major impetus to empirical work), but in the sense of reducing Walras's formal model of \( n \) simultaneous equations in \( n \) unknowns to a manageable model from which implications for the real world could be drawn. Furthermore, like Walras's model in the Eléments (1926, lessons 29–30), Keynes's model in the General Theory is one that integrates the real and monetary sectors of the economy. It is this general-equilibrium aspect of the General Theory that Hicks (1937) was subsequently to develop and formalize in his influential IS–LM interpretation of the book – with respect to which Keynes wrote him that ‘I found it very interesting and really have next to nothing to say by way of criticism’ (JMK XIV, p. 79).

Finally, in ‘Book V: Money-Wages and Prices’, Keynes drops the assumption of a constant money-wage rate and applies the theory of effective demand that he had developed in Books I–IV to an analysis (in the first chapter of this book, ‘Chapter 19: Changes in Money Wages’) of the effects of a decline in this rate. It should be emphasized that Keynes regarded such a decline not as an abstract theoretical possibility, but as what had actually happened to money wages in the years immediately preceding the General Theory. Thus from 1925–33, money wages had declined in Britain by 7 per cent, whereas in the United States they had declined over the much shorter period 1929–33 by 28 per cent (sic!) (see Keynes's allusion to the former on p. 276 of the General Theory, and to the latter on p. 9; on the sources of the above data, see Patinkin, 1976a, pp. 17 and 121). During these periods, however, real wages in both countries actually rose, which was the background of Keynes's oft-cited enigmatic statement (to which I shall return below) that ‘there may exist no expedient by which labour as a whole can reduce its real wage to a given figure by making revised money bargains with the entrepreneurs’ (GT, p. 13, italics in original).

Keynes's basic argument in chapter 19 is that a decline in money wages (which in practice would, because of the resistance of workers, take place only very slowly: GT, p. 267; see also ibid., pp. 9, 251, 303) can increase the level of employment only by first increasing the level of effective demand; that the primary way it can generate such an increase is through its effect in increasing the quantity of money in terms of wage units, thereby decreasing the rate of interest and stimulating investment; that accordingly the policy of attempting to eliminate unemployment by reducing money wages is equivalent to a policy of attempting to do so by increasing the quantity of money at an unchanged wage rate and is accordingly subject to the limitations as the latter; namely, that a moderate change ‘may exert an inadequate influence over the long-term rate of interest’, while an immoderate one (‘even if it were practicable’) ‘may offset its other advantages by its disturbing effect on confidence’ (GT, pp. 266–7).

Indeed, the possible adverse effect of confidence is greater in the case of a wage (and price) decline than in that of a monetary expansion, and this for two reasons: first, the decline may create the expectation of still further declines, thus leading firms to postpone carrying out any decision to increase their demand for labour; second, ‘if the fall of wages and prices goes far, the embarrassment of those entrepreneurs who are heavily indebted may soon reach the point of insolvency – with severely adverse effects on investment’ (GT, p.
This adverse effect will be reinforced by the fact that the 'expectation that wages are going to sag by, say, 2 per cent in the coming year will be roughly equivalent to the effect of a rise of 2 per cent in the amount of interest payable for the same period' (GT, p. 265). (This use of what is essentially Fisher's distinction between the real and nominal interest rates is somewhat inconsistent with reservations that Keynes expressed about it earlier in the General Theory, pp. 141–3.) Hence Keynes's major conclusion – and indeed the negative component of his central message – that 'the economic system cannot be made self-adjusting along these lines' (GT, p. 267). In this way Keynes finally supplies the theoretical basis for his claim in chapter 2 of 'Book I: Introduction' that, contrary to the 'classical' view, 'a willingness on the part of labour to accept lower money-wages is not necessarily a remedy for unemployment' – a claim he had promised would be 'fully elucidated ... in Chapter 19' (GT, p. 18).

The analysis of chapter 19, together with Keynes's acceptance in chapter 2 of the 'classical postulate' that 'the wage is equal to the marginal product of labour' (GT, p. 5), enables us to understand the enigmatic statement cited three paragraphs above. Specifically, if the effect of a decline in the money wage rate on the level of effective demand, hence output, and hence employment is indeterminate, then so too is its effect on the marginal product of labour and hence real wages. Thus Keynes's statement is simply a reflection of his basic view that

the propensity to consume and the rate of new investment determine between them the volume of employment, and the volume of employment is uniquely related to a given level of real wages – not the other way round (GT, p. 30).

And since Keynes also accepts the classical law of diminishing returns (GT, p. 17), he contends that if a sharp decline in money wages should generate only a slight increase in the level of employment – hence only a slight decrease in the real wage rate – then it must also generate a sharp (though proportionately smaller) decrease in the price level (however, Keynes never explains the dynamic market forces that bring this about; see the discussion below of chapter 21). In Keynes's words at the end of chapter 19:

It follows, therefore, that if labour were to respond to conditions of gradually diminishing employment by offering its services at a gradually diminishing money-wage, this would not, as a rule, have the effect of reducing real wages and might even have the effect of increasing them, through its adverse influence on the volume of output. The chief result of this policy would be to cause a great instability of prices, so violent perhaps as to make business calculations futile in an economic society functioning after the manner of that in which we live (GT, p. 269).

Accordingly, Keynes concludes chapter 19 with the policy recommendation that 'the money-wage level as a whole should be maintained as stable as possible, at any rate in the short period' (GT, p. 270).

This is an appropriate point to note that though in Book III, Keynes take account of what might be called the capital-gains effect on consumption (GT, pp. 92–4), he does not do so with reference to the wealth effect as such, and in particular does not do so with reference to the real-balance component of this effect. Correspondingly, his analysis in chapter 19 does not take account of the positive real-balance effect generated by a wage and price decline. But since the operation of this effect in this deflationary context suffers from the same limitations described in this chapter, I do not believe that taking account of it would have affected Keynes's basic conclusion about the inefficacy of a wage decline as a means of increasing employment (Patinkin, 1951, pp. 272–8; 1956, pp. 234–7; 1965, pp. 336–40; 1976a, pp. 110–11).

Thus chapter 19 is the climax of the General Theory. And it is clear from it that, the many contentions to the contrary notwithstanding, the analysis of this book does not depend on the assumption of absolutely rigid money wages. What is, however, true is that, because of the aforementioned adverse effects of flexibility, the relative stability of money wages is the concluding policy recommendation of the chapter. I must also emphasize that were the General Theory to depend on the assumption of wage rigidity, there would be no novelty to its message: for the fact that such a rigidity can generate unemployment was a commonplace of classical economics. Needless to say, this does not mean that Keynes went to the opposite extreme of assuming wages to be perfectly flexible. Instead, his view of the real world was that 'moderate changes in employment are not associated with very great changes in money-wages' (GT, p. 251). At the same time, Keynes emphasizes that there exists an 'asymmetry' between the respective degrees of upward and downward wage flexibility: that, in particular, 'workers are disposed to resist a reduction in their money-wages, and that there is no corresponding motive to resist an increase' (GT, p. 303).

I might note that Keynes's lack of faith in the efficacy of the market-equilibrium process in a macroeconomic context also manifests itself in such earlier writings as The Economic Consequences of Mr Churchill (1925; JMK IX, pp. 227–9 et passim) and the Treatise (I, pp. 141, 151, 244–5, 265). Nor (I conjecture) would Keynes have been impressed by the contention of some exponents of the 'new classical macroeconomics' that the market would not permit a situation of unemployment to persist because contracts could then be made which would make everyone better off. Indeed, I would conjecture that, as one who had seen how the most civilized countries of the world had engaged for four long years of stalemated trench warfare in the mutual slaughter of the best of their young men, Keynes was not predisposed to believe in natural forces that always brought agents to generate a mutually beneficial situation. Because of the uncertainty of how other react to our actions, the actual world for Keynes was one that – in a macroeconomic context – could readily lead to the 'globally irrational' results of the prisoner's dilemma; not to the rational results of the Walrasian auctioneer.

Book V also contains 'Chapter 21: The Theory of Prices'. In 'Book I: Introduction', Keynes had stated that 'we shall find that the Theory of Prices falls into its proper place as a matter which is subsidiary to our general theory' (GT, p. 32). In particular, as already noted, the level of effective demand determines the level of employment, hence the marginal
productivity of labour, and hence the real wage rate; for any given money wage rate, then, the price level is determined. In the words of chapter 21, ‘The general price-level (taking equipment and technique as given) depends partly on the wage-unit [i.e., on the money wage rate] and partly on the volume of employment’ (GT, p. 295). It should again be noted that Keynes's discussion here is completely mechanical and provides no explanation of the dynamic market forces that cause the price level to change as a consequence of a change in money wages.

Chapter 21 also includes a discussion of the quantity theory of money. In the Treatise, as noted above, Keynes regarded this theory to be deficient only because of the absence of a dynamic analysis – which he then supplied. In the General Theory, however, Keynes saw himself as providing a new theory that replaced the quantity theory entirely. For, he claimed, the quantity theory holds only on two unrealistic conditions: first, that the speculative demand for money ‘will always be zero in equilibrium’ (actually, this is not a necessary condition; see Patinkin 1956 and 1965, ch. XII:1); second, that the level of output is constant at full employment (GT, pp. 208–9). Thus Keynes may well have regarded the General Theory as the culminating chapter in The Saga of Man's Struggle for Freedom from the Quantity Theory. Indeed, in his preface to the French edition of the General Theory, Keynes wrote that ‘the following analysis [of money and prices] registers my final escape from the confusions of the Quantity Theory, which once entangled me’ (JKM VII, p. xxxiv). The last Book of the General Theory – ‘Book VI: Short Notes Suggested by the General Theory’ – is, as its title indicates, essentially an appendage to it, one that could have been omitted without affecting the logical integrity of the book as a whole. The Book begins with ‘Chapter 22: Notes on the Trade Cycle’. Here Keynes contends that the cycle is generated by changes in the marginal efficiency of capital – which changes, for reasons discussed in this chapter, ‘have had cyclical characteristics’. He claims no novelty for this interpretation (‘these reasons are by no means unfamiliar either in themselves or as explanations of the trade cycle’) and explains that the purpose of the chapter is ‘to link [these reasons] up with the preceding theory’ (GT, pp. 314–15). Chapter 23 is entitled ‘Notes on Mercantilism, the Usury Laws, Stamped Money and Theories of Under-Consumption’ – whose omnibus title is a further indication that the material of Book VI is not an integral part of the book. The last chapter of the Book – and of the General Theory as a whole – is ‘Chapter 24: Concluding Notes on the Social Philosophy towards Which the General Theory Might Lead’. Only to a minor extent, however, is this chapter concerned with the question of short-run, full-employment policy – and in this context Keynes reiterates his scepticism of sole reliance on monetary policy and his corresponding belief ‘that a somewhat comprehensive socialisation of investment will prove the only means of securing an approximation to full employment’ (GT, p. 378). Most of the chapter is devoted to the long-run implications of a successful full-employment policy for the accumulation of capital, hence the rate of interest and the distribution of income; for the future of laissez-faire versus state socialism; and for the prospects of war and peace.

In chapter 24, Keynes also expresses his belief in the efficacy of the market mechanism, once the ‘socialisation of investment’ has assured the maintenance of full employment. Under these conditions, says Keynes,

there is no objection to be raised against the classical analysis of the manner in which private self-interest will determine what in particular is produced, in what proportions the factors of production will be combined to produce it, and how the value of the final product will be distributed between them. Again, if we have dealt otherwise with the problem of thrift, there is no objection to be raised against the modern classical theory as to the degree of consilience between private and public advantage in conditions of perfect and imperfect competition respectively. Thus, apart from the necessity of central controls to bring about an adjustment between the propensity to consume and the inducement to invest, there is no more reason to socialise economic life than there was before (GT, pp. 378–9).

(In a similar way, Keynes was to argue in his posthumously published article on ‘The Balance of Payments in the United States’ (1946) that it was important to establish a framework for international trade and finance ‘which allows the classical medicine to do its work’ in establishing equilibrium in this context (JKM XXVII, pp. 444–5; see also Cairncross, 1978. But see Keynes's 1926 essay on ‘The End of Laissez-Faire’ (reproduced in JMK IX, pp. 272–94) for some reservations à la Knight's classic 1923 paper on ‘The Ethics of Competition’ about the workings of the market economy.)

5. From the foregoing it is clear that the primary concern of the General Theory is theory and not policy, though Keynes does make brief use of the theory to explain the necessity for public-works expenditures to combat severe unemployment; that the primary concern of its theory is output (or employment) and not prices; and that the primary concern of its theory of output is the explanation of equilibrium at less-than-full-employment and not cyclical variations in output.

Another point which is clear from this summary is that Keynes's repeated use of the term ‘unemployment equilibrium’ (GT, pp. 28, 30, 242–3, 249) in the first 18 chapters of the General Theory must, strictly speaking, be understood as referring to a Marshallian short-period equilibrium (Principles, Book V, ch. v) that is attained under the provisional assumption of a constant money-wage rate (GT, pp. 27, 247). Clearly, such an equilibrium no longer obtains once Keynes drops this assumption in the climactic chapter 19, proceeds to analyse the effects on the economy of a decline in the money wage rate, and shows that such a decline will not necessarily lead to an increase in employment and a fortiori not to the establishment of full-employment equilibrium (see above). Thus in the strict sense of the term, the General Theory is a theory of unemployment disequilibrium: it analyses the workings of an economy in which money wages and hence the rate of interest may be slowly falling, but in which ‘chronic unemployment’ (GT, p. 249) nevertheless continues to prevail, albeit with an intensity that may be changing over time (cf. Patinkin, 1951, part III; 1956, chs XIII:1, XIV:1, and Supplementary Note K:3, reproduced unchanged in the 1965 edition; 1976a, pp. 113–19).

This interpretation would seem to be contradicted by Keynes's explanation that one of his major accomplishments in this book was to have demonstrated the possible existence of

"unemployment equilibrium" (GT, pp. 30, 242–3). I would like to suggest that the answer lies in a letter that Keynes wrote to Roy Harrod in August 1935, in reply to the latter's criticism that Keynes's discussions of the classical position were carried out in an unduly polemical style that exaggerated the differences between the two positions. In Keynes's words:

the general effect of your reaction … is to make me feel that your assault on the classical school ought to be intensified rather than abated. My motive is, of course, not in order to get read. But it may be needed in order to get understood. I am frightfully afraid of the tendency, of which I see some signs in you, to appear to accept my constructive part and to find some accommodation between this and deeply cherished views which would in fact only be possible if my constructive part has been partially misunderstood. That is to say, I expect a great deal of what I write to be water off a duck's back. I am certain that it will be water off a duck's back unless I am sufficiently strong in my criticism to force the classics to make rejoinders. I want, so to speak, to raise a dust; because it is only out of the controversy that will arise that what I am saying will get understood (JMK XIII, p. 548; italics in original).

And what could 'raise more dust' than a seemingly frontal attack on the 'deeply cherished' classical proposition that there could not exist a state of unemployment equilibrium? Conversely, what could be more easily 'accommodated' within the classical framework than the statement that a sharp decline in aggregate demand would, despite the resulting decline in the wage-unit, generate a prolonged period of disequilibrium which would be marked by a continuous state of unemployment?

It also seems to me that it is precisely the attempt to interpret the General Theory as presenting a theory of unemployment equilibrium in the fullest sense of the term that has led to its interpretation (despite the internal evidence to the contrary, and despite the facts to the contrary that existed at the time that the book was being written) as being based on the special assumptions of absolutely rigid money wages and/or the 'liquidity trap'. For by definition there cannot be a state of long-run unemployment equilibrium in the sense that nothing in the system tends to change unless wages are rigid. Alternatively, if money wages are not rigid, then a necessary condition for equilibrium -- in the sense of the level of employment remaining constant over time -- is that the rate of interest remain constant; and a necessary condition for the rate of interest to remain constant in the face of an ever-declining money-wage and hence ever-increasing real quantity of money is that the economy be caught in the 'liquidity trap'. Correspondingly, once we recognize that the General Theory is concerned, strictly speaking, with a situation of unemployment disequilibrium, we also understand that the validity of its analysis does not depend on the existence of either one of these special assumptions.

Three further observations about the General Theory: First, I have already noted that the exposition of the theory of effective demand in Book I is carried out, not in terms of national income -- to which concept Keynes even expresses what he regards as methodological objections (GT, pp. 38, 40) -- but in terms of the level of employment. In part, this was undoubtedly due to the fact that the level of employment was indeed his major concern. But I also feel that this provides an instructive instance in our discipline of a basic characteristic of the physical sciences: namely, the relationship between the development of the theory and the development of tools of measurement. In particular, I conjecture that Keynes's ambivalence toward the use of the national-income concept in the General Theory (for he did make use of it in his chapters on the consumption function (ch. 10) and liquidity-preference function (ch. 15), respectively) was not unrelated to the fact that at the time national-income estimates had not yet become the household concept they are today; indeed there did not then even exist current official estimates of British national income. In contrast, ever since the early 1920s, estimates of British employment -- or rather unemployment, as measured by the 'Number of Insured Persons Recorded as Unemployed' -- were being published monthly in the Ministry of Labour Gazette. Similarly, I conjecture that the change in Keynes's view as manifested in his 1940 How to Pay for the War (JMK IX, pp. 416–17, 429; see the discussion of Figure 1 in section 3 above) -- and his willingness (albeit with reservations) to make use in it of Colin Clark's national-income estimates, about which he had earlier expressed much scepticism -- reflected in part the exigencies of wartime, and in part the increased respectability and acceptability of national-income estimates as a result of their publication (on the work of Simon Kuznets) on an official, current annual basis by the United States beginning with 1935 (cf. Patinkin 1976b, pp. 129–30, 243–5, 248–54; cf. also the discussion of Keynes and national-income statistics in section 7 below).

Second, in the General Theory, Keynes also appears as a historian of economic thought. Thus chapter 2 is entitled 'The Postulates of the Classical Economics' and references to 'classical theory' are strewn throughout the book. Similarly, most of chapter 23 is devoted to his 'Notes on Mercantilism', which are largely based on Heckscher's (1935) classic work. In a comment thirty-odd years later on his 1936 review of the General Theory, Viner, (1964, p. 254) -- who had in 1930 published what was essentially a monograph on mercantilism (reprinted in Viner, 1937, chs 1–2; see ibid., p. xiv) -- explained that the terms of reference of his original review did not include the doctrinal aspects of the book, and went on to express reservations about the 'objectivity and judiciousness' of Keynes as a historian of thought in areas in which he was emotionally involved as a protagonist and prophet. Viner did not specify the areas he had in mind, but Heckscher (1946) explicitly referred to Keynes's treatment of mercantilism and charged him with citing from his (Heckscher's) work 'only … those parts of mercantilist theory that happen to coincide with his own analysis of economic behaviour' (ibid., p. 340; actually, most of Heckscher's article is devoted to a criticism of Keynes's theory itself). However, Hutchison (1978, pp. 127–35) and Walker (1986, part IV), basing themselves on more recent studies of mercantilism and its period, have largely supported Keynes's treatment, particularly with respect to his emphasis on the mercantilists' concern with the problem of unemployment, and his corresponding contention that they advocated a positive balance of trade and resulting inflow of gold not as a fetish, but as a rational means of dealing with this problem (GT, pp. 346–48). But Hutchison (1978, p. 128) also cites Blaug's (1962, pp. 15; 1964, pp. 114–15) dissenting opinion, and Walker (1986, p. 28) notes that Keynes was nevertheless guilty
of ‘excessively broad generalizations’ about the mercantilist literature.

Insofar as Keynes’s treatment of ‘classical economics’ is concerned, both Hutchison and Walker conclude that Keynes’s discussion of Ricardo and Say’s Law, on the one hand, and Malthus’s concern with the possibility of the inadequacy of aggregate demand, on the other (GT, pp. 18–21, 32–4) constitute important contributions to the history of economic thought, though here too they indicate some inaccuracies (see also Patinkin, 1956 and 1965, Supplementary Note L, on Keynes’s misrepresentation of the passage in Mill’s discussion of Say’s Law which Keynes cites on p. 18 of the General Theory). At the same time, both Hutchison and Walker reject Keynes’s contention that classical economics in this sense continued unchallenged through the second half of the 19th century on into the 20th. In particular, Hutchison (1978, pp. 165–6, 175–99) conclusively shows that Keynes was not justified in including Pigou among the ‘classical economists’ (GT, p. 3, n1; see also Corry, 1978, pp. 8–11; see also Walker, 1985, for a favourable view (though it too with some reservations) of Keynes as a historian of thought in his 1933 Essays in Biography).

In sum, though Keynes in the General Theory provided valuable and stimulating insights with respect to certain points in the history of economic thought, Viner did not err in saying that the balanced scholarly treatment of this subject was not Keynes’s forte (cf. also Hutchison, 1978, p. 173 and Walker, 1986, p. 29).

My third and last observation is that in order to understand why the General Theory had such a revolutionary impact on the profession – and indeed on the general public – we must take account of the circumstances that prevailed when it burst on the scene. In the early 1930s, the Western world was desperately searching for an explanation of the bewildering and seemingly endless depression that was creating untold misery for millions of unemployed and even threatening the viability of its democratic institutions. Indeed, largely as a result of the widespread social unrest caused by the mass unemployment, a totalitarian government had already taken power in Italy and a far more evil and oppressive one was doing so in Germany. And the appearance of the General Theory in 1936 offered not only an explanation, but also a confident and theoretically supported prescription for ending depressions within a democratic framework by proper government policies. Thus the General Theory provided an answer not only to a theoretical problem, but to a burning political and social one as well. I might also add that the fact that the theoretical revolution embodied in the Keynes’s General Theory took place concurrently with the Colin Clark–Simon Kuznets revolution in national-income measurement further increased its impact on the profession: for those measurements made possible the quantification of the analytical categories of the General Theory, hence the empirical estimation of its functional relationships, and hence its application to policy problems (cf. Patinkin, 1976b).

Despite the many criticisms and discussions of the General Theory that followed its publication (cf. e.g., the review articles by Harrod, Hicks, Leontief, Lerner, Meade, Pigou, Viner et al. reprinted in Lekachman, 1964 and Wood, 1983), its basic analytical structure not only remained intact, but also defined the research programme for both theoretical and empirical macroeconomics for the following three decades and more. Truly a scientific achievement of the first order. And as with the passage of time we gain a more critical view of the accomplishments – and deficiencies – of ‘monetarism’ and of ‘the new classical macroeconomics’ of the last two decades, an appropriately modified Keynesian model that will take advantage of what we have learned from these developments may yet regain its place as the leading one for macroeconomic analysis (Howitt, 1986; for some conjectures about what Keynes might have thought of these developments, see Patinkin, 1984).

6. Any great work brings in its wake claims of priority for other writers – and the General Theory was no exception. Thus within a year after its publication, Bertil Ohlin (1937) claimed that there were ‘surprising similarities’ between the analysis in this book and that which had been developed in the writings (in Swedish) of what he called the ‘Stockholm school’, under which rubric he included Erik Lindahl and Gunnar Myrdal as well as himself. Similarly, in a review article on the General Theory, the Polish economist Michal Kalecki (1936) claimed that he had anticipated its main arguments in a 1933 monograph in Polish on the business cycle (the ‘essential part’ of which was published many years later in English translation in Kalecki, 1966, pp. 1, 3–16). Ohlin’s claim was presented in the Economic Journal, then the leading journal of the economics profession, and gained immediate attention – so much so that the claim of the Stockholm School became a ‘perennial of doctrinal history’ (in Gustafsson’s, 1973, apt phrase). In contrast, Kalecki’s claim was published in Ekonomista – the professional journal of Poland’s economists, published, of course, in their own language – and so received no attention outside that country. (An English translation of this review has only recently been published; see Targetti and Kinda-Hass, 1982.) Fifteen years later, however, the claim of Kalecki was brought to the attention of the profession as a whole by Lawrence Klein (1951) and Joan Robinson (1952), and has in certain quarters received increasing support ever since.

A detailed examination of these claims, however, has led me to reject them on the grounds that the respective central messages of these writers were different from that of the General Theory (Patinkin, 1982, chs 1–4). In particular, the central message of the Stockholm school (like that of Keynes’s Treatise) was a further development of that of Wick Sell, and had to do with the interrelationships of the rate of interest and prices, and only indirectly with output. And though Kalecki’s central message had to do with output, its concern was not with the forces that generate equilibrium at low levels of output, but with the forces that generate cycles of investment and hence output: more specifically, not with the feedback mechanism of the General Theory that equilibrates planned saving and investment via declines in output, but with the cyclical behaviour of investment in a capitalist economy on the implicit assumption that there always exists equality between planned savings and investment. At the same time I must emphasize that in his primary concern with quantities as against prices; in his concentration on national-income magnitudes and functional relations among them; and in his corresponding emphasis on analysing the relationship between investment and other macroeconomic variables, Kalecki came significantly closer to the General Theory than did the Stockholm School, and this was particularly true of his semi-popular 1935 paper ‘The Mechanism of the Business Upswing’.

7. The foregoing discussion has highlighted the differences between the respective volumes of Keynes’s trilogy. There are, however, also important similarities. Thus a common element of these books is their concern with practical policy problems, and their related concern with the empirical aspects of these problems. At the same time I must emphasize that
Keynes (like the great majority of his contemporaries) largely used empirical data for illustrative purposes, or at most as a basis for rather impressionistic observations about the relations between the variables described by the data. Though there are partial exceptions (see the second paragraph below), Keynes practically never carried out a systematic statistical analysis of empirical data as a basis for conclusions.

Thus, for example, Keynes's excellent presentation of the purchasing-power-parity theory in the *Tract* is supported by charts and diagrams showing the generally corresponding movements of the actual exchange rates of England, France and Italy with those respectively predicted by the theory (Tract, pp. 81–6). Similarly, Keynes's aforementioned analysis of inflation as a tax on real cash balances – and his explanation that this tax will decrease the volume of these balances that individuals will be willing to hold – is illustrated by data from the postwar hyperinflations of Germany, Austria, and Russia (Tract, pp. 45–6). Similarly, in the second, ‘applied’ volume of his Treatise, Keynes presents empirical estimates of the variables that play a key role in the theory he developed in the first volume: namely, the quantity of money, the velocity of circulation, the volume of working capital – and he even adds a long chapter (39) providing historical illustrations of his theory.

Though there is less emphasis on empirical data in the *General Theory*, it is noteworthy that Keynes was quick to make use in it (though somewhat carelessly; see the correspondence reproduced in *JMK XXIX*, pp. 187–206) of Simon Kuznetz's (1934) preliminary estimates of net investment in the United States in order to illustrate his (Keynes's) basic contention about the critical role of wide fluctuations in this variable in generating business cycles (GT, pp. 102–5). What is even more noteworthy is Keynes's use of these data in order to make an empirical estimate (crude as it was) of the magnitude of the multiplier in the United States – and thence of the marginal propensity to consume of that country (GT, pp. 127–8). Thus Keynes not only made the marginal propensity to consume a central component of macroeconomic theory, but also provided the first estimate of its magnitude that was based on an examination of statistical time series!

I must, however, immediately add that there are many problematic aspects of this estimate, not least of which is the mystery of the source of the national-income data which Keynes used (together with Kuznetz's aforementioned data on investment) to estimate the multiplier. Furthermore, despite the fact that he was one of the founding members of the Econometric Society in 1933 and even served as its President during 1944–45, Keynes was actually extremely skeptical of econometric methods. Thus his oft-cited critical review (1939) of Tinbergen's classic work was devoted not to the much better known second volume of this study on Business Cycles in the United States of America, 1919–1932 (1939), but to the first volume (published a few months earlier), A Method and Its Application to Investment Activity, in which Tinbergen set out and exemplified the principles of multiple-correlation analysis. Accordingly, the criticisms Keynes presented in this review were levelled not at Tinbergen's ambitious 46-equation model of the United States economy, but at the use of correlation analysis to estimate a regression for even a single equation! It should, however, be noted that though not all of Keynes's criticisms were well taken, some raised problems that continue to trouble econometricians: namely (though obviously not in the terms that Keynes used), the problems of specification bias and of simultaneous-equation bias (Patinkin, 1976b, sections 1, 3; cf. also Lawson and Pesaran, 1985).

Another aspect of Keynes's interest in the empirical aspects of our discipline was his concern with improving the scope and reliability of economic data. Thus in the course of presenting the aforementioned estimates in the second volume of the Treatise, Keynes repeatedly complains about the inadequacy of the data (TM II, pp. 78, 87). Keynes was also responsible for the final chapter in the Macmillan Report (1931), which was devoted to proposals for extending and improving available economic statistics in Britain. It is, however, noteworthy that these proposals did not include one for the construction of current national-income statistics. Similarly, in the years that followed, Keynes failed to support Colin Clark's pioneering work in this field (1932, 1937). It was only after the outbreak of World War II that this attitude changed, and then Keynes played an important role in promoting the publication of the famous 1941 White Paper, *Analysis of the Sources of War Finance* and an Estimate of the National Income and Expenditure in 1938 and 1940 (Cmd. 6261), for which James Meade and Richard Stone were primarily responsible, and which marked the beginning of official British national-income statistics (Patinkin, 1976b, pp. 230–31, 244–5, 248–54).

Though all three of Keynes's books are concerned with policy issues, they nevertheless differ in the extent and sense of immediacy with which their policy discussions are presented. In view of the origin of the Tract in articles in the *Manchester Guardian*, it is not surprising that discussions on current policy issues are paramount in it. Indeed, having only a short time before dealt so successfully with prime ministers in his *Economic Consequences of the Peace* (1919, JMK II) and in his Revision of the Treaty (1922, JMK III), Keynes had no hesitations in dispensing advice on current problems directly from the pages of the Tract to the finance ministers (or their equivalent), not only of England and the United States, but also of Czechoslovakia (p. 120), Germany (pp. 50–52), and France (pp. xxi–xxii).

In contrast – as befits a comprehensive, scientific work – Keynes's policy recommendations of the *Treatise* are for the most part of a more general nature, though here too there are references to specific, immediate issues (e.g., TM II, pp. 270 ff, 348 ff). Least specific in its policy proposals, for reasons indicated in section 3 above, is the *General Theory*.

What were the policy problems that concerned Keynes? The major one was obviously unemployment. This had plagued Britain in the two years that preceded the publication of the *Tract* (1923) and it continued to be a serious problem in the five years that he was writing the *Treatise* (1930). In contrast, those were years of boom and prosperity in the US; and when in the early 1930s – the period of writing the *General Theory* (1936) – prosperity gave way to depression in the US as well, unemployment in Britain became even more serious. A common characteristic of all three of these books is Keynes's opposition to attempts to combat unemployment by reducing the nominal wage rate. However, it seems to me that there is a difference between the *Treatise* and the *General Theory* on this point: for my impression is that in the *Treatise*, Keynes believed that such a reduction could theoretically help but practically could not be carried out; whereas in the *General Theory*, he opposed it on theoretical grounds as well. In part this difference may have stemmed from the fact that Keynes in 1930 was writing under the influence of the relative inflexibility of British money wages in the years that had preceded, whereas in 1936 he also had before
him the United States experience of the sharp reduction in money wages during 1929–33 that had not succeeded in solving the unemployment problem (note again Keynes's allusion to this experience on p. 9 of the General Theory).

At the same time, a recurrent theme of Keynes's discussion of unemployment was that if by agreement or decree money wages could be instantaneously and uniformly reduced in all sectors of the economy, then the problem would be solved (cf. Economic Consequences of Mr. Churchill, 1925, JMK IX, pp. 211, 228–9; TM I, pp. 141, 151, 244–5, 265, and 281; GT, pp. 265, 267, and 269). For such an instantaneous reduction would be accomplished before it could create adverse expectations, and it would also not change relative wage rates as between workers in different industries (see JMK IX, p. 211 and GT, p. 14 for Keynes's emphasis on the resistance of workers to such relative changes). Thus in the General Theory Keynes writes:

To suppose that a flexible wage policy is a right and proper adjunct of a system which on the whole is one of laissez-faire, is the opposite of the truth. It is only in a highly authoritarian society, where sudden, substantial, all-round changes could be decreed that a flexible wage policy could function with success. One can imagine it in operation in Italy, Germany or Russia, but not in France, the United States or Great Britain (GT, p. 269).

This is a somewhat naive notion of what even a totalitarian government can do. In any event, this passage – and the context in which it and the other passages cited above appear – makes it clear that Keynes's purpose was not to advocate the policy of wage flexibility, but to provide a 'negative proof' of its impracticability for a democratic society. (Today's version of Keynes's statement in the foregoing passage would be that if equilibrium prices and wages were established by means of a stable recontracted tâtonnement carried out by a Walrasian auctioneer, then, by definition, full employment would always obtain).

At the other extreme from the problem of unemployment was that of avoiding inflation. It is not surprising that this was a basic concern of Keynes during the period of the disastrous hyperinflations in Europe that followed World War I, which experience led him in his Economic Consequences of the Peace (1919, p. 148) to write that 'Lenin is said to have declared that the best way to destroy the capitalist system was to debauch the currency' (a statement that was actually due to Preobrazhensky; see Fetter, 1977, p. 78). Similarly, the adverse effects of inflation was a theme which Keynes most eloquently and forcefully presented in his Tract on Monetary Reform (1923). Thus in the preface to this book Keynes wrote: 'Unemployment, the precarious life of the worker, the disappointment of expectation, the sudden loss of savings, the excessive windfalls to individuals, the speculator, the profiteer – all proceed in large measure from the instability of the standard of value.' I must, however, add that in this book, as well as in his subsequent writings, Keynes consistently regarded the harm caused by deflation and its accompanying unemployment to be significantly greater than that of inflation.

It was probably the traumatic post-World War I experience – still fresh in his mind – that led Keynes, even in his 1930 Treatise, after more than five years of deflation and unemployment in Britain, to continue to be concerned with the dangers of inflation. It is also noteworthy that in his Essays in Persuasion (JMK IX, pp. 57–75) – published a year later – Keynes reproduced excerpts of the discussion of the destructive effects of inflation that had appeared in his Economic Consequences of the Peace and in his Tract – including the alleged statement of Lenin's (ibid., p. 57).

Perhaps because of the increasing severity of the depression in Britain in the years between the Treatise and the General Theory – and, even more so, because the depression had then become world-wide – the latter work is little concerned with the problems of inflation, though it does emphasize the undesirability of 'great instability of prices' (GT, p. 269; see the discussion of chapter 19 in section 4 above). It should also be noted that a recurrent theme of the General Theory (pp. 173, 249, 253, 296 and 301) is that as the level of employment in an economy increases as a result of an increase in effective demand, the money wage rate begins to rise even before full employment is reached. This view may be interpreted as something of an adumbration of one aspect of the later Phillips-curve analysis: namely the co-existence of inflation and unemployment.

It is also significant that after Britain began its rearmament programme early in 1937 – and when unemployment was still around 12 per cent – Keynes expressed concern with the possible inflationary outcome of such a programme that might be generated by the geographical immobility of labour. In particular, in two articles in the Times in the spring of 1937, Keynes argued (inter alia) that in order to avoid such pressures, the increased defence expenditure should be directed toward the distressed areas of the economy (JMK XXI, p. 407; see also ibid., pp. 385–6; cf. also Hutchison, 1977, pp. 10–14). And once war broke out, Keynes wrote his influential pamphlet on How to Pay for the War (1940), whose major purpose was to present a programme for financing the war without generating inflation – the main component of the programme being a proposal to adopt compulsory savings.

Two points should be made about the relationship between theory and policy in the Treatise and in the General Theory. First, in both cases the major contribution of the book is with respect to theory – and the purpose of the theory is to provide a rigorous underpinning for a policy position which already had many adherents. As Keynes himself indicated in chapter 13 of the Treatise, this was certainly true for the bank-rate policy he advocated in that work. And it is also true of the public-works-expenditure policy advocated in the General Theory, a policy which had been advocated by other British and American economists as well during the 1920s and early 1930s (cf. Hutchison, 1953, pp. 409–23 and 1978, pp. 175–99; Patinkin, 1969; Stein, 1969, chs 2, 7; Winch, 1969, pp. 104–46; and Davis, 1971). Indeed, as noted above, Keynes himself had already advocated this policy in his 1929 Can Lloyd George Do It?, and even here he was basically repeating views he had expressed five years earlier in the Nation and Athenaeum (JMK XIX, pp. 221–3). Accordingly, as also noted above, the major revolution effected by the General Theory was in the field of theory, and not of policy. And if (unlike the General Theory) the Treatise did deal at length with policy, it was not because it made any basic, new contribution to this question (at least in a domestic context), but because it was – as its name indicated – a comprehensive treatise, designed, inter alia, to describe the state of the art with respect to both theory and practice.
Second, and relatedly, it seems to me that the change in Keynes's policy views between the Treatise and the General Theory stemmed less from the transition from the fundamental equations to the \( C + I + G = \gamma \) than from British economic developments in the quinquennium between the appearance of those two books. For, as we have seen, Keynes advocated public-works expenditures for the purpose of combating unemployment even in the Treatise, albeit as a second-best policy to be carried out in special circumstances. And what caused him to seek such expenditures as a necessary addition to interest-rate policy (which, as in the Treatise, he continued to regard as an essential component of full-employment policy; cf. GT, p. 316) was the experience of five additional years of deep depression in the face of a 'cheap-money' policy that had brought the rate of interest down to unprecedented lows. In brief, I conjecture that it was this experience that led Keynes of the General Theory to conclude:

For my own part I am now somewhat sceptical of the success of a merely monetary policy directed towards influencing the rate of interest. I expect to see the State, which is in a position to calculate the marginal efficiency of capital-goods on long views and on the basis of the general social advantage, taking an ever greater responsibility for directly organizing investment; since it seems likely that the fluctuations in the market estimation of the marginal efficiency of different types of capital, calculated on the principles I have described above, will be too great to be offset by any practicable changes in the rate of interest (GT, p. 164).

8. Just as Keynes's trilogy is bound together by a common concern with the problem of unemployment, so is it bound by a common lack of concern with the problem of economic growth. With respect to the Treatise and the General Theory, this omission is an understandable characteristic of the economic literature of the depression years. For at a time when a dismaying percentage of the existing productive potential was idle, it would have taken an unrealistic soul indeed to have concerned himself with the problem of ensuring the further growth of this potential. But I think that this lack of concern reflected an additional element in Keynes's thought – and probably in that of many of his contemporaries as well. In particular, I think that Keynes originally viewed economic growth as a process that would emerge naturally – and at a satisfactory pace – from a free-market system in which households saved, and then used these savings to purchase the securities which firms issued in order to finance their expansion. ‘For a hundred years [before World War I] the system worked, throughout Europe, with an extraordinary success and facilitated the growth of wealth on an unprecedented scale’ (Tract, p. 6) – and Keynes, like his contemporaries, was not much concerned with things outside Europe, in the broad sense of Western civilization. Now, what had seriously interfered with the growth process of Europe after the World War were the disastrous inflations, which had wiped out the real value of past savings and had accordingly discouraged further saving. Correspondingly, a necessary – and sufficient – condition to reactivate the growth process at a satisfactory pace was to reestablish the confidence of the public in the future real value of its savings (Tract, pp. 16–17). The General Theory introduced another factor that interferes with steady growth: unemployment. And parallel to his view in the Tract, Keynes felt that once this disturbing factor was eliminated, growth would again proceed at a satisfactory pace. Indeed, if full employment could be maintained, ‘a properly run community equipped with modern technical resources, of which the population is not increasing rhythmically, ought to be able to bring down the marginal efficiency of capital in equilibrium approximately to zero within a single generation’ (GT, p. 220): the ‘zero’ of the classical stationary state.

In brief, I would conjecture that in Keynes's view at this time there was no need for any special analysis of the process of economic growth. All that one had to do was to ensure the maintenance of two necessary preconditions: a stable value of money and full employment. And growth – to the extent that the economy was interested in it (cf. GT, p. 377) – would take care of itself.

(Though Keynes did not concern himself with the problem of growth, the analytical framework of the General Theory served as the point of departure for the growth models which were subsequently developed. In this context it is interesting to note the transformation that took place over the years in the attitude toward saving: whereas the spirit of the General Theory hovers over the early contributions by Harrod (1939) and Domar (1946), which regard the increase in potential savings generated by increasing income as a threat to full employment, and growth as the means (via the accelerator principle) of generating the level of investment necessary for absorbing these savings and thus eliminating this threat, the later contributions regard savings as a desirable act necessary for financing the additional investment required for the growth process. Correspondingly, growth was transformed from being a means to an end to being an end in itself.)

Another common bond of the Treatise and General Theory, in quite a different plane, is the fact that the highly novel theoretical developments which mark both works were first presented to the profession at large as finished products, i.e. in the form of published books. In neither case did Keynes attempt to exploit the relatively long period of preparation that was involved (roughly, five years) in order to publish articles in the leading scientific journals on the salient features of his new theories and thus to benefit from the exposure of these theories to the criticism of the profession at large before formulating them in final book form. It is true that such a ‘research strategy’ was much less customary at the time Keynes wrote than it became later. But I would conjecture that Keynes's failure to follow such a strategy also reflected his belief that the quintessence of economic knowledge was in Cambridge – which geographical point need at most be extended to a triangle that would include London and Oxford. So why bother publishing articles in order to benefit from criticism, if the most fruitful criticisms could be reaped more conveniently and efficiently simply by circulating draft-manuscripts and galley proofs among his colleagues in this fertile triangle?

And as the materials in JMK XIII show us, this is indeed the procedure that Keynes employed in the writing of the General Theory. On the other hand, there is little if any evidence that the Treatise was subjected to much effective prepublication criticism even within this triangle. And this is particularly true for what Keynes considered to be its major theoretical innovation – the fundamental equations (Patinkin, 1976a, pp. 20–21, 29–32). Correspondingly, there are many serious deficiencies in the Treatise which were pointed out...
immediately after its publication and which (I conjecture) would have been avoided if only it had been subjected to such criticism. I would also conjecture that it was precisely this unfortunate experience with the Treatise that Keynes had in mind when in the preface to the General Theory he wrote that ‘it is astonishing what foolish things one can temporarily believe if one thinks too long alone, particularly in economics (along with the other moral sciences), where it is often impossible to bring one's ideas to a conclusive test either formal or experimental’ – and that accordingly made him so eager to seek out criticism at every stage of the writing of the General Theory.

Might I also digress to suggest that another cause of the deficiencies in the Treatise was the simple but frequently neglected fact that Keynes too was of flesh and blood, subject like all mortals to the inexorable constraint that there are only 24 hours in the day; and there can be little doubt that Keynes just did not have enough hours to devote to the writing of the book, and especially of its final version. In particular, in August 1929, Keynes informed his publisher that he felt he had to ‘embark upon a somewhat drastic rewriting’ of what was then a one-volume book, for the most part already in galley and page proof (JMXXXIII, pp. 117–18). But three months later Keynes was appointed to the famous Macmillan Committee and proceeded to play a leading role in its deliberations. Then at the beginning of 1930, he became a member – and a most active one – of the newly appointed Economic Advisory Council (see section 11 below). All this makes it difficult to believe that Keynes could have had enough time during 1930 to devote to the rewriting of the Treatise that he deemed necessary.

Another indication of this pressure of time is the fact that though Hawtrey had provided Keynes with basic criticisms of the Treatise before its publication (specifically, in the spring and summer of 1930), Keynes did not take account of them and did not even answer Hawtrey until a month after the book was published in October 1930. Keynes apologised then for this delay by explaining that he was, as we can well believe, ‘overwhelmed’ with work of the Macmillan Committee, the Economic Advisory Council ‘and a hundred other matters’ (JMXXXIII, p. 133). And I suspect that this was also the reason that in 1930 Keynes did not give the series of lectures on monetary economics that it was his custom to give every autumn term at Cambridge (see section 11 below), and that in autumn 1931 he deferred his lectures to the following spring.

And though it may sound like a morality play – like a didactic reaffirmation of the victory of good scientific procedures over bad – I would like to point out that in the writing of the General Theory this pressure of time was much less evident. In particular, after the completion of the Macmillan Report in June 1931, Keynes seems to have been much less occupied than before with activities on behalf of the government. Similarly, after 1933 there was (to judge from an enumeration of the relevant entries in Hudson's unpublished and admittedly incomplete bibliography of Keynes's writings) a falling-off in the intensity of his journalistic activities. Correspondingly, I would conjecture that in the last two years before their respective publication, Keynes was able to concentrate far more on the writing of the General Theory than he had been able to on the writing of the Treatise.

9. I turn now to some observations on Keynes's style – both analytical and literary. Insofar as the analytical style is concerned, let me again note Keynes's failure to make use in his writings of graphical techniques – and this despite the fruitful precedent on this score set by his teacher Marshall, and despite the many passages (see, e.g., the reference on pp. 25 and 30 of the General Theory to the 'intersection of the aggregate demand function with the aggregate supply function') that almost cry out for a diagram. Here and there in the trilogy there are diagrams of a statistical or schematic nature (Tract, pp. 83, 87; TM I, pp. 290–91; II, p. 317). But, as noted above, in all of these books there is only one diagram of an analytical nature – and that diagram is due to Harrod (GT, p. 180, n. 1). Similarly – to judge from the student notes that have survived (reproduced in Rymes (ed.), 1988) – Keynes made practically no use of diagrams in his lectures.

Keynes's failure to use graphical techniques in the General Theory is even more puzzling in light of the fact that his chief disciples and critics during the formative period of writing the book – namely, Richard Kahn and Joan Robinson – played a leading role in the breakthrough that was then taking place in the use of such techniques! I am, of course, referring to Joan Robinson's Economics of Imperfect Competition (1933a), in the writing of which she acknowledged the 'constant assistance of Mr R.F. Kahn' (ibid, p. v).

Marshall's influence on Keynes did, however, manifest itself in the fact that the analysis of both the Treatise and the General Theory is carried out in terms of 'demand price' and 'supply price' (see sections 2 and 3 above). It has also been contended in section 5 above that Keynes's 'unemployment equilibrium' in the General Theory must be understood in terms of Marshall's short-period equilibrium. A more subtle manifestation of Marshall's influence is the fact that the formal organization of the argument of the General Theory is that of partial-equilibrium analysis. In particular, if this argument had been organized in accordance with the Walrasian general-equilibrium approach, then (as in present-day textbooks of macroeconomics), Book III of the General Theory would have been devoted to the market for goods (both consumption and investment) and Book IV in a parallel fashion to that for money, and there would then follow a discussion of the interaction between these two markets. In point of fact, however, both Book III ('The Propensity to Consume') and Book IV ('The Inducement to Invest') are formally devoted to the market for goods, with the market for money being discussed in Book IV not as an equal partner, but as the source of an influence (via the rate of interest) on the market for investment goods. Nevertheless, as emphasized in the discussion in section 4 above of chapter 18 of the General Theory, the analysis of this book is essentially that of general equilibrium. The voice is that of Marshall, but the hands are those of Walras. And in his IS–LM interpretation of the General Theory, Hicks quite rightly and quite effectively concentrated on the hands.

In connection with Keynes's analytical style, I should also note his oft-cited criticism in the General Theory of 'symbolic pseudo-mathematical methods of formalizing a system of economic analysis … which allow the author to lose sight of the complexities and interdependencies of the real world in a maze of pretentious and unhelpful symbols' (GT, pp. 297–8). Let us, however, not take this statement too seriously. First of all, Keynes's own analysis in his earlier Treatise on Money (1930) was, in fact, largely based on fairly mechanical applications of the so-called fundamental equations. Similarly, an entire chapter (20) of the Treatise is devoted to 'An Exercise in the Pure Theory of the Credit Cycle', in which Keynes explored in a very formalistic manner – and under a variety of alternative assumptions – the mathematical properties of his model of the cycle. Thus, if ever an author made use of 'a maze of pretentious and unhelpful symbols', that author was Keynes of the Treatise.

Furthermore, I strongly suspect that a comparison of the General Theory (and fortiore the Treatise) with other works on economic theory that were written during that period would
actually show Keynes's works to be among the more mathematical of them. Indeed, in his review of the General Theory, Austin Robinson commented that 'even for the ordinary economist, the argument, being largely in mathematical form, is difficult' (1936, p. 472).

It may have been Keynes's lack of success with formal model building in the Treatise that led him to the more critical attitude expressed in the passage from the General Theory just cited. In any event, it is significant that in the General Theory – in contrast with the Treatise – Keynes did not attempt to provide a formal mathematical model of the theory of employment that constitutes the central message of the book. This was left for the subsequent exegeses of such writers as Hicks (1937) and Lange (1938). Instead, to the extent that Keynes made use of mathematical analysis in the General Theory, he did so with respect to such secondary themes as the relationship between the own-rates of interest of different goods (ch. 17, section II) and the theory of prices (ch. 21, section VI). And even in these instances, the mathematical formulation adds little to the exposition, and so could be deleted without much loss of continuity. Indeed, in a letter he wrote a year after the publication of the book in response to criticisms of the formulas in the first section of his chapter on 'The Employment Function' (chapter 20), Keynes himself admitted:

I have got bogged [sic] in an attempt to bring my own terms into rather closer conformity with the algebra of others than the case really permits. When I come to revise the book properly, I am not at all sure that the right solution may not lie in leaving out all this sort of stuff altogether, since I am extremely doubtful whether it adds anything at all which is significant to the argument as a whole (JMK XXIX, p. 246).

Actually, the General Theory reveals an ambivalent attitude toward the role of mathematical analysis in economics; for with all his reservations about the usefulness of such analysis, Keynes (as one who had once been bracketed Twelfth Wrangler; see Harrod, 1951, p. 103) could not resist the temptation to show that he too could employ it. Thus the foregoing quotation from the General Theory so critical of mathematical analysis actually occurs in section III of the same chapter 21 that I have just cited as providing an instance of the use of such analysis – and indeed this quotation appears as part of Keynes's apologia for nevertheless going ahead and resorting to it in section VI of that chapter!

Furthermore, judging from the critical literature that subsequently grew up around chapters 17 and 21, I think it fair to say that the mathematical analysis that appears in these chapters is not only not essential to the argument, but sometimes even incorrect (thus see Palander (1942) as cited by Borch (1969), as well as Naylor (1968, 1969), on the incorrect elasticity formula used to analyse the implications of the quantity theory in chapter 19 of the General Theory (p. 305); see also Patinkin (1982, p. 151, n. 33) on the erroneous formula in n. 2 on p. 126. And this fact, together with the ineffectualness of the fundamental equations of the Treatise, makes it clear that whatever may have been Keynes's attitude toward the proper role of mathematical methods in economic analysis, his strength did not lie in the use of such methods.

Nor in general did Keynes's analytical strength lie in rigour and precision: indeed, we run the risk of distorting the original intention of Keynes's writings – and reading meaning into them – if we try to view them through analytical lenses that are more sophisticated and more finely ground than those that he was wont to use. Thus in both the Treatise and the General Theory Keynes frequently failed to specify the exact nature of the assumptions that underlay his argument. Furthermore, there are many ambiguities in these books. And the best evidence of the existence of such ambiguities and obscurities is the fact that fifty years later disagreements continue about the role played in the General Theory by such crucial assumptions as wage rigidities, the liquidity trap, the interest elasticity of investment, unemployment equilibrium, and the like – not to speak of the protracted debate about the meaning of Keynes's aggregate supply function.

Instead, Keynes's analytical strength lay in his creative insights about fundamental problems that led him to make major breakthroughs, leaving for those that followed him to correct, formalize, and complete his initial achievements. In the Treatise, Keynes thought (erroneously, as it turned out) that his fundamental equations constituted such a breakthrough. In the General Theory, he saw his breakthrough as lying in his theory of effective demand – and this time he was undeniably right.

In view of this basic aspect of Keynes's analytical style, I should in all fairness also emphasize that the aforementioned lack of rigour and completeness in part reflects the natural deficiency of many a pathbreaking work. As Keynes wrote to Joan Robinson: 'My own general reaction to criticisms always is that of course my treatment is obscure and sometimes inaccurate, and always incomplete, since I was tackling completely unfamiliar ground, and had not got my own mind by any means clear on all sorts of points' (JMK XIII, p. 270). Keynes made this comment in 1932 with reference to the Treatise; it is even more relevant for the General Theory.

Another characteristic of Keynes's style that should be noted is his constant striving to present the conclusions of his analysis in the form of paradoxes. Sometimes this is very effective, as in the case of the 'paradox of thrift' in the General Theory. Sometimes, however, Keynes's love for the paradoxical tempts him into extreme statements that do not stand up under critical scrutiny, as in the case of the paradox of the widow's cruse in the Treatise (I, p. 125; see Joan Robinson, 1933b). And sometimes it tempts him into delphic pronouncements, such as his oft-cited contention that 'there may exist no expedient by which labour as a whole can reduce its real wage to a given figure by making revised money bargains with entrepreneurs' (GT, p. 13, italics in original; but see the discussion of chapter 19 of the General Theory in section 4 above for an interpretation).

A related characteristic of his style are occasional seemingly profound statements that upon closer examination lose much (if not all) of their profundity and are sometimes even involved in error. Thus consider the following passage from the Treatise:

We have claimed to prove in this treatise that the price level of output depends on [1] the level of money incomes relatively to efficiency, on [2] the volume of investment (measured in cost of production) relatively to saving, and on [3] the ‘bearish’ or ‘bullish’ sentiment of capitalists relatively to the supply of savings deposits.
available in the banking system (TM II, p. 309, bracketed numbers added).

This is simply a verbal rendition of the second fundamental equation (itself a tautology) written as the weighted average of the respective prices of consumption goods \( P \) and investment goods \( P' \)

\[
\Pi = (P \cdot R + P' \cdot C) / O
\]

where, by definition,

\[
O = R + C
\]

(TM I, p. 123). More specifically, the first fundamental equation in section 2 above can be written as

\[
P = (W / \omega) + \left( (I - S) / R \right)
\]

(TM I, p. 122); expressions [1] and [2] in the foregoing passage thus correspond to the first and second terms, respectively, of this equation. And expression [3] in turn is a brief summary of Keynes's explanation of the determination of \( P' \) (TM I, pp. 127–9, 229–30). (For other instances of obscure statements in the Treatise which are simply verbal renditions of the fundamental equations, see TM I, pp. 144 and 248–9; for further details, see Patinkin, 1976a, ch. 6).

Or consider the following well-known passage at the end of chapter 19 of the General Theory:

If, as in Australia, an attempt were made to fix real wages by legislation, then there would be a certain level of employment corresponding to that level of real wages; and the actual level of employment would, in a closed system, oscillate violently between that level and no employment at all, according as the rate of investment was or was not below the rate compatible with that level; whilst prices would be in unstable equilibrium when investment was at the critical level, racing to zero whenever investment was below it, and to infinity whenever it was above it (GT, pp. 269–70).

As at other points in the General Theory, Keynes assumes here that there is a fixed consumption function, so that the level of effective demand and hence employment is determined by that of investment. In the case where that level is greater than the level of employment corresponding to the fixed real wage rate, the argument is a straightforward application of the analytical framework of the book: viz, there will then be an excess demand for goods which will drive their price higher; but since the real wage rate is being held constant, the money wage rate must increase in the same proportion. Thus prices will 'race to infinity', unless (Keynes goes on to say) the resulting decrease in the real quantity of money and consequent increase in the rate of interest will decrease investment, and hence effective demand and employment to the level corresponding to the fixed real wage rate. It is, however, not clear why – in the case where the level of effective demand and hence employment is less than that corresponding to the fixed real wage rate – the economy should be driven down to a situation of 'no employment at all'. For the firms’ marginal productivity of labour corresponding to that lower level of employment is higher than the fixed real wage rate; on the other hand, that fixed rate is higher than the minimum one upon which workers insist in order to provide that level of employment. Hence this lower level can constitute a stable equilibrium in Keynes's sense of the term. Correspondingly, there is no reason in this situation for prices to 'race to zero'. (See the discussion at the beginning of section 5 above of Keynes's use of the term ‘unemployment equilibrium’.)

Note the key to interpreting the above passages: each is a mechanical application of the basic formula of the book in question (the fundamental equations in the case of the Treatise,
and the theory of effective demand which determines employment hence the real wage rate in the case of the *General Theory* – combined with Keynes's propensity to shock (see his letter to Harrod cited at the beginning of section 5 above). Obscurities such as these, as well as those mentioned above, frequently impede the flow of the reading. But despite these difficulties, there are constant reminders throughout the trilogy that we are in the presence of a master of English style. The language is generally rich and incisive, enhanced occasionally by well-turned phrases and apt literary allusions. For Keynes's objective is to appeal not only to the intellect but also to the sense of literary appreciation. This is particularly true of the *Tract*, and for two related reasons: because it is the least technical of the three books and because of its origin as a series of articles on current policy in the *Manchester Guardian*, where Keynes could give full expression to his brilliant journalistic style.

Least enjoyable as a reading experience is the *Treatise*, whose generally heavy and constrained style reflects the stately scientific objective that Keynes set for himself in it. Indeed, when one reads the *Treatise* against the background of Keynes's other writings, one cannot escape the feeling that it represents a Keynes out of character, a Keynes attempting to act the role of a Professor, and a Germanic one at that.

In the *General Theory* we once again find the true Keynes. Here (as in so many of Keynes's writings) is the stirring voice of a prophet who has seen a new truth and who is convinced that it – and only it – can save a world deep in the throes of crisis. It is a sharp, polemical voice directed at converting economists all over the world to the new dispensation and combating the false prophets among them who perversely continue with the erroneous teachings of the gods of classical mythology whom Keynes had already abandoned.

And so it is that these writings of Keynes are famous not only for their basic scientific contributions but also for having become part of the literary heritage of every economist. For who does not know that ‘in the long run we are all dead’ (*Tract*, p. 65)? Or that

> The ideas of economists and political philosophers, both when they are right and when they are wrong, are more powerful than is commonly understood. Indeed the world is ruled by little else. Practical men, who believe themselves to be quite exempt from any intellectual influences, are usually the slaves of some defunct economist. Madmen in authority, who hear voices in the air, are distilling their frenzy from some academic scribbler of a few years back .... The power of vested interests is vastly exaggerated compared with the gradual encroachment of ideas (*GT*, p. 383).

10. The foregoing discussion of similarities and differences among the volumes of Keynes's trilogy brings us finally to the question of the justification for reading them today. From the substantive viewpoint, all of these volumes are now in the domain of the history of monetary doctrine: their basic scientific contributions have long since been incorporated in the current literature, so that, by definition, the volumes themselves are of importance only to students of this history. From a broader viewpoint, however, there are sharp differences among these volumes in this respect too. Thus, in these times of worldwide inflation, one can still read with both pleasure and profit Keynes's brilliant discussion of this problem in the *Tract*. On the other hand, the recent revival of interest in the *Treatise* notwithstanding, I can (from the viewpoint of macroeconomic theory) see little profit (and certainly no pleasure) in reading it today. Nor do I think that the *Treatise* is important as a key to an understanding of the major innovation of the *General Theory*, namely, the theory of effective demand. What the *Treatise* does help us understand are certain terminological aspects of Keynes's presentation of this theory (viz., his exposition in terms of ‘demand price’ and ‘supply price’; cf. *GT*, pp. 24–6 and *TM* I, pp. 186, 189); but it contributes little towards an understanding of the substance of the theory itself, which differs so fundamentally from that of the *Treatise*.

As for the *General Theory*: the work over the years of students of Keynes's thought has deepened our understanding of this book, but has also brought to light deficiencies and errors. Some of these are due to the stylistic excesses described in section 9 above; some are inconsequential mathematical ones, like those noted in the same section; but some (e.g., the ambiguities and errors in Keynes's discussion of the aggregate supply curve referred to in section 3 above) are more significant. But even these last should be regarded as the kind that naturally occur in a pioneering work that breaks new ground and develops a radically different analytical framework. We do no service to the place of Keynes in the history of economic thought – and *a fortiori* not to the history itself – by ignoring these errors. At the same time, they do not change the basic fact that this is the book that made the revolution which has continued to mould our basic ways of thinking about macroeconomic problems. And so the reading of it – at least in part – is an intellectual experience that no aspiring economist even today can afford to forego.

To this I must add the following related plea. In reading the *General Theory*, let us do so in order to acquaint ourselves with one of the classics of our discipline, and, more generally, in order to enjoy the pleasures of intellectual history: not in order to invoke Keynes's alleged authority with respect to further developments in macroeconomic theory. Thus, for example, if we feel that this theory should provide a more detailed analysis of the way expectations and hence behaviour decisions are formed under conditions of uncertainty; or of the role of money wages and prices in the equilibrating process generated by the interaction between aggregate demand and supply; or of the influence of the structure of interest rates on the respective markets for money and commodities – then let us by all means devote ourselves to the analysis of these important questions. At the same time, let us make a clear distinction between this objective and that of the history of thought – and thereby do a service both to Keynes and to the further development of macroeconomic theory: for we then permit the study of Keynes's thought to concern itself not with what Keynes might have said or should have said about current theoretical questions, but with what he actually did say; and we permit the attempts to improve upon the current state of macroeconomic theory to be judged substantively, on their own merits, without confusing the issue with arguments about ‘what Keynes really meant’. As Keynes said in concluding a long and tiresome correspondence in 1938 on a note that some economist had sent him on an aspect of the *General Theory*, ‘... the enclosed, as it stands looks to me more like theology than economics! ...I am really driving at something extremely plain and simple which cannot
possibly deserve all the exegesis’ (JMK XXIX, p.282; cf. also Patinkin, 1984, pp. 100–101).

11. Having devoted so much attention to Keynes's trilogy, I must emphasize that it would be a serious mistake to think of Keynes as devoting his major efforts in the interwar period to writing these books in the quiet halls of academia. On the contrary, after he became a public figure in the wake of his Economic Consequences of the Peace (1919), he resigned his lectureship at Cambridge (though he continued as an active Fellow of King's College) and earned his living from his publicistic writings and from speculation on the stock market (Johnson and Johnson, 1978, pp. 1–37; Harrod, 1951, pp. 288, 294–304). Correspondingly, Keynes's normal routine became one in which he divided his time between London and Cambridge, living in the former during most of the week and coming down to Cambridge for long weekends. In London he was absorbed in his publicistic and political activities; during the weekends at Cambridge he dealt with both academic and (as bursar of King's) business matters. On Monday mornings of the autumn term during most of the interwar years he also gave a course of lectures on monetary economics which were widely attended by students, faculty and visitors, and in the process of which he expounded his new theories as he developed them. It is of these lectures that we have the notes of Bryce, Tarshis and others mentioned at the beginning of section 3 above. On Monday evenings Keynes would then preside over his famous Political Economy Club, whose participants were drawn from the most promising undergraduates, and at which one of them would read a paper which would then be discussed (Harrod, 1951, pp. 149–52, 327–30; see also the reminiscences of Bryce and Tarshis of both the lectures and the Club in Patinkin and Leith, (eds.), 1977, pp. 39–63, 73–74). And the following morning he would be back in London.

Keynes's intensive public activity with respect to the policy discussions of the interwar period was reflected in the more than three-hundred articles he wrote for the 'highbrow' news magazines of the time (particularly the Nation and Athenaeum – of whose board Keynes was chairman in the 1920s – and its successor, The New Statesman and Nation) as well as for the popular press. Many of the latter articles were syndicated in newspapers all over the world. A selection from these and similar writings was reissued by Keynes in 1931 under the title Essays in Persuasion. These are marked by a brilliant style, truly the work of a literary craftsman.

There was one pressing and recurrent politico-economic issue of the postwar world of the 1920s – German reparations – which Keynes discussed not only in books addressed to the general public (1919, 1922) and in numerous magazine articles (reproduced in JMK XVII–XVIII), but also in the pages of the Economic Journal (which Keynes edited from 1912 to 1944; some of the interesting correspondence which he carried out in this capacity is reproduced in JMK XII, pp. 784–868). The reference is, of course, to Keynes's 1929 debate with Ohlin about the possibility of Germany's carrying out the payments imposed upon it by the Versailles Treaty: the famous debate about the 'transfer problem'. In light of the central role that the notion of effective demand was a few years later to play in the General Theory, it is ironic to note that in this debate it was Ohlin who emphasized the role of 'buying power' in carrying out the reparations, and Keynes who overlooked it. One cannot help suspecting that Keynes's thinking here was coloured by his violent objections to the Treaty itself (see introductory section of this essay). It should, however, be noted that a similar neglect of 'buying power' characterizes Keynes's other writings of this period: namely, his discussion of the effects of public-works expenditures in both Can Lloyd George Do it? (1929) and the Treatise (1930) (see Patinkin, 1976a, p. 129).

Keynes's accomplished literary style also characterizes his Essays in Biography (1933b), in which Keynes reprinted his impressions of the leading political figures he had known, as well as his biographical essays on various British economists. Most notable among the latter are his stimulating essay on Thomas Malthus and his perceptive and evocative memorial essay on his teacher, Alfred Marshall.

At various critical junctures in the interwar period, Keynes also published influential pamphlets in which he analysed the questions at issue and proclaimed his prescriptions. Such were his Economic Consequences of Mr Churchill (1925), in which he criticized the decision of the then Chancellor of the Exchequer to return to the gold standard at prewar parity, claiming that the resulting overvaluation of the pound generated depression in British export industries which then spread to the rest of the economy; Can Lloyd George Do It? (1929) (written with Hubert Henderson), in support of the Liberal Party's pledge in the 1929 election campaign to reduce unemployment by means of public works; The Means to Prosperity (1933a), in further support of this public works (this time making use of the newly developed notion of the multiplier) as the depression deepened in the early 1930s; and How to Pay for the War, as in 1940 the problems of depression gave way to those of wartime inflationary pressures. (All of these pamphlets have been reproduced in JMK IX.)

I should, however, note that already in 1943 Keynes also began to concern himself with post-war problems and wrote a memorandum on 'The Long-Term Problem of Full Employment' advocating a programme in which 'two-thirds or three-quarters of total investment is carried out or can be influenced by public or semi-public bodies' (JMK II, p. 326). And in reply to a comment on it by James Meade, he wrote (letter of 27 May 1943):

It is quite true that a fluctuating volume of public works at short notice is a clumsy form of cure and not likely to be completely successful. On the other hand, if the bulk of investment is under public or semi-public control and we go in for a stable long-term programme, serious fluctuations are enormously less likely to occur (JMK XXVII, p. 326).

Similar views were expressed by Keynes in an unpublished February 1944 ‘Note on Postwar Employment’ and in a December 1944 letter to Beveridge (JMK XXVII, pp. 365, 381). Thus to the end of his days, Keynes continued to advocate public-works expenditures as a necessary component of a full-employment policy. It should, however, also be emphasized that – as in the General Theory and a fortiori the Treatise – Keynes also continued to stress the essential role of a low rate of interest in carrying out this policy. Indeed, in a series of articles in the Times which he published in 1937 entitled ‘How to Avoid the Slump’, he wrote that ‘we must avoid it [i.e., ‘dear money’] as we would hell-fire’ (JMK XXI, p. 389). Keynes influenced policy not only through his publicistic activities, but also by his active membership in various official government bodies. Thus he was the leading figure of the
Committee on Finance and Industry (the Macmillan Committee, 1929–31) and of the Economic Advisory Council (1930–39), and he also served as chairman of the Committee of Economists (1930) – all of which were charged with advising the British government on different aspects of the policies it should follow in order to overcome the serious depression in which Britain, together with the rest of the Western world, then found itself (cf. Howson and Winch, 1977). Similarly, at the outbreak of World War II, Keynes was appointed adviser to the Chancellor of the Exchequer, a position he held until his death. He also played a leading role in the negotiations with the United States government, first for lend-lease support in 1941 and again in 1944, and then for a special postwar loan in 1945. Keynes was also one of the architects of the International Monetary Fund and the International Bank for Reconstruction and Development (the World Bank). Indeed, the Fund's original policy of fixing par values for the various exchange rates, but permitting fluctuations of up to 10 per cent about them, is clearly reminiscent of Keynes's advocacy in the Treatise (II, p. 303) of maintaining the fixed exchange rates of the international gold standard, but widening the gold points so as to permit fluctuations of the rates within a range of two per cent. In the foregoing capacities, Keynes wrote countless letters, memoranda, reports, draft proposals, and the like, the major ones of which are reproduced in the relevant Activities volumes of his Collected Writings (JMK XX–XXVI; see also Kahn (1976), Williamson (1983) and Moggridge (1986) on Keynes's views on the international monetary system from his earliest writings up to and including the IMF).

As indicated above, Keynes's concern with policy questions also exerted a strong influence on the direction of his scientific writings. This was clearly the case for his Tract on Monetary Reform (1923), which had its origins in newspaper articles that Keynes had written on current economic problems. Similarly, the predominant emphasis of the Treatise on Money (1930) on the problems of unemployment and of the workings of the international gold standard reflected the major economic concerns of the period. By the time the General Theory (1936) was being written, however, the gold standard had collapsed, while the problem of unemployment had become increasingly severe. Correspondingly, the General Theory is concerned almost exclusively with the problem of mass, long-run unemployment in a closed economy: that is, one not subject to the restrictions imposed by the gold standard.

Keynes's interests ranged far beyond the confines of economics. He was for many years a member of the famous Bloomsbury Circle. His cultural activities included the theatre, dance, paintings, and rare-book collecting. He was instrumental in establishing the Arts Council, which provided state patronage of the arts. In all these ways Keynes played a prominent role in the cultural and intellectual life of the Britain of his day (see Harrod, 1951; White, 1974; Milo Keynes (ed.), 1975; Crabtree and Thirlwall (eds.), 1980; and Skidelsky, 1983 and 1988).

Abstract

Since Don Patinkin's article on Keynes appeared in the first edition of *The New Palgrave*, two major biographies have increased our understanding of Keynes's life. There has developed a large literature on the relation between his work on probability and his involvement in the Bloomsbury group, and the relation to both of these to his economics. This article reviews and assesses that literature along with more recent work on his economics.

Patinkin on Keynes

Don Patinkin's article on John Maynard Keynes, reproduced here from the first edition of *The New Palgrave*, is a classic. Patinkin had first grappled with Keynesian theory as a student in Chicago in the 1940s, going on to write *Money, Interest and Prices* (1956), which was the leading graduate textbook in macroeconomics from the 1960s until the early 1970s. Apart from offering a theoretical interpretation of Keynesian economics, as the economics of disequilibrium, the book contained detailed appendices on the history of many of the concepts with which he was working. When the publication of the volumes of
Keynes's *Collected Writings* (cited here as *JMK*) made available extensive correspondence and other previously unpublished material, Patinkin turned to this to provide an account of how Keynes had reached the ideas that he (Patinkin) and others had struggled so long to understand. Patinkin's scholarship was meticulous, and his ideas on Keynes were documented in a series of books published between 1974 and 1982. It was a case of one outstanding theorist exploring the mind of another, which explains the questions he chose to ask: how did the Marshallian quantity theorist of the early 1920s become the author of the *General Theory*? What were the theoretical innovations that marked the *General Theory* apart from works by others seen as having 'anticipated' Keynesian ideas? Patinkin's article sums up the results of this thinking, which explains why, at the start, he wrote that he was not going to offer a biography but would reflect on the development of Keynes's thinking on economic theory and policy.

When Patinkin made that remark, the only biography available was the official biography by Sir Roy Harrod (1951). The first volume of Skidelsky's biography (1983) had appeared, but it covered only the period up to 1920, a long way short of the work for which Keynes is now famous. Since then, Skidelsky has concluded his biography with two further volumes (1992; 2000) and has produced a one-volume abridgement, of a mere 1,000 pages (2003). The co-editor of the *Collected Writings*, Don Moggridge, has also written an important biography (1992: for two useful comparisons that explain why both need to be read, see Dimand, 1993, and Blaug, 1994). Apart from these, Keynes has been the subject of an earlier short biography by Moggridge (1976) as well as ones by Charles Hession (1984), David Felix (1999), and a short study by Skidelsky (1996). There has also been extensive research on the Keynesian revolution and Keynes's role in it, some prompted by Patinkin's conclusions, others by other concerns. Here, the work of the Peter Clarke (1988; 1998) is worth noting, being the result of a political historian taking the time to get to grips with circumstances that produced Keynesian economics.

A further development was that in the mid-1980s scholars were beginning to see Keynes not simply as an economist but as a philosopher, exploring the philosophical grounding of his King's College Fellowship Dissertation which later became the *Treatise on Probability* (1921; *JMK*, VIII) and the relationship of these ideas to his discussion of uncertainty in the *General Theory* (notably Chapter 12) and in the article in 1937 where he argued that his main thesis was the fact that we know virtually nothing about the future (*JMK*, X, pp. 108–23). The appearance, within a very short period, of three studies of Keynes's philosophical development (Carabelli, 1988; O'Donnell, 1989; Bateman, 1987; 1988; 1996) was an important factor behind the rapid growth of a very detailed ‘Keynes and philosophy’ literature during the late 1980s and early 1990s. The first volume of Skidelsky's biography also located Keynes, much more firmly than Harrod's had done, in the artistic and literary environment of the Bloomsbury group, stimulating further reassessments of the context in which Keynes's economics should be interpreted.

During the 1970s, the foundations were laid for a transformation in macroeconomics by the work of Phelps, Lucas, Sargent, Barro and others. Keynes was reinterpreted, many times, and the theoretical framework within which Patinkin had worked ceased to define the questions that became of primary concern to macroeconomists, which now concerned problems such as dynamics, expectations, and strategic decision-making. Though Keynes still had some relevance (witness the New Keynesian macroeconomics), it became much easier to see Keynesian economics as a historical episode than had been the case for members of Patinkin's generation. Studies such as Dimand (1988), Young (1987),
Meltzer (1988), Littleboy (1991) and Laidler (1999) reflected this new perspective: it had become much easier to see Keynes apart from the theoretical context that Patinkin and his contemporaries had developed.

**Keynes's life - Bloomsbury, art and economics**

When Patinkin wrote his account of Keynes's economics, he had two contrasting accounts of Keynes's early life on which he could have drawn had he considered it relevant to his task. Harrod's biography had been constrained not only by older Victorian conventions about biography but also by his view that it was important that nothing should be revealed about Keynes that would threaten the acceptance of Keynesian economics. He thus ignored Keynes's homosexuality and minimized Keynes's involvement with Bloomsbury. In contrast, Skidelsky's first volume presented a Bloomsbury Keynes. His was a psychological biography in the Bloomsbury tradition, in which Keynes's sexuality and personal relationships were to the fore. Where Harrod had portrayed Keynes's sense of duty – the famous 'presuppositions of Harvey Road', combining a strong sense of duty and a belief in the power of social science – as constraining any immoralism, Skidelsky emphasized the influence on Keynes of G. E. Moore, mentor to the group of Cambridge undergraduates who would ultimately form the male corps of the Bloomsbury group. Skidelsky attached much more importance than Harrod to Keynes's essay 'My Early Beliefs' (JMK, X, ch. 39, first written in 1938), creating a picture of someone dominated by a very private set of values, significantly insulated in his youth from the world of public affairs into which he was later thrust. The story ended in 1919, with the book that Keynes wrote when he resigned from the Treasury in protest over the impending outcome of the Paris peace negotiations, *The Economic Consequences of the Peace* (JMK, II). Not only did this thrust Keynes into the public arena, but it marked the shift from a Victorian belief in automatic economic progress to a world in which prosperity would need to be fought for. Skidelsky writes of Keynes fearing not the material but the organizational and moral destruction wrought by the war: prior to the war, it had been liberating for Keynes and his friends to be freed from their parents' belief that God could be relied on to maintain the social order. After the war, that was no longer the case. Thus Skidelsky (1983, p. 402) concluded his first volume, by arguing that 'In the last resort Keynes's post-war fear of the future of capitalism was profoundly influenced by the Victorian fear of a godless society'. The prospect of civilisation briefly opened up by Moore's *Principia Ethica* (1903) had receded over the horizon. The rest of Keynes's life was spent in trying to bring it back into sight. *Economic Consequences of the Peace*, Skidelsky (1983, p. 384) claimed, was Keynes's 'best book', in which, more than in any other, he brought 'all' his gifts to bear on the subject in hand. Harrod could never have raised doubts about the merits of the *General Theory* in this way.

Subsequent work has continued the process, begun with Skidelsky's volume 1, of correcting many of the errors in Harrod's biography. These were significant because Harrod had used his sources selectively: he was 'a master of selective quotation', aiming to cleanse Keynes's statements for public consumption. For example, in the quotation from a 1905 letter, 'I want to manage a railway or organise a Trust …', the omitted words denoted by the dots were 'or at least swindle the investing public', a sentiment that Harrod would not have wished his readers to encounter (Skidelsky,1983, p. xviii). Harrod had carefully not discussed Keynes's views on conscientious objection (where he supported his Bloomsbury friends),
even though surviving documents clearly attest to his position (Johnson, 1960). Neither had he discussed
the ‘search for love’ that Keynes himself described as his main preoccupation before 1908, now
carefully documented (‘boy by boy’, according to Keynes's own records) by Moggridge. Both Skidelsky
and Moggridge explain that Keynes's search for love eventually was calmed for several years through
his intimate relationship with the painter Duncan Grant that lasted from 1908 to 1912 and that would
become a lifelong friendship. Moving beyond this sexual biography, however, both Skidelsky's
subsequent volumes and other work such as Moggridge's biography have served to narrow the gap
between the pictures of ‘Keynes the economist’ and ‘Keynes the member of Bloomsbury’. Thus,
although as late as 1921 Keynes was expressing doubts about his vocation (the values of Bloomsbury
were still important to him and he lamented the lack of a true artistic talent), his turn to economics had
deep roots: though his first formal training was after graduation, when preparing for his Civil Service
examination, he came to this having studied a formidable list of books on economics. His philosophical
views, discussed separately below, also serve to bridge the two interpretations.
The early 1920s were a crucial period for Keynes in several respects. The Economic Consequences of
the Peace had made him a celebrity, and given him the financial basis for his earliest speculative
activities (which came to grief in 1920 when the currencies on which he had speculated moved in the
wrong direction). His Treatise on Probability (1921; JMK, VIII) was published, although he left behind
any ideas of further work in philosophy. Though he had left the Treasury (something he had planned to
do even had he not resigned in protest) he chose not to resume his heavy pre-war teaching duties in
Cambridge, and spent much time offering policy advice from the position of an outsider to the Whitehall
system. In giving up his income as a university lecturer at Cambridge and his income as a fellow of
King's College following the First World War, Keynes now needed new streams of income to support
his lifestyle. Journalism and attempts to influence public opinion became major activities. He also
embarked on a long-term career as an investor, losing his investments (and that of his friends) through
commodity speculation when the post-war boom collapsed, but then began to rebuild them again. There
was also the change in his private life. To the horror of his Bloomsbury friends, he fell in love with a
ballerina from Diaghilev's company, Lydia Lopokhova, whom he eventually married in 1925. In the
opinion of his family and many of his friends, this gave him a new lease of life and may, at least in part,
account for the enthusiasm with which he was willing to entertain and explore new ideas. Their
relationship (Hill and Keynes, 1989) clearly refutes the allegation that Keynes's emphasis on the short
run stemmed from a belief that he would not have children.
With his marriage to Lydia, he became more distant from Bloomsbury, though contacts remained strong,
even though Lydia and Vanessa Bell were never on good terms. Keynes (as Moggridge has shown)
certainly found relaxation from his hectic schedule as a professional economist amongst his Bloomsbury
friends, both in London and in the houses they acquired in the Sussex countryside. He also built
professional and social contacts outside Bloomsbury. His experience as an investor grew, and his
position as a director of the Provincial Insurance Company as well as Chairman of the National Mutual
Insurance Company gave him regular contact with the City. He made money during the 1920s, but lost it
a second time in 1929, and had a further setback in 1937. His speculative activities were not a success,
though he regularly extricated himself from disaster. At one point he had to take delivery of a contract
for wheat because the price had fallen too low for him to wish to sell it. Though he went so far, on one
occasion, as to estimate the capacity of King's College Chapel to serve as a place to store wheat, he
never had to try to use it for that purpose because he ingeniously realized that he could forestall the
delivery of the wheat by demanding that it be cleaned before delivery. When he eventually established
his fortune, it was through a very different strategy: of holding, long term, a small number of stocks, in
companies that he understood and in which he had confidence.
Keynes had suffered from recurrent bouts of appendicitis and influenza while in the Treasury during the
First World War, both problems to which he was made vulnerable because of overwork and exhaustion.
In 1937 he had a major heart attack and, though he was gradually brought back to health, the last decade
of his life, as demanding as any in his career, were plagued by heart problems. However, recent work,
notably by Craufurd Goodwin (1998; 2006) has argued that, despite this broadening out beyond
Bloomsbury, strong intellectual links can be found between Keynes, Roger Fry, and the artists and
novelists of Bloomsbury.
These intellectual links bear on Keynes's economics in both broad and narrow ways. One of the links
that Goodwin uncovers is a consistent concern throughout the works of the Bloomsbury novelists (such
as Virginia Woolf, E.M. Forster, David Garnett), art critics (such as Roger Fry, Clive Bell), and political
theorists (such as Leonard Woolf) with the problem of inconsistent and disappointed expectations, a
theme that would run through the General Theory. Another shared theme with his fellow Bloomsburies
was a fascination with the emerging study of psychology and the varieties of human motivation. Again,
it is difficult to read the General Theory without realizing the extent to which Keynes was decades ahead
of the discipline in using psychological explanations of economic behaviours such as investment and
consumption. And this points to another area of shared interest amongst the Bloomsburies crucial to
understanding Keynes's mature theoretical work: like their mentor G.E. Moore, they completely
eschewed utilitarian explanations of human behaviour and did not take utilitarian ethics as a reasonable
guide for behaviour or policy.

Keynes and philosophy

Beginning in his years at Eton, Keynes demonstrated a keen interest in political and philosophical
questions. As an elected member of College Pop, a debating club, Keynes frequently spoke in support of
Liberal positions. In his final year, he wrote a long essay on the poet and monk Bernard of Cluny, which
he would revise and read again several times later in his life. The central fascination of Bernard for
Keynes was the tension between the following a path of contemplation and the path of active
engagement with the world.
The skills that Keynes had begun to develop at Eton came into full bloom when he matriculated to
Cambridge in the autumn of 1902. At the centre of his many engagements at Cambridge was his
membership in the secret society known as the Apostles, one of Cambridge's most distinguished
societies at the time, which the years immediately preceding Keynes's matriculation had begun to
develop a concern with philosophical questions. Both Bertrand Russell and G.E. Moore had been active
in the society in the years before Keynes's election and on occasion both would still attend the group's
Saturday evening meetings. Moore's classic, Principia Ethica, was published at the end of Keynes's first
year and it became the most important single text for Keynes in his undergraduate years. ‘[I]ts effect on
us, and the talk which preceded and followed it, dominated, and perhaps still dominate, everything
else’ (JMK, X, p. 435).
For several reasons, this early devotion to Moore and philosophy was still not generally understood as a
part of Keynes's life and work when Patinkin wrote his entry on Keynes. On the one hand, as mentioned
above, Harrod chose to minimize this influence on Keynes's work because he feared that it would point toward his sexuality and so risked diminishing the status of his economic work. On the other hand, when the decisions were made to publish Keynes's *Collected Writings*, the editors concluded that, apart from including his *Treatise on Probability* so as to have all his published books in the edition, no effort would be made to include his philosophical correspondence or any of the early philosophical essays written for the Apostles. Following Harrod, the Keynes of the *Collected Writings* was to be an economist only. Thus, when Patinkin undertook his project he would have had little or no idea that this philosophical work even existed. As the early volumes of the *Collected Writings* began to appear, there was a flood of new material to absorb, and little or no indication of this additional trove of untapped material. By the late 1980s, however, as scholars began to explore the Keynes Papers deposited in the King's College Modern Archive, the importance of this philosophical material began to become clear. The times were perhaps propitious for such a discovery since macroeconomics in the 1980s had taken a sharp turn to questions of probability and uncertainty, and much of Keynes's early philosophical work involved the philosophy of probability. The discovery of this previously unexplored part of Keynes's work offered the possibility to see what Keynes himself had said about uncertainty and expectations, a topic that had become central to many critiques of his work (for example, rational expectations).

Two early Cambridge University dissertations on the topic by Anna Carabelli and Roderick O'Donnell opened this field, and became the basis, if somewhat altered, of Carabelli (1988) and O'Donnell (1989). These two early interpreters took diametrically opposed approaches to Keynes's work in probability, with Carabelli arguing that Keynes had authored a subjective theory of probability while O'Donnell argued that, quite to the contrary, Keynes had authored an objective theory of probability. Both agreed that Keynes's contribution hinged on his articulation of a logical theory of probability, in which Keynes argued that probability represented the logical degree of belief in a proposition rather than a frequency distribution of outcomes. This much, of course, was indisputable, but the question remained of how to interpret what Keynes had said. Was the logical relation an objectively known (and identical) value for all rational persons with the same knowledge, or was the logical relation subjectively known, unique for each individual?

The source of the possible confusion came from the well-known critique of Keynes's work in probability made in the 1930s by the great Cambridge philosopher Frank Ramsey (1931). Ramsey argued that there were no such things as Keynes's logical relations of probability, or that he at any rate could not identify them; rather, Ramsey argued, we form our own subjective probabilities, subject only to the consistency required of them by the Dutch book, gambling argument (that they should not be willing to accept combinations of bets that guarantee that they will lose money). Ramsey's work was published posthumously, after his tragic early death, and Keynes's review of it seems to make clear his acceptance of Ramsey's criticism. Thus, after recapitulating Ramsey's criticism, Keynes would report, ‘So far I yield to Ramsey – I think he is right’ (*JMK*, X, p. 339). Against this, Carabelli seemed to argue that Keynes had always had a subjective theory of probability, and that Ramsey's criticism amounted to an argument over whether the subjective probabilities represented a logical entity. O'Donnell, on the other hand, argued that Keynes had held an objective theory of probability in *Probability*, and that he had never capitulated to Ramsey.

In Bateman (1987; 1988; 1996) a very different argument is made that takes at face value both Keynes's statements about objectivity in *Probability*, as well as his capitulation to Ramsey's critique. This work approaches Keynes initial position through the same route that he took himself, his engagement with and
critique of Moore's ethical theory. In *Principia Ethica*, Moore had made one argument that Keynes did not accept, namely, that in a person should follow the general rules of conduct (for example, do not murder, do not steal, do not commit sodomy) because of the uncertainty of the outcome of one's actions. Keynes began his critique of this position while he was a second-year undergraduate in one of the earliest papers he read to the Apostles; and he developed the insights in that paper into his fellowship dissertation (submitted in 1909) and eventually into *Probability* (*JMK*, VIII).

The crux of Keynes's critique of Moore's ethical position was that he had defined probability incorrectly. In his argument, Moore depended on a frequency theory of probability and assumed the impossibility of knowing long-run frequencies with any certainty. In the face of this radical uncertainty about the possible outcomes of committing murder or committing adultery, for instance, Moore argued that the best course of action was represented by the general rules of conduct, which he argued gave the highest frequency of good outcomes. Moore felt that, since we would not know when an act of murder might turn out to have a good outcome, the best course of action was not to murder at all.

For Keynes, who was a practising homosexual and who generally enjoyed the youthful pleasure of making up his own mind about when rules were reasonable (and when not), this argument needed to be proven wrong. His method was to posit that probabilities are logical relations that are, indeed, capable of being known when we act. His argument had the added twist of drawing on Moore's Platonic treatment of the good. Like Moore, who argued that we know the good through intuition of an indefinable quality, Keynes argued that the logical relations of probability are Platonic entities, not reducible to anything else, and known through intuition. On this argument, any bright young man with the same knowledge could intuit the probabilities of the various possible outcomes of an action, as well as the amount of goodness that would attach to each one. On this argument there was no need to follow traditional rules of conduct. The argument seemed to be persuasive, as Moore dropped his argument for following rules in *Ethics* (1912) and included a logical theory of probability in the same book.

But it was exactly the idea that probability was a Platonic entity that Ramsey criticized. He had written about this as early as 1922 in a review of *Probability* in which he talked about fog-shrouded mountains which were not visible to the human eye. And his posthumously published essay, ‘Truth and Probability’ (*Ramsey*, 1931) says simply that, if these logical relations exist, he is unable to recognize them and certainly does not act on them. Perhaps the most convincing explanation of Keynes's ultimate position comes from Donald Gillies and Grazia Ietto-Gillies (1991) who describe Keynes as embracing ‘intersubjective’ probabilities. Gillies and Ietto-Gillies accept Keynes's capitulation to Ramsey but go on to point out that the positive result of this in the *General Theory* was a world in which most people formed their subjective probabilities by guessing what others were thinking. Thus in Chapter 12 of the *General Theory*, in Keynes's well-known description of how stock markets function, investors seek stability in an uncertain world by depending on the mass psychology of the market. This same idea is borne out in his description elsewhere in his magnum opus in his description of liquidity preference and the ways that bond traders make their portfolio decisions. This entire line of thought is most strongly emphasized in Keynes's famous restatement of his book's argument in response to his critics in his 1937 article in the *Quarterly Journal of Economics*.

There are many dimensions to Keynes's early work in ethics, probability, and political philosophy, but perhaps the most crucial for understanding his work in relation to mainstream economics as it evolved in the 20th century is his refusal to embrace utilitarianism. Bateman (1988) and Goodwin (2006) have noted this, but the philosopher Tom Baldwin (2006) has put it in a form that makes it particularly
Keynes, John Maynard (new perspectives) : The New Palgrave Dictionary of Economics

striking for an economist. This comes in his observation that, despite his place at the centre of a long tradition of British liberal political philosophers, Keynes never seriously engaged John Stuart Mill's work during his long and prolific career. There is perhaps no Briton in the first half of the 20th century who so acutely explored the meaning of liberalism as John Maynard Keynes. Both in his economic work on the appropriate role of the state in the economy and his essays on political liberalism (reprinted in JMK, IX), Keynes explored the frontier questions of the autonomy of the individual, the possibilities for human freedom, and the role of the state. And yet, as Baldwin makes clear, Keynes's acceptance of Moore's argument that Mill had misidentified utility as good kept Keynes from ever seriously tackling Mill's work. For much of the 20th century, this meant a kind of deep misunderstanding and misapprehension of Keynes's work on the part of those economists who were unable to work outside a framework of individual utility maximization as both a positive description of human behaviour and a normative goal of policy. Much of Keynes's writing and his modelling are opaque to mainstream neoclassical economists for this reason. Perhaps with the recent shift to behavioural economics Keynes's work will seem less difficult to understand and appreciate on its own terms. But, whichever is true, much of the time since the publication of the *General Theory* has been marked by a deep chasm caused by the fact that Keynes did not assume that people seek to maximize utility in most situations, or that they should.

**Keynes's economics**

Where Skidelsky painted a brilliant portrait of the economist as operating in a broader intellectual environment, encompassing not simply Cambridge economics but also the philosophical and political concerns of the Apostles and Bloomsbury, Moggridge sought to redress the balance with what his subtitle described as ‘an economist's biography’ (cf. Moggridge, 2002). Keynes's complete dismissal of utilitarianism distanced him from much economic theory, but Keynes was an original thinker of the first rank, especially in areas such as international finance and monetary economics where utilitarian thinking has always had a limited influence. Thus, what emerges from Moggridge's account is an economist who, to an extent greater than implied by Patinkin, with his focus on theory, was primarily an applied economist whose career was dominated by issues of international finance (see Mundell, 2008). Though politicians may not have always accepted his arguments, throughout his career he had the ear of governments and his ideas were avidly sought. Sometimes he was invited to serve on committees, but in other cases he sent a memorandum to the Treasury that caused him to be brought into the discussion. He may have been an outsider, but even in the 1920s he had considerable access to officials and government ministers. Thus he was never an economic theorist as the term is now understood, but was for ever analysing institutions, estimating rough magnitudes and formulating policy proposals on the basis of those estimates. When, during the Second World War he acted as mentor to James Meade and Richard Stone in constructing the British national accounts, this came after a lifetime of promoting the collection of economic statistics, a passion that he developed as a young man when he developed his ideas on probability to include an extended treatment of induction (Bateman, 1990).

His first appointment in the Civil Service was in the India Office, but it was after he had left and returned to Cambridge that, in 1913, he was invited to sit on the Royal Commission on Indian Finance and Currency. Several of his fellow commissioners worked in the Treasury or had done so recently, and
so his distinguished service on this appointment helped him to make the contacts that eventually would lead to his appointment to the Treasury during the First World War. Keynes's work on the Royal Commission was a harbinger for much of his later government service; he was appointed to the Commission largely on the basis of the proofs of his book *Indian Currency and Finance* that he was circulating in 1913. The book appeared within a month of the start of the Commission's work and Keynes used the analytical framework of the book to drive his questioning and to bring the other Commission members around to his own views.

This pattern of writing, demonstrating expertise and being invited into the inner circles of policymaking, would repeat itself over and over again during his career. It was the general pattern of his next assignment advising the government, when he entered the Treasury in January 1915 as an adviser to Sir George Paish, a special assistant to the Chancellor of the Exchequer, David Lloyd George. In summer and autumn 1914 Keynes had been asked his opinion on the crisis that initially rocked the London financial markets at the outset of the war. Using the information he had gained while consulting at the Treasury, he wrote and published articles that autumn in the *Economic Journal* and the *Quarterly Journal of Economics* explaining what had happened when the joint stock banks had, in his opinion, unnecessarily called loans and so restricted credit. These two pieces caused some consternation in the banking community, but they won him more invitations to write memoranda for the Treasury and eventually led to his appointment. Once inside the Treasury, Keynes moved through several committee assignments and served on inter-ally financial working groups to help keep the finances of France, Britain, and Russia coordinated and well functioning; after America's entry into the war in 1917, the group of allies expanded. Keynes rose to a position of considerable stature for such a young man, being made the head of A Division, the senior person in charge of Britain's external financial relations during the war.

As the war wound down, Keynes was asked to write a memorandum on German indemnity and the limits of what Germany could be expected to pay. This in turn led to more committee assignments and his eventual appointment to the Treasury team that was sent to Paris for the peace negotiations, where he served as the senior Treasury official in Paris. With this pattern of mastering his brief quickly and advancing in the Treasury well established, Keynes became the lead financial negotiator for Britain in many circumstances during the negotiations. The work was dispiriting to him because of the political machinations and the lack of any goodwill towards Germany. He seemed to see only avarice, revenge and political gain as the means and end of the negotiations, with little or no concern for the starving peoples of Europe. Keynes was also working to exhaustion in poor conditions in Paris, and eventually he felt compelled to submit his resignation. In June 1919, he left Paris unable to see any good in the outcome of the negotiations.

Resignation from the Treasury did not mean an end to his involvement as a policy adviser at the highest level. As early as February 1920, he was advising the Chancellor of the Exchequer on whether to raise interest rates, and was kept informed of discussions in official circles. In 1921, he began his career in journalism, the primary issue initially being reparations, on which international negotiations continued throughout the 1920s. This took him into questions of post-war reconstruction and exchange rates. Though his was not the dominant voice, his arguments were not without influence, as when, in 1924, his views and those of Reginald McKenna helped steer the Chamberlain Committee away from the idea that deflation would be the likely result of a return to gold. In coming to his decision to return to power, Churchill listened to Keynes and had his advisers respond to his arguments. His position in policy circles
was recognized by his being appointed to the Macmillan Committee on Finance and Industry in November 1929, and the newly formed Economic Advisory Council in January 1930, both of which were established to address the unfolding problems of the slump.

It was against this background of extensive journalism and advising on policy that Keynes's economics evolved. His attempt to write a major work on monetary economics started in 1924, whilst he was involved in debates over the return to gold. In the next two years he worked closely with his fellow Cambridge monetary economist, Dennis Robertson, whose *Banking Policy and the Price Level* (1926) strongly reflected his discussions with Keynes; but Keynes's own book, *A Treatise on Money* (1930; JMK, V and VI) did not appear for several years, its final drafting coming while Keynes's life was dominated by the Macmillan Committee, in whose deliberations Keynes played a dominant role, and by the attempt by the economists on the Economic Advisory Council to produce a unanimous report on measures to combat the slump. From November 1929 to April 1931, Keynes attended over 100 meetings of the Macmillan Committee alone, this at the time when he was preparing his *Treatise on Money* for publication.

Though Keynes's writings early in the 1920s were concerned with exchange rates and inflation, and were conducted within an essentially Marshallian framework, the basis for his advice changed. In the *Tract on Monetary Reform* (1923) he had argued for the importance of monetary management, but by 1925 he was focusing on the overvaluation of sterling involved in returning to gold at $4.86 to the pound. In 1924 he began to write specifically on unemployment, asking whether unemployment needed a drastic remedy, and this became an increasingly important theme in his writings as the decade went on, taking him into issues ostensibly far from international finance, such as the need for restructuring in the cotton industry. However, international monetary issues never went away. Of particular significance, given that it revealed his failure at this time to attach importance to the income effects central to the *General Theory*, was his 1929 exchange with Bertil Ohlin on the transfer mechanism, still in the context of reparations. Also, his policy recommendations concerning unemployment, though focused more on domestic issues, were never far from questions of international finance. In 1924, his argument for action against unemployment rested on arguments about diverting resources ‘from relatively barren foreign investment into state-encouraged productive enterprises at home’ (quoted in Moggridge, 1992, p. 421).

In his writings later in the 1920s, the possibility of raising employment became more prominent, especially in the confrontation with the Treasury view in 1929, but the background was the constraint imposed by the restored gold standard. It was the fact of the restored gold standard that led Keynes, in early 1931, to support a limited introduction of tariffs.

The story of Keynes's theoretical development, discussed in detail by Patinkin, took place against this background. The *Treatise*, with its Wicksellian approach, taking Keynes away from the Marshallian framework of his earlier work, was written at a time when his public commitments left him precious little time for more academic pursuits. For example, Hawtrey offered detailed criticisms of drafts of the *Treatise*, but Keynes did not have time to read them until after publication. This may account for the unsatisfactory nature of the resulting book and hence the rapidity with which he moved on. Furthermore, when sterling was allowed to float in 1931, the case for public works made in the *Treatise* was no longer relevant, and, now that the need to defend sterling was removed, Keynes began to argue for low interest rates. Though he remained active in both journalism and policy advice, he made sure that what was to become the *General Theory* was subject to much more systematic academic criticism from his colleagues in Cambridge.
The process whereby Keynes made the crucial step taking him from the ‘classical’ framework of the
*Treatise on Money* to the *General Theory* has been examined in great detail. Evidence for this comes
from his publications, public statements on policy, recollections of scholars who visited Cambridge, and
students’ notes of his lectures. Patinkin's conclusion was that Keynes reached a ‘full understanding’ of
the ideas in the book some time in 1933: not until then did Keynes have in place the three crucial
elements (the multiplier, equilibration through changes in output, and an unemployment equilibrium).
Some scholars have supported this conclusion; others have argued for dates in 1932 and 1934 (for a
concise survey see Skidelsky, 1992, pp. 443–4, including note 48; see also Clarke, 1998, ch. 4). What is
of interest there is as much the reasoning underlying such arguments as the conclusions themselves. For
Patinkin, an idea existed when it could be written down as a model. On the other hand, for Clarke, the
intuition was more important, a conclusion endorsed by Skidelsky (1992, p. 444, quoting student lecture
notes), who has pointed to Keynes's belief that one can think ‘accurately and effectively’ even before
being able to formalize ideas. A further dimension is the weight to attach to practical theorizing in the
context of policy arguments in relation to theorizing at a more abstract level. There is also the issue of
whether an idea has to have been conceived in someone's mind, written down privately, or placed in the
public domain. Thus it is because he believes that Keynes did not confine himself to what followed
rigorously from the *Treatise* framework that Clarke (1998, pp. 92–5) is willing to date Keynes's
understanding of aggregate demand to the summer of 1932: not only were his lectures that autumn
significantly different from those the previous session (so that students well versed in the *Treatise*
found them hard to follow), but by November 1932 he was writing about the contrast between Malthus
and Ricardo in ways that clearly anticipated the break with Ricardian orthodoxy found in the *General Theory*.
The Second World War took him into the Treasury again, though as an unpaid adviser rather than a
salaried official, where he had a possibly unparalleled combination of access to officials and freedom to
pursue whatever he thought important. Once again, it was his brilliant writing that helped him to be
called into the Treasury: *How to Pay for the War* (1940; *JMK*, IX), perhaps his clearest success in the
policy arena, providing the theoretical and statistical framework for controlling wartime inflation.
Though this has been seen as an application of Keynesian theory to problems of inflation at full
employment, it is worth noting that it relies more on the doctrine of forced saving, discussed by other
economists in the years before the *General Theory*, a fact that acquires significance given that this is the
theory of inflation first used by Milton Friedman (Laidler, 2002, pp. 103–4). However, because the path
from Keynesian ideas to their implementation in the 1941 budget was relatively smooth, this did not
serve as a drain on Keynes's time and health in the same way as his international negotiations. Here he
was up against the Americans who, for a variety of reasons, were much harder to convert. Isolationist
tendencies were strong in American politics, and there was widespread hesitation about using American
resources to support a country that was still the centre of a worldwide empire. There was even a belief in
some circles that a contributory factor behind America's over-expansion of 1928–9 and hence the
subsequent collapse had been pressure on the Federal Reserve to keep interest rates low, due to the
pressure on sterling after the return to gold in 1925. Britain was bankrupt and the burden of negotiating
American financial support under difficult conditions fell substantially on Keynes. Given this weak
bargaining position, it is thus not surprising that, in negotiating the post-war economic order, he failed to
persuade the Americans to give the new international monetary authority greater resources to assist
countries with balance of payments problems, for they were the ones who would, at least in the early
years, be paying. Nonetheless, his success in helping to establish the International Monetary Fund was
significant, given that, after the previous war, the Americans had entered into negotiations only to walk away before agreement was reached.

Conclusions

The debate between Patinkin and Clarke over the exact dating of the birth of Keynes's new ideas in the General Theory is a classic in the history of ideas. As Moggridge (1992, p. 559) and Skidelsky (1992, pp. 443–4) have noted, however, there will never be a clear answer to the question of exact dates because of Keynes's lifelong style of work. Keynes always depended on working from fundamental intuitions that he would sketch out, sometimes years ahead, sometimes days ahead, of the final, formalized version of his newest work. Thus Clarke can be correct in the precise dating of Keynes's initial working out of the intuitions that might later become the concepts of aggregate demand and liquidity preference, and Patinkin may be correct in his dating of when Keynes published a theoretically satisfactory account of his theory; neither need be wrong in establishing two important points along the trajectory of one of Keynes's ideas. Although there is clear historical value in fixing the arc of these trajectories in Keynes's work, the real value of the recent work on Keynes to economists does not lie in the exact dating of his various contributions. Rather the value to economists of the work of historians like Clarke, biographers like Moggridge and Skidelsky, and commentators on his life in Bloomsbury such as Goodwin lies in seeing the full range and complexity of his ideas and understanding the nature of the influences that led him to his breakthroughs.

In his entry on Keynes, Patinkin argued that ‘a basic contribution of the General Theory is that it is in effect the first practical application of the Walrasian theory of general equilibrium’, and likewise that, ‘The voice is that of Marshall, but the hands are those of Walras’. This reflected Patinkin's own effort in Money, Interest and Prices (1956) to capture Keynes's ‘central message’ in the Walrasian general equilibrium framework and the effort throughout all of his historical writing on Keynes to identify the origins of elements of that Walrasian version of Keynes in Keynes's own writings. Whilst this remains a legitimate interpretation, for that is how Keynesian economics was conceived during the Keynesian era, understanding Keynes himself requires paying attention to other possibilities. Thus Leijonhufvud (2006) and others have reinterpreted the Marshallian dimension to his work, arguing that the gap between Keynesian and Walrasian theorizing was deeper than architects of the neoclassical synthesis believed. Rather than seeing Keynes as endorsing a Walrasian interpretation of his work when he responded favourably to the efforts of John Hicks and others to translate his work into simultaneous equation systems, it is better to see Keynes as concerned with his basic intuitions, content for them to be developed in different ways. The intuitions were more important to him than any specific model (Backhouse and Bateman, 2008). This helps justify both his radical statements about uncertainty and his endorsement of analysis that subsequent generations of Post Keynesians have found excessively orthodox and have needed to explain (for references to the Post Keynesian literature on Keynes see King, 2002; Chick, 1983; Dostaler, 2007; Lawlor, 2006; and a significant proportion of the 40 chapters in Harcourt and Riach, 1997). At least in part, this was because Keynes was not interested in the elaboration of his fundamental insights beyond the form in which he needed them for making successful policy arguments. In both the Treatise and the General Theory, he sought to formalize his insights enough to persuade fellow economists, but his main concern was to provide a workable basis for policy:
he was, in the words of Hoover (2006), primarily a physician creating a ‘diagnostic science’.

Keynes's focus on fundamental assumptions was the approach of the pre-war Apostles, and his intuitions about the economic system arose out of the Bloomsbury understanding that the modern world was built upon a set of inconsistent and easily disappointed expectations. This insight first appears in the *Economic Consequences of the Peace* and suffuses the *General Theory*. It was neither an argument for the impossibility of economic modelling, as some Post Keynesians have argued (Shackle, 1972; 1974; Davidson, 1972), nor was it, as Patinkin argued, of no central importance. Rather, it was a key insight that Keynes built into the *General Theory* and that he believed would have to be a part of any analysis relevant to formulating policies that would help to support the type of civilization that he believed was possible in a humane, well-managed capitalism.

However, though Keynes's involvement in Bloomsbury was fundamental, the intuition about the importance of uncertainty and expectations that he encountered amongst his artistic friends did not carry over into his economics in a simple and straightforward way. Though it animated the *Economic Consequences of the Peace* and the *General Theory*, it was not a feature of his work in the intervening years (Bateman, 1996). In the *Treatise* Keynes denied that expectations were an important factor in explaining the business cycle. When, in response to Keynes's questioning before the Macmillan Committee, Pigou put forward the standard Cambridge trade-cycle theory in which expectations were important, Keynes dismissed the idea, insisting that it was interest rates alone that explained the behaviour of the cycle. To understand the story of how he came, once again, to see the relevance of the old Bloomsbury concern with inconsistent expectations to economic modelling, one has to work carefully through his management of the Provincial bond portfolio (Westall, 1992), his work as bursar of King's College, his policy advice to the government at the time of Britain's abandonment of the gold standard in 1931, and his own investments in the stock market during the Great Depression (Moggridge, 1992).

There is also no straight line from Keynes's early work in the philosophy of probability to the *General Theory*. By the time he came back round to the view that expectations were central to the workings of a capitalist economy, he had abandoned his earlier conception of probability and was left with an adaptation of Ramsey's work in the form of intersubjective probabilities that are shaped by the mass psychology of investors (Gillies and Ietto-Gillies, 1991; Davis, 1994; Gillies, 2006). It is necessary to look at the whole of Keynes's life – as Apostle and Bloomsbury, as student of Marshall, as journalist, government adviser and City investor – to see all the pieces that came together in *General Theory*.

The part of Keynes's philosophical background that perhaps most consistently influenced his economic theorizing throughout his career was not his work in probabilities but his rejection of utilitarian thinking. Keynes never used utility maximizing in a thoroughgoing or consistent way during his long career as an economist. It was, in his view, neither an adequate description of human behaviour nor the desideratum of policy analysis. This, no doubt, is a significant reason why his work has been such a puzzle to economists, leading to misunderstanding of his motivations, modelling, and policy advice. Perhaps in the emerging era of behavioural economics, this part of his work should seem less puzzling and disturbing. It is not the case, of course, that Keynes foreshadowed work in behavioural economics, but rather that, like the behavioural economists, he looked for alternative explanations of suboptimal outcomes and behaviours that were clearly not driven by utility maximization.

John Neville Keynes was born in Salisbury and died in Cambridge, outliving his famous son, John Maynard Keynes, by over three years. He was a promising early pupil of Alfred Marshall, who on leaving Balliol in 1885 persuaded Oxford University to hire Neville, then a Cambridge lecturer and Fellow of Pembroke College, to fill the gap in its economics lectures, and then backed him strongly for the Oxford professorship when it became vacant in 1888. Keynes, however, was unwilling to leave Cambridge; he lectured for only two terms in Oxford, was not sorry when the Drummond professorship went to Thorold Rogers, and refused all offers of posts elsewhere (including the offer of a Chicago chair in 1894), devoting himself increasingly to his beloved family and to university administration – in which he held the top bureaucratic post, University Registrar, from 1910 to 1925.

Keynes published only two books, both textbooks, arising out of his university lectures: one in 1884 on formal logic, and the other, on which his reputation as an economist depends, *The Scope and Method of Political Economy* (1891), which grew out of the lectures he gave in Oxford in 1885. He also wrote a number of (mainly methodological) articles for Inglis Palgrave's *Dictionary of Political Economy*. The importance of Keynes's *Scope and Method* lay in its becoming the standard text on economic method for the new Cambridge school led by Alfred Marshall. Its later drafts were composed at the same time as the later drafts of Marshall's *Principles of Economics* (1890), on which Keynes was commenting for Marshall while the latter was performing a similar critical service for *Scope and Method*. For the proponents of the new orthodoxy, the main contribution of Keynes's monograph was that it signalled the end of the methodological debates of the 1870s and 1880s, which had seemed to many, inside and outside the discipline, to call into question the scientific credentials of classical political economy.

It did so in three main ways: (1) by its lucid, judicious, low-key mode of exposition, deliberately occupying the middle ground in the methodological disputes and shifting the most controversial
arguments to appendices; (2) by redefining the hard scientific core of economic theory so as to insulate it from the charges of ideological bias, or immorality, or relativity, as well as from failures in practical economic policies; Keynes's threefold classification of economic enquiry claimed positive scientific status only for pure theory; the normative aspects and the policy aspects (the ethics and the art of political economy) constituted a protective belt which could absorb the attacks of historicists, socialists or nationalists, and so shift the doctrinal battle-ground away from fundamental principles; (3) by systematically minimizing the differences between the old economics and the new, by suggesting that the latter was a synthesis of the most fruitful of the conflicting views which characterized the period of methodological crisis and by stressing the continuity of economic ideas – so depicting a cumulative advance in economic knowledge analogous to the progressive improvements in knowledge claimed by researchers in the natural sciences.

In each of these ways, Neville Keynes successfully reflected the spirit of a new economic age, emergent not only in England but also in Europe and the USA, whose activists were bored with methodological argument and confident that they were in at the start of an exciting new research programme. At this point one might have expected the ambitious young academic to develop new research interests of his own in that programme.

The evidence of Keynes's diaries and letters leaves no doubt that he would have preferred to commit himself to political economy rather than logic, but the university's needs dictated otherwise. His appointment to a university lectureship coincided with Alfred Marshall's return to Cambridge as professor of political economy (and Mary Marshall's return as director of studies in economics at Newnham College), so that henceforth Keynes's opportunities to teach economics to Cambridge undergraduates were confined to an elementary course for Indian Civil Service candidates. One can thus date Keynes's loss of active interest in political economy from the completion of his *Scope and Method*. He was evidently bored by its long gestation, often depressed by Marshall's criticisms of successive draft chapters, but delighted with the flattering reviews or letters which its publication evoked from Marshall, Edgeworth, Palgrave, Taussig and Cossa, among other leading economists. Yet he made no attempt to embark on another book and was deaf to Edgeworth's pressing invitations to write for the new *Economic Journal* on topics outside the methodological field (though ready enough to rehash chunks of *Scope and Method* for Palgrave's *Dictionary*). Nor by then did he show any interest in being elected to an economics chair outside Cambridge, though in 1896 he seriously considered standing for the vacant registrarship in the University of London. The fact is that by the 1890s Keynes was fully committed elsewhere. His diaries show that he spent his working days trying to inject common sense into university politics (from the infighting on the Moral Sciences and Economics Boards to the perennial issue of women's degrees), while his leisure hours were absorbed in the ambitions and hobbies he shared with a lively, intelligent wife and three remarkable children – Maynard, Margaret and Geoffrey. These proved sufficiently demanding and fascinating concerns to distract him from the new economics which his colleagues (but not he) were then teaching in Cambridge.

Keynesian revolution

David Laidler
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The term ‘Keynesian Revolution’ suggests that Keynes's General Theory (1936) overthrew a defective and discredited classical orthodoxy and created a new understanding of how economies work. However, Keynes's critique of earlier work seriously misrepresented it, and his new system was, in fact, a synthesis of components drawn from it. Keynes's analysis nevertheless embodied an original and radical vision of how a monetary economy functions. The widespread adoption of the IS–LM interpretation of his system began a process of obscuring that vision, and economics has now largely lost sight of it.

Article

The words ‘Keynesian Revolution’ conjure up the story of how a new intellectual framework, created by John Maynard Keynes and set out in his General Theory of Employment, Interest and Money (1936), challenged and quickly replaced an old-established but discredited classical orthodoxy. The term, first popularized by Klein (1947), now has a permanent place in the vocabulary of economics, but this article follows Laidler (1999) (where references to relevant literature more extensive than space here permits are given) in suggesting that this revolution was fabricated, in two senses. First, Keynes to an extent invented the classical orthodoxy that he claimed to be overthrowing; but, second, he nevertheless constructed a radically new vision of how the economy functions, using components drawn
from his predecessors’ work. It then suggests that the ideas underlying Keynes’s revolution, always less influential than he intended, and currently barely recognized by economists, might nevertheless not be quite beyond revival.

**Keynesian influences on economics**

Economics saw enormous changes between the mid-1930s and the 1950s. To highlight only developments relevant to this essay, a new sub-discipline, *macroeconomics*, emerged; econometric modelling came into its own; and economic policy found a new anchor in the idea that ongoing government intervention in economic life can do more to promote economic and social well-being than the unregulated workings of the market. This whole apparatus is often labelled ‘Keynesian’, but to do so attributes too much to one man’s influence.

Keynes was a sharp though perceptive critic, rather than a pioneer, of econometric modelling (Patinkin, 1976). His main contribution to the area was indirect and posthumous, lying in the adoption of the IS–LM model, extracted by some of his followers from the *General Theory*, as the template around which were built the forecasting models which became ubiquitous among central banks and departments of finance throughout the non-socialist world from the 1950s onwards.

As to economic policy, governments had begun to abandon laissez-faire long before the First World War, and the experiences of the inter-war years hugely accelerated this process, quite independently of the influence of economics in general or of the *General Theory* in particular. The American New Deal was already well advanced before that book appeared; the famous Swedish model of a social-democratic mixed economy was mainly home-grown; and the government's major presence in the post-war British economy owed at least as much to the Fabian Society and William Beveridge as to Keynes. Even the use of fiscal and monetary policy for controlling the overall levels of economic activity and employment had many advocates before 1936, though the *General Theory* did significantly clarify the theoretical case for such macro-activism.

**Keynes’s intended revolution**

Even so, this clarification was incidental to the book’s purpose, which was, as its full title makes clear, to expound a *theory*, *general* in character, that would explain the determination of the level of *employment*, by referring to the roles played in economic life by the phenomena of *interest and money*. And, as Keynes told George Bernard Shaw in an oft-quoted letter dated 1 January 1935, he expected his book to ‘largely revolutionise … the way the world thinks about economic problems’.

The central tenet of Keynes’s intended revolution was that ‘A monetary economy … is essentially one in which changing ideas about the future are capable of influencing the quantity of employment and not merely its direction’ (1936, p. vii). By this Keynes meant that private investment decisions were heavily dependent upon expectations about the future profitability of the projects involved, and that, in a money economy, when those expectations varied, the result would be fluctuations in the level of employment. The outcome of similar shocks to a barter economy would be different: labour would simply be reallocated between the investment goods and consumption goods sectors.

*Say’s Law of Markets* (that no one offers to sell goods except with the intention of buying goods with the
proceeds, so that their general oversupply is impossible) guaranteed a barter economy against unemployment, apart from that generated by frictions as workers moved among sectors; and variations in the rate of interest would induce changes in saving to match those in investment no matter how large and irregular the latter might be.

But, Keynes argued, Say's Law did not hold in a monetary economy, because the monetary system itself could, and often would, prevent the rate of interest from playing its equilibrating role. Since the days of David Ricardo, his predecessors, with a few honourable heterodox exceptions, had been blind to this, and his contemporaries remained so. They routinely, albeit often unself-consciously, applied Say's Law to monetary economies characterized by large-scale unemployment, thereby blundering into fundamental analytic inconsistency.

Not only did Keynes claim to have identified a ubiquitous error in the dominant economic theory of the preceding century and a quarter, but in the *General Theory* he also showed how an alternative system that avoided it could explain the mass unemployment plaguing market economies, and inform the design of a new policy framework. The latter's salient feature would be a government that took responsibility for guiding long-term investment decisions – whether only their overall volume or also their make-up was left unclear – this being an activity that both Keynes's theorizing and recent economic experience suggested were beyond the capacity of the private sector. Keynes provided only a sketch of this new policy framework, but emphasized its compatibility with a liberal-democratic political order. Offered at a time when some important protagonists of economic and political liberalism, notably the Austrian school (Hayek, 1931; Robbins, 1934), were arguing that activist policy would only make the Great Depression worse, and when the apparent successes of the Soviet Union, Nazi Germany and Fascist Italy in conquering mass unemployment were tempting many in Britain, the United States, and elsewhere to embrace political totalitarianism as a necessary prerequisite for the conduct of effective economic policies, the political importance of Keynes's message is hard to overestimate. One cannot read Tarshis's (1987) first-hand account of his exposure to Keynes's radical and wide-ranging assault on received economic theory without sympathizing with the enormous excitement that it generated.

But such sympathy must be tempered by the knowledge that Keynes himself, perhaps inadvertently, presented a very particular and sometimes very inaccurate view of his *General Theory*’s place in the history of economics. He claimed to have overturned more than a century of economics and to be rebuilding the subject on new foundations, but it is more accurate to say that the *General Theory* first seriously misrepresented earlier work, and then selected from it components to be synthesized into what was, nevertheless, a strikingly original framework.

**Keynes on classical economics**

In the depressed period following the Napoleonic Wars, Ricardo had attacked Malthus's argument that too rapid a rate of capital accumulation had created a state of affairs in which the economy was no longer able to consume all that it was capable of producing. Deploying Say's Law, Ricardo had argued that a *general glut* of commodities, such as Malthus postulated, did not, indeed could not, exist. There was merely a temporary, though serious, mismatch between the compositions of output and demand as the economy continued to switch from wartime to peacetime patterns of production and consumption. Ricardo's logic initially carried the day, but it was soon subjected to an important qualification.
Specifically, John Stuart Mill (1844) pointed out that Say's Law, when applied to a money economy, ruled out only a general glut of everything including money, but left open the possibility that an oversupply of everything except money would appear at times when agents were trying to build up their stocks of the latter. Mill associated such behaviour with financial crises, and thought it would be short-lived, but as the 19th century progressed his insight became incorporated into accounts of the upper turning point of the business cycle.

There, in tandem with the hypothesis of nominal wage stickiness, it helped to provide a monetary explanation for the onset of cyclical unemployment which still found an influential expression among Keynes's contemporaries in the work of Ralph Hawtrey (for example, 1919). In Hawtrey's view, cyclical interactions of the supply and demand for money led to fluctuations in what he (like Malthus, and later Keynes) called effective demand – the rate of flow of money spending on goods and services in the aggregate – which would impinge upon income and employment to the extent that money wage and price stickiness prevented those fluctuations from being absorbed by movements in the general price level.

Keynes was thus wrong to assert (1936, p. 33) that Ricardo's version of Say's Law had for more than a century dominated an orthodox economics that had lost sight of the very concept of effective demand, and, as a corollary, he was also wrong to claim novelty for his own account of how cuts in money wages, and hence prices, might affect employment for the better through an indirect channel involving the interaction of the supply and demand for money (1936, p. 266).

These errors are arguably mere slips when viewed in the context of the General Theory's central claim that large-scale unemployment was not, after all, due to money-wage stickiness, but to fundamental problems posed by the nature of a monetary economy for the capacity of the rate of interest to coordinate saving and investment; but Keynes was by no means the first to explore the latter issues either. From Wicksell (1898) onwards, increasing attention was paid to the influence of the rate of interest set by the central bank on saving and investment decisions, and to its capacity to disrupt their coordination by the capital market. Swedish, Austrian and British economists (for example, Myrdal, 1931; Hayek, 1931; Robertson, 1926) all investigated ways in which monetary mechanisms might create fluctuations in output and employment, albeit none of them with complete success.

Keynes's contribution, then, was not to emphasize that monetary factors could disrupt the smooth allocation of resources over time, but to show precisely how they might do so, what the consequences would be, and how economic institutions could be adapted to cope with such problems. Before the General Theory there was no coherent and widely accepted analytic framework in terms of which these issues could be discussed, but after it there was.

**Keynes's new framework**

That framework had three major components: a theory emphasizing the role of expectations in driving investment decisions, a theory of the demand for money that explained why the rate of interest could not be relied on to coordinate these with saving decisions, and a theory of saving–consumption behaviour that implied a self-limiting multiplier process. Each already existed before 1936, but they had not been brought together. When they were, output and employment variations were revealed to be what equilibrated saving and investment when, as would happen in a monetary economy, the interest rate
failed to do so.

Keynes called the central concept of his theory of investment the *marginal efficiency of capital*, the rate of discount that would equate the present value of the profits expected from a unit of investment to the cost of producing the capital equipment involved. Forward-looking maximizing firms would push the flow of investment to the point at which this rate of return was just equal to the rate of interest at which the expenditure was to be financed.

There was nothing revolutionary in this concept, which Keynes acknowledged to be essentially identical to Irving Fisher's (1907) *rate of return over cost*, but his views on the relationship between profit expectations and the real productivity of investment that, in Fisher's analysis, underlay them, were less conventional. For Keynes, this connection was essentially non-existent: the passage of time was a fundamental fact of economic life, and the future was simply too uncertain for calculations of productivity to be made in a rational fashion. Profit expectations therefore were inevitably driven by the essentially irrational *animal spirits* of investors. When these were high or low, so would be the marginal efficiency of capital.

Though arguably radical, this idea was not particularly new. It restated, using a new vocabulary, the view of other Cambridge economists – not least the ‘classical’ *bête noire* of the *General Theory*, A. C. Pigou (for example, 1927) – that investment decisions were largely driven by contagious and cumulative waves of errors of optimism or pessimism on the part of businessmen. Keynes's account of how the development of stock markets had deepened the wedge between long-run economic fundamentals and the short-term and ill-informed expectations on which investment decisions were actually based was also foreshadowed in earlier Cambridge work.

So too was his treatment of money-holding behaviour. Cambridge monetary analysis had been conducted since the 1870s in stock supply and demand terms, with demand being driven by money's role as the economy's means of exchange. In 1921 Keynes's former student Frederick Lavington had extended this analysis to an economy characterized by sophisticated financial markets. Here, he noted, money had the particular virtue of being always readily tradable at a market value that was subject to less uncertainty than that of other assets. Lavington concluded that, while remaining its means of exchange, money would also serve as a store of value in such an economy, providing a hedge against the uncertainty inherent in its financial markets.

Keynes himself considerably elaborated this idea in his *Treatise on Money* (1930), and under the label *liquidity preference*, it in due course appeared in the *General Theory*, where it provided a rationale for the incapacity of the rate of interest to maintain equilibrium between saving and investment. Holding money to obtain security against financial market uncertainty involved forgoing the interest yielded by alternative assets. In a monetary economy, then, interest was the price of liquidity, and its performance of this, its major role, would sometimes fatally interfere with its capacity to coordinate the allocation of resources over time.

When animal spirits were up and expectations optimistic, to be sure, financial market uncertainty would be a minor matter, liquidity preference would be both weak and relatively insensitive to the rate of interest, and these considerations would not be crucial to the economy's functioning. But when animal spirits and expectations were depressed they would be. Under these circumstances, which Keynes believed to be chronic in the market economies of the 1930s, the marginal efficiency of capital would be low and a low rate of interest would be needed to match it; but liquidity preference would simultaneously be strong with only very small movements in the interest rate being needed to induce
large changes in money holding.
The very nature of a modern monetary economy thus inhibited the interest rate's accommodating itself to a depressed marginal efficiency of capital, and such an economy could, and very likely would, settle into an equilibrium characterized by large-scale unemployment. This final implication was established by the logic of the multiplier relationship, which Keynes took over, not from earlier theoretical work, but from a much more practical literature dealing with the use of public works expenditures to fight unemployment.

Long before the First World War it had been recognized that prosperity and depression in one sector of the economy could spill over into others, and this idea helped establish the desirability of using public expenditure to put the unemployed to work. Sometimes, however, the implications here seemed too good to be true: if spending geared to employing previously unemployed workers would generate further expenditures on their part that would then put others to work, and so on, what was there to stop one small injection of public expenditure eliminating any level of unemployment?

A satisfactory answer to this awkward question was finally provided in 1931 by Keynes's student Richard Kahn: there would be some leakage of expenditure at each round in the process, and each successive increment to employment would be smaller than its predecessor. The effects of public expenditure on employment would be multiplied beyond their immediate impact, to be sure, but not infinitely so. They would converge to a limit that would be smaller the greater the size of the aforementioned leakages.

The Danish economist Jens Warming (1932) then offered a crucial modification to this analysis. Instead of applying it to employment, he applied it to output, and hence real income; and instead of invoking a number of possible leakages from the circular flow of expenditure as Kahn had done, he emphasized one, namely, saving. Postulating in his illustrative numerical example that consumers would spend 75 per cent of each increment to their income and save the balance, Warming showed that a given injection of public expenditure would generate a fourfold increase in national income.

Warming's version of the multiplier was incorporated in the *General Theory*, though only Kahn was cited there. In Keynes's hands, however, the stable fraction spent out of any increment to income – still 75 per cent in his own numerical example – became the marginal propensity to consume, the embodiment of a 'fundamental psychological law' of consumer behaviour, and the multiplier itself elucidated not merely the practical consequences of public works expenditures, but the fundamental theoretical links between investment and the economy's overall level of effective demand – consumption plus investment – and hence output and employment. When the rate of interest was unable to offset fluctuations in the marginal efficiency of capital because of its role as the price of liquidity, the multiplier would ensure that output and employment moved so that savings matched investment. Hence it lay at the very heart of Keynes's revolutionary message that, ‘a monetary economy … is essentially one in which changing views about the future are capable of influencing the quantity of employment…’ (1936, p. vii).

**IS–LM and after**

By the 1950s, what was still called Keynesian economics had largely lost track of this message. In part, this was because the Second World War and its aftermath had seen the restoration of high employment as the economy's apparently normal state of affairs, but more importantly it was the consequence of the
way in which Keynes himself had developed his results. Before 1936, many economists had paid attention to expectations and their evolution over time, but available analytic techniques were not up to tackling such problems, and their efforts, though sometime yielding valuable insights along the way, routinely ground to a halt in confusing, not to say confused, complexity. The critical step enabling Keynes to tell an analytically tractable story where others had failed was to treat expectations as exogenous to the mechanisms he analysed, and this simplification also made it possible for others to extract a formal comparative-static model from the General Theory that could be expressed either in simple algebra or in equally simple geometry.

This, the IS–LM (investment equals saving – liquidity preference equals the supply of money) model, was, in its simplest form, a set of simultaneous equations that linked consumption to income, investment to the rate of interest, and the demand for money to income and the rate of interest, and characterized the money stock as exogenous. These components were all to be found in the pages of the General Theory, and the IS–LM system could also be manipulated to demonstrate some of that book's central conclusions – for example, about how a fall in the rate of investment spending at any level of the rate of interest would put downward pressure on the equilibrium values of output as well as the rate of interest, and about how a high degree of interest sensitivity on the part of the demand for money would force more of this adjustment onto income. It was, furthermore, easily extended to accommodate analyses of monetary and fiscal policy. All of this gave IS–LM a strong claim to be a legitimate representation of Keynesian economics, as Alvin Hansen (1953), its most influential exponent, would in due course claim. By and large, this is how it came to be treated, despite the protests of some who had been close to Keynes when he had tried set his revolution in motion, not least his younger Cambridge colleague Joan Robinson, who memorably characterised IS–LM as ‘bastard Keynesianism’.

It is not necessary to take sides in this debate here. It will suffice to note that IS–LM proved remarkably flexible. In the 1960s it accommodated versions of not just Keynesian but also monetarist doctrine, and provided a framework in which some of the issues separating them could be debated. Hence it dominated both research and teaching within macroeconomics for close to two decades; but its dominance came at a cost (Backhouse and Laidler, 2004). In particular, under this model's influence macroeconomics lost sight of the importance of time in economic life. Ideas, including those that had lain at the heart of Keynes's intended revolution, about the crucial role played by expectations and uncertainty in inter-temporal coordination mechanisms, and the essential differences between the ways in which money and barter economies coped with such matters, were pushed into the background. They have never quite disappeared, however. For example, Axel Leijonhufvud's (1968) restatement of Keynes's economics attracted much attention. So did his suggestion that Keynes had been forced by his analytic framework to treat as equilibria the disequilibria that coordination failures in fact created, though his suggestion that a new and explicitly disequilibrium dynamic economics be built on Keynesian foundations was not taken up. Instead, in the 1970s economists in large numbers embraced analytically more tractable New Classical analysis, built on the principle that markets are continuously in equilibrium.

This technically convenient clearing-markets assumption in fact had huge substantive significance, implying the total irrelevance of Mill's (1844) critique of the application of Say's Law to a monetary economy, and all that had followed from it. When Lucas and Sargent (1978) announced the demise of Keynesian economics, therefore, more than activist policies supported by macroeconometrics was under
attack. The discipline's very comprehension that a monetary economy might suffer coordination failures, let alone Keynes's specific analysis of these issues, already weakened by IS–LM, was threatened. It is just as well, then, that the New Classical revolution, like its Keynesian forerunner, has been less than totally successful, perhaps leaving room for these old problems to be debated once more.

Keynesianism

Roger E. Backhouse and Bradley W. Bateman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In the post-war years, Keynesianism became the label for the mixed economy, for an approach to fiscal policy that entailed fine-tuning the economy, and for the revolution in economic theory that brought macroeconomic analysis to the fore. This article debunks many of the myths that grew up around Keynes's legacy by examining his attitude to fiscal and monetary policy over the course of his career. By differentiating what Keynes said from what his followers and his critics said after his death, it is possible to understand the broad switch to demand management during the 20th century in a clearer light.

Article

Keynesianism has many meanings. It is the label for the political philosophy that dominated most Western countries in the 30 years after the Second World War, embracing a mixed economy and the welfare state, steering a course between what were believed to be the dead hand of socialism and the social injustices of free-market capitalism. Keynesianism is also used to refer to something narrower: to the use of macroeconomic policy to stabilize the economy and to maintain low levels of unemployment. In this usage, Keynesianism is associated with fine-tuning the level of government spending and taxation so as to use variations in the budget deficit to counteract shocks that would otherwise cause high
unemployment. Beneath all of these meanings, of course, lies Keynesian economic theory, which provides the theoretical foundation for these policies. (For further discussions of Keynes, Keynesianism, and the Keynesian Revolution, see Backhouse and Bateman, 2006.)

According to popular mythology there are clear historical links between these various meanings of Keynesianism. This mythology comprises the claim that Keynes's *General Theory* (1936) provided the basis for a new economics, marking a revolutionary break with previous orthodoxy, justifying the use of debt-financed government budget deficits to stimulate the economy and cure unemployment. Governments turned to Keynes to provide a way out of the Great Depression and to justify maintaining high levels of demand after the Second World War. In doing this they ensured that mass unemployment would not recur, thereby making possible the development of the welfare state. However, this policy had two unintended effects. It undermined an unwritten fiscal constitution, according to which governments would normally balance their budgets, except in wartime. Also, by removing the fear of unemployment, it undermined the willingness of workers to restrain their wage demands. The combination of budget deficits and high wage demands eventually caused the stagflation of the 1970s, thereby bringing about the demise of Keynesianism.

Fortunately for Keynes's reputation, modern scholarship has shown that most of the claims on which this account is based are mythical. Things simply did not happen this way. As the Keynesian Revolution in economic theory is discussed elsewhere in this dictionary, the focus here is on Keynesianism as economic policy and political philosophy. We start by showing how ‘Keynesian’ ideas actually entered policy, in many cases before 1936, the year that Keynes's *General Theory* was published. From there we outline Keynes's own views on fiscal policy, differentiating them from what came to be known as Keynesianism. In conclusion, we suggest that Keynesianism in economic policy is more alive than is often assumed.

**The spread of Keynesianism**

In a path-breaking comparative study, *The Political Power of Economic Ideas: Keynesianism Across Nations* (1989, p. 367), Peter Hall was surprised to discover ‘the degree to which Keynes's ideas about demand management were resisted or ignored in many nations’. Demand management was adopted in many countries, but often without reference to Keynes's ideas. The United States provides an excellent example. President Franklin Delano Roosevelt, in his 1932 and 1936 election campaigns, ran on the promise of balancing the budget. In his first administration he managed to limit deficits to what was spent on relief projects. It was only in his second term, as the economy slid into recession again in 1937, that Roosevelt submitted a budget that was purposely in deficit to stimulate the economy. He did this, not because he was influenced by Keynes, but because other options to raise prices and stimulate recovery had failed. Attempts to buy up gold had raised the price of gold but not prices of basic commodities. The National Industrial Recovery Act had been declared unconstitutional. The idea of running a deficit came from a group of economists (Laughlin Currie, Leon Henderson and Isador Lubin), recruited by Harry Hopkins, a New Deal administrator about to become Secretary of Commerce. They noted that the fortunes of the economy in 1936–7 had exactly mirrored the change in the government's fiscal position, caused by the ending of the First World War Veterans’ bonus and the imposition of taxes to support the new Social Security system. It was this evidence, not Keynesian theory, that was used to make the case for fiscal stimulus. Though young Keynesian economists did
eventually enter the government, the initial arguments for using fiscal policy to stimulate the economy were without reference to or influence from Keynes. Herbert Stein (1969, p. 131) thus went so far as to say, ‘it is possible to describe the evolution of fiscal policy in America up to 1940 without reference to him [Keynes]’.

In Germany and France, too, deficits came independently of Keynesian ideas. In Germany, the formation of a democratic government in the economic chaos that followed the First World War meant satisfying various interest groups, which implied deficits: businesses demanded tax cuts and workers and farmers demanded higher spending. Deficit spending was the ‘social cement’ (James, 1989, p. 234). In France, the General Theory was not translated until 1942, and few people at this time read it in English. Britain and Canada, where Keynes and young Keynesians were involved in government, were exceptional cases. However, even in Britain the precise nature of Keynes’s influence is far from clear (Peden, 1988; 2006). His influence was clearest in the 1941 budget, which he believed marked a revolution in public finance; but his ideas about balancing aggregate supply and demand were used to control inflation, not to ensure full employment. In general there was considerable resistance to Keynes's ideas, often on grounds of administrative practicality. Even after the Second World War, it has been argued that Keynesian ideas were not applied till 1947, and then, as in 1941, to control inflation. Furthermore, though demand management was certainly in vogue after that, high employment was not achieved by running government deficits. If deficits are calculated on a traditional Gladstonian basis, excluding separately funded capital expenditure from the budget, the British government ran a surplus in every year from 1948 to 1972 (with the possible exception of 1965; see Clarke, 1998, pp. 210–11). Even if the result was sometimes an overall deficit, this hardly justifies the charges of profligacy and undermining an implicit fiscal constitution levelled by critics such as Buchanan and Wagner. And this was the country in which Keynes's influence was strongest.

The early arguments for counter-cyclical fiscal policy were independent of Keynes. They were what Hall (1989) described as ‘proto-Keynesianism’ – Keynesianism without the theoretical foundations provided by Keynes's General Theory. However, during the 1940s Keynes's name eventually came to be attached to such policies. One reason for this was simply that Keynes's model of aggregate demand was the most advanced economic theory at the time and it could easily be used to provide an ex post imprimatur to a change that was already under way. Keynesian economic theory, combined with national accounts constructed along Keynesian lines, provided a common language in which economists, in government and outside, could talk about macroeconomic problems. The combination of mathematical economic theory and statistical data analysis opened up an apparent gulf with pre-Keynesian work on money and the cycle. The credibility of this new economics, comprising Keynesian theory and counter-cyclical policy, was given an enormous boost from the apparent success of wartime demand management: Walter Salant (1989, pp. 45–6) has claimed that ‘The elimination of unemployment during World War II was one of the greatest influences on post-war views about the role of government in attaining and maintaining high employment’. It has, however, been argued that this was based on a misperception, in that the war economy in the United States was an example of a successful command and control economy, not successful demand management (Higgs, 1992).

The association of Keynes with counter-cyclical policy was actively fostered by Keynes's disciples, Alvin Hansen and young Keynesians in Britain and the United States, James Meade, Joan Robinson, Abba Lerner, Paul Samuelson and Walter Salant. Lerner's The Economics of Control (1944), ironically a
Ph.D. thesis supervised by Friedrich Hayek, then still at the London School of Economics, used Keynesian theory to advocate a high degree of fiscal fine tuning. In *A Guide to Keynes* (1953), Hansen wove together an exposition of Keynesian economic theory with his own policy recommendations on deficit spending, creating an indelible link between the two.

**Keynes and Keynesianism**

Though Keynes's views on economic policy were famously fluid, there was little change in his views on deficit spending. From the late 1920s till his death, he supported using public works projects to stimulate aggregate demand at appropriate points in the cycle. However, this did not imply support for government deficits. New housing or investment in the transport infrastructure were capital projects that would generate revenue streams capable of paying back any money that had been borrowed to finance their construction. Such spending would therefore appear on the capital budget, meaning that it would not affect the government's regular budget or the government's deficit. Keynes's opposition to funding such projects through the government budget, partly on the grounds that it might frighten businessmen, was strong enough for him to argue, from 1924, for the creation of a separate capital budget into which such funding could be placed. He also argued that payments to the sinking fund (the fund destined to repay the national debt) could be diverted into the capital budget, obviating the need to raise any new funds to undertake public works projects. A major part of Keynes's battles with the Treasury, therefore, was to argue for new accounting procedures so that such projects could be undertaken without unbalancing the budget.

Keynes continued his opposition to budget deficits to the end of his life. In working on the White Paper on full employment (Great Britain: Ministry of Reconstruction, 1944 – a set of proposals published by the government as the basis for legislation) and the National Debt Inquiry (Keynes, 1945), he insisted repeatedly that he was not arguing for deficits in the ordinary budget. Historians have even taken the failure to separate the capital and ordinary budgets in the White Paper as evidence on Keynes's limited impact on Treasury thinking at this time, so closely was he associated with the idea. He also argued against the young Keynesians, who were advocating the adjustment of social security taxes to regulate demand.

In these decades, Keynes's emphasis was on increasing investment, not consumption. Public investment might be increased directly, and private investment could be increased through a policy of cheap money. In the *General Theory* he argued that interest rates should be kept low, and maintained that view for the next ten years of his life. Nowhere did he support the view, commonly associated with Keynesianism, that monetary policy was ineffective.

Neither was Keynes especially enthusiastic about the welfare state. William Beveridge was the person who championed the development of Britain's post-war welfare state, and Keynes was never a close collaborator with Beveridge in this work. Keynes did look at several drafts of Beveridge's draft reports as a Treasury official, and he once wrote to Beveridge praising the plans. The fact remains, however, that his work within the wartime government on the implementation of the Beveridge plan consisted largely of efforts to trim the size of Beveridge's plan, limit child payments so that they did not cover the first-born in any family, and to delay implementation of the plan. For Keynes, the most important issue was policy to ensure full employment, and he never linked that objective directly to the welfare state in his own writing.
How, then, did Keynesian economics come to be associated with policies that Keynes clearly rejected throughout his life, such as the fiscal fine tuning of Lerner's ‘functional finance’? The answer is that his ideas came to be seen through the work of the young Keynesians, who claimed Keynes's imprimatur for their ideas. Lerner (1936, p. 435), in his review of the *General Theory*, wrote ‘this article has been read in manuscript by Mr. Keynes himself, who has expressed his approval of it’. Though this article was about model building, not policy, Lerner subsequently wrote as if Keynes's approval extended to all his work. Hansen, too, wove his interpretation of Keynesian economics together with his own policy recommendations on deficit spending. As a staple of undergraduate and graduate education in the 1950s and 1960s, this helped create the view that Keynes supported deficit spending (despite a caveat that Keynes had not endorsed such policies hidden away towards the end of Hansen's book). In Britain, young Keynesians such as James Meade had the advantage that they had actually worked with Keynes: even though they had disagreed on some policy recommendations, this personal link meant that their ideas came quickly to be associated with Keynes. Keynesianism became the policies of the Keynesians, not of Keynes himself.

Blame for the mislabelling of what came to be known as ‘Keynesian’ policies also rests with Keynes's critics. In the same way that supporters of using counter-cyclical policy to maintain a high level of aggregate demand wanted to claim Keynes's authority for their ideas, critics wanted to make the same identification, to give more significance to their own attacks on such ideas: had it been known that Keynes himself was critical of these policies, questions would have been raised concerning whether there were alternative policies to those being proposed. While Keynes was alive, Hayek was well aware of the differences between Keynes's own views and those of the young Keynesians; he recalled having a conversation in which Keynes agreed with him when he complained about the dangerous things that the young Keynesians were saying on Keynes's behalf (Hayek, 1995, p. 232). Yet, after Keynes's death, and in particular in the 1970s when he returned to writing about money and inflation after a decades doing other things, he too spoke of Keynesianism as though it reflected the ideas of Keynes. Buchanan and Wagner were even more explicit, in their *Democracy in Deficit: The Political Legacy of Lord Keynes* (1977), in claiming that it was Keynes who had called forth a world of ever-increasing budget deficits, never pointing out that Keynes was avowedly hostile to this idea (for an assessment of this view, see Bateman, 2005).

At the level of economic theory, Keynesian economics came to be associated with a theory that led to conclusions that were different from those advocated by Keynes himself. Within a year of the *General Theory*’s appearance, economists began reformulating its ideas as a simple two or three simultaneous equation system that eventually became known as the IS–LM model. This model was then given more formal microfoundations and seen as a miniature general equilibrium model. As with Lerner's review of his book, Keynes was willing to encourage such models, writing positively to Roy Harrod and John Hicks about their early papers that provided the initial foundation for the IS–LM model. However, while these models captured something of what Keynes was doing, there was much in the *General Theory* that they left out, and as a result the theory became simplified. The theory became shorn of many of the elements that related most closely to time, resulting in a static model in which the only mechanism that would ensure the economy did not return to full employment was inflexibility of the money wage rate (see Backhouse and Laidler, 2004). For example, Keynes’s dynamic arguments about how wage cuts might have perverse effects through causing expectations of future wages to change were ignored. Keynesian economics thus came to be seen as ‘the economics of sticky wages’, even though Keynes had
written the *General Theory* to combat the view that this was the cause of the depression. This theoretical reinterpretation probably happened because of another change that took place after the Second World War: economists began conducting their arguments in terms of mathematical models (either algebraic or geometric). Ideas, even if they were important to Keynes, that could not be forced into a model were forgotten. This reinterpretation of Keynesian theory tied in with the emerging Keynesianism in economic policy in that in these models, which analysed the determinants of a homogeneous aggregate output, the distinction between current and capital expenditure played a minor role. Government spending, in most models, was equated with current expenditure, and investment was seen as a private sector activity. These assumptions were largely unquestioned, at least in the mainstream of the discipline, until Axel Leijonhufvud's *On Keynesian Economics and the Economics of Keynes* (1968). This argued explicitly that Keynesian economics was very different from the economics of Keynes: Keynes's followers had come to the conclusion that Keynesian economics was a special case of the more general classical theory only because they had misrepresented his ideas.

**Are we all Keynesians now?**

In the 1970s governments moved away from Keynesianism, as the term had by then come to be understood. This parallels developments in economic theory, and had much to do with the apparent breakdown of the Phillips curve, and the failure of Keynesianism, as it was then understood, to provide guidance appropriate to a time of stagflation. However, governments were mainly moving away from doctrines that were associated with Keynes's followers, not with Keynes himself. Fiscal fine tuning to maintain full employment was abandoned in favour of focusing on money and inflation. Paradoxically, in Britain at least, it was only in the 1970s that the government began to run budget deficits (defined in the Gladstonian manner), perhaps because of its policy of drastically cutting public investment. Keynesianism appeared dead. And yet, as governments learned about the problems with using monetary targets, there was a move, by the end of the century, towards policies that were much more in line with what Keynes himself had advocated. Interest rates were kept as low as was consistent with reasonably stable prices (a slightly positive interest rate). Monetary policy, not fiscal policy, came to be seen as central to stabilizing the economy. There is much here that is not in Keynes – hardly surprising given the changes that took place during the preceding 60 years – but he would probably have had much sympathy with the broad framework of policy: targeting domestic prices, creating the conditions for high levels of investment, and perhaps even limiting the role of the welfare state. There were parallels in economic theory, where Keynesianism came to be used to refer to those who believed various market frictions opened up a role for activist policy. Perhaps the abandoning of ‘Keynesian’ political philosophy was what paved the way for implementing some of the ideas that were important to Keynes.

International economist and economic historian of the late 20th century, Charles Kindleberger was an astute observer of the world around him and a master prose stylist. His most influential works made the case for irrationality in capital markets and the need for a lender of last resort to minimize the damage from bubbles and mania. His work was narrative rather than abstract, but no less convincing for that. His most famous book is *Manias, Panics and Crashes*.

**Article**

Charles P. Kindleberger was born in New York City. He received his B.A. at the University of Pennsylvania in 1932 and his Ph.D. at Columbia University in 1937. He had a distinguished career in public service (including the Federal Reserve and the Office of Strategic Services during the Second World War) before going to teach international trade at MIT. His wartime experiences directed his interests towards the interaction of countries and gave him a keen sense of how academic ideas play out among real people and governments. His scholarship was characterized by its realism and willingness to consider actual – as opposed to idealized – behaviour.

Kindleberger made his mark on the field of international trade through his textbook and through papers and books about the recovery of Europe after the Second World War. He was active in the analysis of the dollar scarcity and then the dollar glut that characterized the short life of the Bretton Woods System. He also wrote a prescient book, *Europe's Postwar Growth: The Role of Labor Supply* (1967), on the role of immigrants and guest workers from eastern and southern Europe in alleviating the labour scarcity of western Europe. Kindleberger's emphasis on the evolution of labour supply has been echoed in many subsequent studies. The legacy of these post-war policies has been evident in political and economic conflict between the children and even grandchildren of these immigrants and other residents. As
Kindleberger said (1967, p. 213), the short-run benefits of labour migration are clear, but there are dangers in the long run: ‘To rely heavily on foreign labor in one’s economy constitutes a positive risk.’ Kindleberger made his entry into economic history with *Economic Growth in France and Britain, 1851–1950* (1964). He surveyed the extensive literature on these two countries and concluded that there was no single convincing explanation for the differences between them. He ended the book with the following famous words: ‘Economic history, like all history, is absorbing, beguiling, great fun. But, for scientific problems, can it be taken seriously?’ This ironic comment set the tone for Kindleberger’s future work in economic history. His books and papers are distinguished by his command of the previous literature. His reasoning is informed by an intelligent, if sceptical, use of economic theory. His prose is sprightly. And his conclusions are clear, forcefully presented, and always worth debating. Kindleberger’s impact on economics and economic history comes primarily from two books first published in the 1970s. The first, *The World in Depression, 1929–1939* (1973), provided a comprehensive narrative of the Great Depression from an international perspective. Instead of seeing the Depression as a succession of national stories, Kindleberger argued persuasively that it was the result of a failure of the international economic system. The economic structure built around the gold standard had allowed the pre-war industrial economies to weather various economic shocks in the late 19th and early 20th centuries, but it proved unable to contain or offset the shocks arising in the period after the First World War.

Why so? Kindleberger argued that the inter-war economy lacked a hegemon, a dominant leader. The hegemonic power in the pre-war period was the United Kingdom, more specifically the Bank of England, which acted to contain crises wherever they started. But England was exhausted by the effort to defeat Germany in the First World War, and the Bank of England was in no shape to continue this role. Although the United States was the obvious candidate to pick up the baton, Americans were isolationist after their wartime efforts and declined to act. In the shortest summary: no longer London, not yet New York. Without a hegemon, the shocks to the world economy in the late 1920s were allowed to drag the world into the Great Depression.

The costs of encouraging immigration of foreign workers after the Second World War emerged only slowly; the costs of poor macroeconomic policies in the early 1930s became evident more quickly. Kindleberger recounted the abortive efforts of central bankers and government officials to organize some kind of cooperative solution to the economic shocks. Failing in this endeavour, the world was subjected to competing devaluations and deflations. Among the costs was extensive damage to financial institutions and to the operation of those economies that held on to the gold standard.

Kindleberger generalized his argument in *Manias, Panics, and Crashes: A History of Financial Crises* (1978). He surveyed financial crises in the past two centuries that were important enough to have macroeconomic effects. He described the various irrationalities that preceded crises, as suggested in his title, and synthesized a vast literature in a small and engaging book. He argued that irrationally optimistic expectations frequently emerge among investors in the late stages of major economic booms, differing sharply from most modern models of finance and relying on a more impressionistic theory of financial crises. When these optimistic expectations appear, investors grossly overestimate the future profitability of some promising firms. These overestimates lead unscrupulous managers to over-promote their firms vigorously and to issue bogus debt and equity with abandon. They may lead even well-meaning, sober managers to issue unsupportable amounts of debt. The more a firm’s managers sincerely overestimate their firm’s growth opportunities or successfully promote a Ponzi-style fraud, the more
securities they try to issue. When the unrealistically high profits fail to develop as predicted, debt and stock values collapse. Markets for over-promoted financial assets may even dry up. The more severe the price decline, the more the collapsing value of previously high-flying assets spreads insolvency to creditors of both the over-expanded firms and their stockholders.

Kindleberger observed that speculation in a bubble often develops in two stages. In the first, sober stage of investment, seasoned professional investors and analysts are gradually persuaded that bubble assets offer a good chance of high returns. In the second stage, ‘professional company promoters – many of them rogues interested only in quick profits – tempted a different class of investors, including ladies and clergymen’. It is of course hard for any market participant or observer to know when the bubble has progressed from the first stage to the second.

Kindleberger concluded that stability is promoted when a lender of last resort exists and follows the recommendations of Walter Bagehot over a century ago in his *Lombard Street* (1873) to lend freely at punitive rates during a crisis. This is what a hegemonic power – the United States government internationally and the Federal Reserve domestically – should have done in the 1930s, in Kindleberger’s view; it is what the International Monetary Fund should do today. His book has proved exceedingly popular with a varied audience: economists, investors and the general public alike. It was revised and expanded several times; the fourth edition was published shortly before Kindleberger’s death, when he was 90 years old.

King, Gregory (1648–1712)

Phyllis Deane
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Davenant, C.; demand analysis; Gregory King’s Law; King, G.; national income accounting; population estimation

Article

King was born in Lichfield in 1648, the son of a jobbing technician who had acquired a sufficient practical competence in mathematics to earn a modest livelihood practising as a surveyor, a sundial maker, a landscape gardener and even a teacher of bookkeeping. King himself, according to his autobiography, was educated partly at the local Free School and partly at home (for example, in bookkeeping and surveying) until he became clerk to Sir William Dugdale, then Norray King of Arms, whom he served for five years. This appointment set the course of his professional career as a herald, though he was to work for several years in London as a cartographer and engraver before being appointed Rouge Dragon in 1677, Registrar to the College of Arms in 1684 and eventually Lancaster Herald in 1688. After the accession of Queen Anne, when King’s Tory bias ceased to be an obstacle to advancement in the public service, he held several appointments of an accounting nature, for example the secretarship of the Commission of Public Accounts and secretary to the Controller of Army Accounts.

It was in the mid-1690s that King began to take an active interest in political arithmetic, or what contemporaries called ‘the art of reasoning upon things relating to government’, mainly as a result of his friendship with Charles Davenant, who was then playing a major role in the current debate on how to pay for the war. Davenant's Essay upon Ways and Means of Supplying the War appeared in print in 1695 and in the following year King wrote his Natural and Politicall Observations and Conclusions upon the State and Condition of England, the work that established him as the leading political arithmetician of his day. Henceforth, he and Davenant, a prolific pamphleteer, systematically exchanged ideas and statistical estimates on the main policy issues facing government, and King owed his considerable early 18th-century reputation largely to the polemical use Davenant made of his estimates. Indeed, King’s most famous pamphlet was not published in full until 1802, when George Chalmers printed it as an
appendix to his bestseller, *An Estimate of the Comparative Strength of Great Britain During the Present and Four Preceding Reigns*, which had already gone through several editions. It then directly inspired Patrick Colquhoun to produce a comparable estimate of social income, first for England and Wales in *Treatise on Indigence* (1803) and later for the United Kingdom as a whole in *Treatise on the Wealth Power and Resources of the British Empire* (1812). Much later still, in 1936, King's *Observations* was published again, this time together with his only other tract, *Of the Naval Trade of England 1688 and the National Profit Arising Thereby* (MS dated 1697), and with an introduction by the Professor of Statistics at The Johns Hopkins University. His estimates then acquired fresh importance as part of the evidence used by the growing army of mid-20th-century economic statisticians researching long-term trends in population and national income.

Gregory King's claim to fame as a demographer and a national income statistician rests on the imaginative skill, methodical consistency and intellectual integrity with which he compiled and applied the severely limited statistical raw material available to him. His deep respect for the truth and his readiness to respond fully and frankly to those of his contemporaries who doubted the validity of his estimates is exemplary and illuminating. Modern statisticians may argue with his results, but they cannot fail to take them seriously as informed estimates of the dimensions of population, national income and national capital of England at the end of the 17th century and of immediate past trends in those dimensions. Similarly, modern social historians may query the details of social structure implicit in King's oft-reprinted ‘Scheme of the Income and Expence of the several Families of England Calculated for the year 1688’, but the overall picture it presents and the notion of distinguishing between those groups which he conceived of as ‘increasing the wealth of the kingdom’ and those decreasing it, remains a pioneering and instructive analytical device.

The other field to which King is generally believed to have made an original pioneer contribution as an economic statistician is that of demand analysis. The law which is generally referred to as ‘Gregory King's Law’ postulates a systematic relationship between downward deviations from the normal corn harvest and upward deviations in the price of corn. It was attributed to King by Lauderdale in 1804 (though not by Davenant, who first spelt it out with the aid of a numerical example in 1699) and, among others, by Tooke in his *History of Prices*. Jevons estimated the equation implicit in the Davenant exposition in his *Theory of Political Economy* (1871) and so did G. Udny Yule in 1915. Whether it really did originate with King has not yet been established, but the attribution to him rather than to Davenant is highly plausible.

kinked demand curve

V. Bhaskar
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The kinked demand curve, one of the staples of oligopoly theory, was originally formulated as a theory of price rigidity. We review dynamic game-theoretic reformulations, which give rise to a theory of collusive price determination.

Keywords

Bertrand competition; collusion; Cournot competition; duopoly; folk theorem; kinked demand curve; Markov perfect equilibria; oligopoly; price rigidity; quick response equilibria; repeated games

Article

The kinked demand curve (Sweezy, 1939; Hall and Hitch, 1939) has been one of the staples of oligopoly theory. It was originally formulated as a theory of price rigidity. A firm conjectures that its rivals will match its price if it reduces the price, but will not match its price if it initiates a price increase. This gives rise to a kink in the firm's perceived demand curve, at the prevailing price. The consequent discontinuity in its marginal revenue curve implies that the firm will not adjust its price in response to small changes in costs, giving rise to price rigidity.

In contrast with the standard Cournot or Bertrand models, the theory represents one of the first attempts at a dynamic model of oligopoly. However, this modelling has been criticized. Implicit in the analysis is the assumption that the firm is motivated by its profits after all price adjustments have taken place. That is, profits in the time interval, where a firm has cut its price and before its rivals have responded, are insignificant. However, if this is so, why does a firm in a symmetric oligopoly not initiate a price increase? If its rivals fail to respond in kind, it can rescind the original increase. Knowing this, its rivals would have an incentive to match its price increase, as long as the original price was below the monopoly price.

To address these questions, one needs to formulate oligopolistic interaction as an explicit dynamic game.
The first option is the standard repeated game model, where one obtains an embarrassment of riches –
the ‘folk theorem’ states that every individually rational feasible payoff is an equilibrium payoff, as long
as firms are sufficiently patient. (Anderson, 1988, provides a foundation for the kinked demand curve in
terms of ‘quick response equilibria’ of a repeated game, where the period length shrinks to zero.)
Second, one can model price setting as a dynamic ‘pre-game’ with profits depending only on the profile
of final prices that results. This is the modelling choice adopted by Bhaskar (1988) and Kalai and
repeated game where firms take turns in choosing price. These theories of the kinked demand curve are
not theories of price rigidity. In all these models, a firm is deterred from undercutting price by the
knowledge that its rivals can respond. In consequence, they may be thought of as models of oligopolistic
collusion.

We set out a variant of the model of Kalai and Satterthwaite, possibly the simplest of these models.
Consider a homogeneous good oligopoly with \( n \) firms, where firm \( i \) has constant marginal costs \( c_i \). Let \( D(p) \) denote market demand when \( p \) is the lowest price in the market, and assume that the revenue
function, \( pD(p) \), is strictly concave. The game played by the firms has two stages, as follows. In stage 1,
firms simultaneously choose prices. Given the vector of prices chosen, \( (p_1, p_2, \ldots, p_n) \), let \( \bar{p} \)
denote the smallest of the prices chosen. In stage 2, firms may choose any price greater than or equal to
\( \bar{p} \). Our focus is on subgame perfect equilibria where firms do not use weakly dominated strategies in stage 1,
given subgame perfect continuation play in stage 2. Let \( p_i^* \) denote firm \( i \)'s optimal common price, that is
the unique maximizer of firm \( i \)'s profits when all firms choose the same price,

\[
p_i^* = \arg\max_p \left( \frac{1}{n} (p - c_i)D(p) \right).
\]

Without loss of generality we may assume that firm 1 has the minimum optimal common price. If the cost asymmetries between firms are not too large, then this game
has a unique equilibrium. In the first stage, each firm chooses \( p_i^* \), and in stage 2 all firms reduce their
prices to \( p_1^* \). That is, the equilibrium outcome is at the minimum optimal common price. The intuition
for this result is as follows. In stage 2, one has Bertrand competition with a price floor at \( \bar{p} \), the smallest
price chosen at stage 1, and all firms will choose \( \bar{p} \) as long as it is not too low. Given this, a firm knows
that it influences the common equilibrium price only in the event that its price is lower than everyone
else's. This ensures that it is weakly dominant at stage 1 for the firm to choose \( p_i^* \).

The model set out here incorporates a restriction on stage two behaviour, namely, that no firm can price
below the lowest price chosen at stage 1. To avoid this restriction on undercutting one must formulate a
dynamic game without a last stage, since otherwise the Bertrand outcome is irresistible. Bhaskar (1988)
sets out a duopoly formulation where firms may repeatedly revise prices downward, and the pre-game
ends when no firm seeks to reduce its price. This game produces a similar equilibrium outcome to the
one set out above. The theory does not imply price rigidity – if costs increase for firm 1, then this will
increase the equilibrium price. The theory also has a flavour of price leadership, since the lowest-cost
firm effectively selects the equilibrium price, with the follower firms having to follow suit. Indeed, the
follower firms perceive a kinked demand curve at the equilibrium price. If a follower firm were to
choose a higher price, firm 1 would not follow suit, thus ensuring that no other firm does so, while if it
reduces price, all firms would match this.

Maskin and Tirole (1988) analyse a repeated duopoly where a firm's price is kept fixed for two periods,
and where firms alternate in choosing price. They find multiple Markov perfect equilibria, with the unique symmetric renegotiation proof equilibrium giving rise to a kinked demand curve at the monopoly price.

The traditional kinked demand theory has been criticized on empirical grounds (Stigler, 1947; Primeaux and Bomball, 1974) since oligopoly prices do not appear to be excessively rigid, nor do they show the predicted asymmetry. However, this is not a prediction of the reformulated theories. These theories do predict that in any market, \( n - 1 \) firms (that is all firms except the leader) should expect their rivals to respond asymmetrically to their price changes, at the equilibrium price. Bhaskar, Machin and Reid (1991) analyse survey evidence, where firms were asked how they expected their rivals to respond if they changed price. The survey data finds evidence of asymmetry in expected responses that is consistent with the prediction.

Kitchin, Joseph (1861– 1932)

S.N. Solomou

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Kitchin, J.; trade cycles

Article

In 1888 Kitchin joined the staff of the Financial News as a compiler of statistics, with particular reference to the South African goldfields. In May 1897 he took up a business career in the South African mining industry. As a businessman Kitchin established a wide reputation for his statistical compilations and came to be regarded as a leading authority on the statistics of precious metals. He produced numerous articles on the theme and provided evidence before the Indian Currency Commission (1926), the Committee on Finance and Industry (1930) and the Gold Delegation of the Financial Committee of the League of Nations (1930).

Kitchin's work on money and gold gave him an interest in the study of trade cycles. His first study, which was a description of trade cycles since 1783, was published in The Times Financial Review in early 1921. In 1923 he published a study of British and American cycles during 1890–1922. Kitchin distinguished minor cycles of 40 months, major cycles of between 7 and 11 years, and trends dependent on the movement of world money supply. Although the existence of major cycles and secular trends was well established, the existence of a 40-month cycle was original to Kitchin. This cycle was seen to result from the psychological reactions to capitalistic production.

Article

Lawrence Robert Klein, 1980 Nobel laureate in economics, has been a pioneer in economic model building and in developing a worldwide industry in econometric forecasting and policy analysis. As Klein's Nobel citation states, ‘Few, if any, researchers in the empirical field of economic science have had so many successors and such a large impact as Lawrence Klein.’ When one thinks of macroeconometric models, his name is the first that comes to mind. Spanning six decades, his research
achievements have been broad, covering economic and econometric theory, methodology, and applications. In emphasizing the integration of economic theory with statistical methods and practical economic decision-making, he played a key role in establishing the directions and in accelerating the development of the theory, methodology and practice of econometric modelling.

His pioneering efforts in the 1940s built on the earlier works of Tinbergen (in the League of Nations Secretariat in 1936–8) and Haavelmo (1943), the seminal treatise of Keynes (1936), and the then emerging toolkit in mathematics and statistics for economic analysis. He was one of the first to establish an operational paradigm for macroeconometric models, and he developed statistical techniques for the estimation and application of these models. Always willing to give generously of himself as he interacted with students and colleagues, he has provided a training ground in applied econometrics for an impressive and long list of academicians, government officials and corporate executives from all over the world. Lawrence Klein continues to contribute in developing and applying econometric methodology for high-frequency forecasting, using weekly and daily information, and for analysing current world economic issues.

Lawrence Klein was born in Omaha, Nebraska on 14 September 1920. He obtained his undergraduate degree from the University of California at Berkeley in 1942 and completed his Ph.D. in Economics at Massachusetts Institute of Technology (MIT) in 1944. He has been professor of economics at the University of Pennsylvania since 1958. He founded Wharton Econometric Forecasting Associates (WEFA) and, as a principal investigator at the University of Pennsylvania, helped with Bert Hickman and Aaron Gordon to establish Project LINK. Together with Michio Morishima, he founded the International Economic Review as a joint publishing endeavour of Osaka University and the University of Pennsylvania. He has been President of the American Economic Association (1977), President of the Econometric Society (1960), editor-in-chief of International Economic Review (1959–65), and John Bates Clark Medalist (1959).

In 1980, he was awarded the Nobel Prize in Economics ‘for the creation of econometric models and their application to the analysis of economic fluctuations and economic policies’ (prize citation in the Alfred Nobel Memorial Prize in Economic Sciences, 1980; also in Lindbeck, 1992, p. 411).

Klein's experience as a youth in the Great Depression and his intense desire to understand what was going on led him to the study of economics. After spending two years in Los Angeles City College, Klein completed his last two undergraduate years at the University of California in Berkeley. With a keen interest in seeing how mathematics and statistics can be used in analysing economic problems, he worked with students of pioneers like Griffith Evans (professor of mathematics and a founding member of the Econometric Society) and Jerzy Neyman (professor of statistics and key developer of statistical theory). He also worked as a summer research assistant of George Kuznets in the Giannini Foundation. This summer work exposed him to perhaps his first foray into applied econometrics – estimating demand functions for Californian lemons! It was also during this time that Klein was introduced to the early scholarly works of Paul Samuelson, a serendipitous preparation for a long-time relationship that was to blossom as Klein moved to MIT for his doctoral studies.

On graduate scholarship at MIT, Klein was Paul Samuelson's research assistant from the outset. As Klein himself remarked:

Working with Samuelson, who was at the forefront of interpreting Keynesian theory for teaching and policy applications, I was put immediately in the midst of two challenging
Klein, Lawrence R. (born 1920) : The New Palgrave Dictionary of Economics

contests – one to gain acceptance for a way of thinking about macroeconomics and another to gain acceptance for a methodology in economics, namely, the mathematical method. Later, both challenges were to be overcome, but for ten or twenty years, opposition was fierce. (Breit and Hirsch, 2004, p. 18)

He would elaborate further on this:

working as an assistant for Samuelson was something that is very hard to duplicate anywhere in the world. He generates ideas so fast. At that time, there was a whole succession of ideas concerning Keynesian macroeconomics and econometrics and the development of mathematical methods in economics. It was a very exciting time, and I felt very fortunate to be in that background. (Mariano, 1987, p. 411; and Klein, 2006)

At that time, when Haavelmo's celebrated *Econometrica* paper (Haavelmo, 1943) was circulating as a working paper, the treatment of identification in econometric models led Samuelson to ask Klein to investigate the mathematical equivalence between the problems of identification in supply–demand models and in saving–investment analysis.

It was during his graduate student days that he started working on two papers that were later published in *Econometrica* and the *Journal of Political Economy*. The first, published in 1943, studied the specification of the investment function, while the second (1947) dealt with alternative theories of effective demand. Considered a seminal paper in the debate between the Keynesians and the classical economists, this latter paper formulated the Keynesian system in mathematical terms and argued that the specification of the liquidity preference function and determination of money wages are keys to the Keynesian system.

Klein completed his degree in two years, as Samuelson's first Ph.D. student. His thesis, dealing with Keynesian economics, led in 1947 to the publication of *The Keynesian Revolution*, which was to become one of Klein's best-known works. The book provided the mathematical specification of Keynes's ideas that served as the foundation for the economic models that Klein formulated subsequently.

After finishing at MIT, Klein accepted Jacob Marschak's invitation in 1944 to become a research associate in the Cowles Commission at the University of Chicago. This turned out to be a defining period for Klein's professional career. His interactions with an unusually talented group that included J. Marschak, T.W. Anderson, H. Rubin, M. Girschick, T. Haavelmo, T. Koopmans, D. Patinkin, L. Hurwicz, K. Arrow, H. Simon, R. Leipnik, H. Chernoff, and visitors such as J. Tinbergen, R. Frisch and M. Kalecki proved to be a catalyst for his development into an applied econometrician par excellence.

His MIT work on Keynesian economics began to evolve at this time into applied econometric modelling. While teams were formed to work on various aspects of an emerging econometrics field, Klein focused his energies on what was to become his lifelong endeavour. He described his task in the Cowles Commission as follows:

The central problem posed for research at Cowles by Jacob Marschak and Tjalling Koopmans was a fresh attempt at U.S. model building by using Haavelmo's new ideas about econometric theory. … Jacob Marschak insisted that I base my econometric
modelling on received economic theory and that I justify macroeconomic specifications on the basis of reasoning about individualistic decision making, with proper attention to the problem of aggregation. … It turned out to be an exciting time for me and enabled me to build on the Keynesian lessons that were taught to me at MIT by Paul Samuelson. … That was the beginning of my long association with the problems of macroeconometrics that were then being tackled afresh at the Cowles Commission. (Marwah, 1997, pp. xx–xxii)

At Cowles, Klein completed his first series of macroeconometric models. The celebrated Klein Model 1 was part of this series. It was initially developed as a compact prototype model of the US economy to study computational methods. It has now become a standard reference in most introductory econometrics textbooks. Klein also put his models to work to answer pressing questions about the post-war US economy posed by professional colleagues like Albert Hart from the Committee for Economic Development, Theodore Yntema (former director of the Cowles Commission), and Alfred Cowles himself, who was a member of the Budget Committee of the Community Fund in Chicago. Klein's models proved useful in forecasting what was in store after the war – predicting that the US economy would not return to the Great Depression.

Klein's interactions with his peers at Cowles deepened his interest in statistical methodology, especially in estimation and prediction in simultaneous equations models. He developed a keen attention to detail in estimation in empirical work and a firm belief in the value of 'high technology' estimation procedures. At this juncture, he also started his joint work with Herman Rubin on the linear expenditure system for studying cost-of-living indexes in the context of a neoclassical demand model (see Klein and Rubin, 1947) as well as on aggregation issues and demand systems. During this period, Klein completed most of the material for another major work, *Economic Fluctuations in the United States, 1921–1941*, which was published in 1950.

In the summer of 1947, Klein left the Cowles Commission, briefly to help in the initial econometric model building effort in Canada, then to spend the greater part of the year to visit Ragnar Frisch's Institute in Oslo and Jan Tinbergen's office in the Central Planning Bureau in the Netherlands. Klein then joined the National Bureau of Economic Research (NBER), at the invitation of Arthur Burns, to undertake econometric studies of production functions. Interested in investigating the influence of liquid assets on saving behaviour, Klein moved to the University of Michigan in 1949, initially as researcher in the Survey Research Center for one year, then lecturer in economics from 1950 to 1954. Having become involved with the sample survey studies in the Center, Klein produced a number of publications on savings and consumption behaviour using survey data, culminating in a book on the contributions of survey methods in economics (Katona, Klein, Lansing and Morgan, 1954). While at Michigan, Klein noticed a considerable interest in the forecasts about the state of the economy and the use of econometric models and also resumed the econometric modelling work that he started at the Cowles Commission. With Arthur Goldberger, his doctoral student at Michigan, he developed what has come to be called the Klein–Goldberger model of the US economy. As the first substantial effort at an empirical representation of a large economy with a theoretical Keynesian structure (see Klein and Goldberger, 1955), this model has become an important reference to students and researchers in econometrics. This model has become a standard example in econometric textbooks, making very realistic simulation projections about the small recession following the Korean War. Klein and
Goldberger initially published this result in the *Manchester Guardian* to challenge a very pessimistic econometric forecast by Colin Clark. Another major piece of work during this time was his textbook on econometrics, the first to provide a blend of theoretical, methodological and applied developments in econometrics (Klein, 1953).

The University of Michigan was to promote Klein to full professorship but then reneged when Klein testified in a Detroit hearing that he had been a member of the Communist Party for about six months in 1946. (Subsequently, in 1978, the university awarded Klein an honorary doctoral degree in which the citation stated that he would probably be a Nobel laureate.) Oxford University's Institute of Statistics quickly invited him to join its staff, which he accepted, becoming first Senior Research Officer from 1954 to 1955 and Reader in Econometrics from 1956 to 1958. As Klein himself explained in Breit and Hirsch (2004): ‘In the McCarthy era, I left Michigan for the peace and academic freedom in Oxford.’ At that time, the Oxford Institute of Statistics was undertaking the Oxford Savings Surveys in partnership with the UK government, an enterprise in which Klein played a substantial role. He also developed an econometric model of the UK economy, which was published in Klein, Ball, Hazlewood and Vandome (1961).

In Oxford, Klein was ‘given the green light to do what he thought could be done within the confines of the Oxford system in teaching, attracting attention in seminars, and doing research activities in econometrics’ (Mariano, 1987, p. 422). It was in this period that he produced his more intuitive instrumental variable interpretation of Theil's two-stage least squares estimator (Klein, 1955). Carrying over research initiatives from Cowles Commission work, Klein also looked into the statistical efficiency gains from imposing a priori restrictions on an economic system. Klein had numerous productive discussions with colleagues, including Peter Vandome and Michio Morishima, and with A. W. Phillips about the Phillips curve and how it relates to his own ideas about closing the Keynesian system for the determination of absolute prices and wages. His discussions with Jim Ball and Peter Newman about growth theory and growth models led to his idea of constructing a total growth model of the economy in terms of stable ratios as limiting conditions in economics. Some of these ideas that circulated in Oxford were eventually refined in Klein's early years at the University of Pennsylvania (for example, Klein and Kosobud, 1961).

Klein returned to the United States in 1958 – partly under family pressure, to help ageing parents – and joined the economics faculty of the University of Pennsylvania. University President Gaylord Harnwell and Provost Jonathan Rhoads told Klein that they did not have any interest in his political beliefs and simply wanted him at the University of Pennsylvania to teach econometrics: the University of Pennsylvania remains his main base of operations. He produced a host of academic publications and contributions to both economics and econometrics and he created innovative ways of financing major economic research with fresh linkages with industry and government. He also played a key role in shaping the Economics Department into its position today as one of the top economics departments in the United States.

Klein's academic research at the University of Pennsylvania returned to favourite themes such as estimation and prediction in simultaneous equations models of economic systems (Johnston, Klein and Shinjo, 1974; Klein, 1969; Klein, Dhrymes and Steiglitz, 1970; Klein and Howrey, 1972; Klein and Nakamura, 1962; and Klein and Young, 1980). Some work opened up new issues such as the theoretical and empirical difficulties involved in measuring and tracking capacity utilization (Klein, 1960a; Klein and Summers, 1967; Klein and Preston, 1967; Klein and Su, 1979). Klein's subsequent research themes...
delved into economic techniques, analysis, and policy, dealing with diverse topics in economic theory, econometric methodology and forecast uncertainty, microfoundations and linkages of the macro Keynesian paradigm, the role of expectations in empirical economic models, anticipations and forecasting, the Phillips curve, international economics and finance, economic growth, and policy formulation. At the same time, in a synergistic fashion, he continued and sustained his work on macroeconometric modelling, developing numerous econometric models for a vast array of applications. Prominent examples of these are the SSRC–Brookings model of the US economy, the Wharton School models of the US economy (medium-term and long-term), and the Project LINK world model. Klein's methodological approach in econometrics blends economic analysis, statistical method and mathematics. Many times in his writings he would strongly recommend that the best approach to applied economic modelling is to first develop an underlying theory, then move on to observation and the preparation of a database with the statistical methodology to construct, test and apply the empirical model.

He is wary of oversimplification in economic modelling, because, he says, the problems are complicated and can be understood only in the context of large complex systems. His starting premise is that ‘the real world is very complicated and cannot be effectively understood or guided by simple rules, such as those that underlie monetarism or those that can be treated by single equation time series methods or even those that can be treated by vector autoregression (VAR) methods’ (Marwah, 1997, p. xxiv). It is his long-standing conviction that detailed structural modelling is the best kind of system for understanding the macroeconomy through its causal dynamic relationships, specified by received economic analysis. However, with more time-series information becoming available on weekly, daily, hourly, and real-time basis, he also feels that there are related approaches, based on indicator analysis, that are complementary, especially for use in high-frequency analysis.

Klein disagrees with the notion that macroeconomics is simply an adding up of the propositions of microeconomics (for example, see Klein, 1993). He argues that macroeconomics stands on its own as a separate subject and cannot be entirely derived from microeconomics. In his view, there are important concepts and analyses that are inherently macroeconomic. And, of course, there are also important macroeconomic propositions that can be derived from microeconomics, but only after paying painstaking attention to the formulas and processes of aggregation. And on the issue of aggregation, which he had studied since his undergraduate days in Berkeley, he maintains in subsequent analyses that ‘macromodeling in terms of unweighted aggregates or, even worse, in terms of the “representative agent”, fails to deal with the relevant distribution issues’ (Marwah, 1997, p. xxi). There are two dimensions to aggregation, over commodities and services and over economic units (firms and households). Specific and narrow market analyses, involving intricate aggregation over economic units, are important in price determination; yet they are not purely microeconomic since they involve aggregation in various dimensions.

Klein believes that the market system cannot provide adequate self-regulatory responses in an economy. The economy definitely needs guidance and Klein looks to professional economists to provide policymakers with the right information for appropriate decision-making and leadership. On methods for doing this, according to Klein, there is no alternative to the quantitative approach of econometrics, but with the realization that not all policy issues are quantitative and measurable, and that subjective decisions must also be made (see Klein, 1992). Furthermore, econometric information must be detailed if it is to be useful in policy formation. In general, there is a need to move in the direction of preparation.
of large-scale complex systems in order to help policymakers. Significant advances in computer technology and the provision of detailed information through associated telecom processes make it possible to push econometrics in the direction of truly serving policymakers (see Klein, 1986).

Klein also sought to extend the narrow Keynesian model serially to the supply side, the open economy and the developing economy by integrating his conception of Keynesian theory with other branches of economics such as international trade and economic development. And he enhanced his model structure further not only with the flow-of-funds accounts but also with the introduction of input–output analysis. He felt strongly that the economic model structure must interface with the social accounts especially when supply side, industry, and longer-term analysis are of major concerns in the study. Thus, Klein's modelling team at the University of Pennsylvania produced standardized procedures for combining input–output analysis with macroeconometric modelling in a feedback mode (see Klein, 1989; Klein, Bodkin and Marwah, 1991).

Klein draws upon explicit surveys of consumer and manufacturer expectations to develop a powerful and meaningful way of dealing with expectations in macroeconometrics. He believes that the 'rational expectations' approach – where expectations are treated to be fully consistent with the model being estimated – is 'unrealistic and singularly unhelpful in guiding economic policy or in forecasting' (Marwah, 1997, p. xxiii). The most important analyses of expectations will come through the in-depth use of the sample survey method. Along these lines, Klein's research sought to endogenize measured expectations and to include anticipatory variables in his macroeconometric models (orders, investment intentions, housing starts, building permits, survey responses about future spending, incomes, or price movements: see Klein, 1972; Adams and Klein, 1972; and Klein and Ozmucur, 2007).

In the early stages of his career, Klein considered the real sector as the key focus of the analysis and that a good understanding of the economy is possible without careful reference to the monetary sector. But in studying the macroeconomy, he has increasingly come to appreciate the role of money and of the whole monetary sector. For example: ‘Monetarism is fundamentally flawed, and dangerous when used as a doctrinaire policy approach, but I do believe that money matters; it is not everything but it does matter’ (Klein, 1992, p. 188; also in Marwah, 1997, p. xlviv). But he remarks further that science, technology, development, and innovation play important roles in the dynamics of the economy and that this interpretation of the supply side is different from and far more important than the simplistic and populist approaches through tax cuts.

In using his empirical models to forecast, Klein has always been concerned with how to adjust the model so that it would start on a forecast extrapolation at prevailing initial values. A particular concern was the frequent data revisions and new information flows about exogenous and endogenous variables at the very moment of forecast calculation. One approach – subjective adjustments to initialize the extrapolation process – is not replicable and is not satisfactory. Since the 1980s, Klein has been using time series methods to extrapolate higher frequency indicators for purposes of initializing the empirical macromodel (Klein and Young, 1980; Klein and Sojo, 1989; Klein and Park, 1993; Klein and Ozmucur, 2007).

Klein has always been conscious of the statistical uncertainties involved in the results of econometric model building and application. Consequently, coping with forecast errors from macroeconometric models is a constantly recurring theme in his research agenda. And he has developed methods for assessing the degree of uncertainty in econometric inference, in particular model simulation techniques to evaluate forecast errors of large-scale models and to perform sensitivity analyses of these models.
Construction of the Wharton models started with a Rockefeller Foundation grant in the early 1960s. This was followed by the establishment of the Wharton Econometric Forecasting Unit as a research group at the Wharton School for general quantitative studies in economics, financed by the Ford Foundation and the National Science Foundation. Subsequent funding came from several major corporations that sought Klein's help in econometric model building to assist their economic research departments. Since this activity thrived, the unit was formally incorporated in 1969 as a non-profit entity, fully owned by the University of Pennsylvania, and with the name Wharton Econometric Forecasting Associates (WEFA). Through WEFA, Klein was able to tap major sources of funding and channel these towards the establishment of the University of Pennsylvania as a premier centre of academic research in applied econometric analysis. Through the 1960s, 1970s, and 1980s, WEFA earnings from research consultancies for private companies, and public agencies were ploughed back to support economics faculty, graduate students, and visiting scholars in the University of Pennsylvania. The commercial work within WEFA itself also pioneered the logical development and computer handling of large-scale systems.

While at the University of Pennsylvania, Klein also pursued his interests in international model building. In the 1960s, he started his work on modelling the economies of Japan, the Organisation for Economic Co-operation and Development (OECD), and Latin American countries, starting with Mexico, Brazil and Argentina. These model-building efforts then spread out into many developing countries in Asia, including China, and some in the Middle East. Klein headed the first delegation of academic economists from the US to China in 1979. The following year, in collaboration with Lawrence Lau, Klein convinced the Chinese Academy of Social Sciences to host an econometric workshop at the Summer Palace in Beijing. The workshop staff, consisting of Klein, T.W. Anderson, Albert Ando, Lawrence Lau, Gregory Chow, Cheng Hsiao and Vincent Su, introduced econometrics and related aspects of empirical economic model building to the then nascent community of Chinese economists. Klein also directed related efforts to socialist nations. All these efforts naturally led to Project LINK.

Project LINK was one of the biggest and most ambitious projects that Klein mounted, with initial funding support in 1968 from the Ford Foundation, National Science Foundation, the International Monetary Fund and the Federal Reserve Board. The project sought to integrate the macroeconomic models of different countries, which eventually included Third World and socialist nations, into a total simultaneous system through international trade and financial flows (for example, see Klein, 1983; and Klein and Hickman, 1984). The main objective was to improve understanding of international economic linkages and to make improved forecasts of world trade. Over the years, this worldwide project has provided an important research forum that brings together model builders from many countries to share each other's developments and to discuss in a systematic way world economic prospects and pressing economic policy challenges. Project LINK also has provided a critical impetus for the development of economic and econometric analysis in socialist and Third World countries. Today, Project LINK is headquartered at the University of Toronto and the United Nations office in New York. It involves approximately 100 countries worldwide.

One of Klein's research works now deals with forecasting with high-frequency data through the University of Pennsylvania Current Quarter Model (CQM) (see Klein and Sojo, 1989; Klein and Park, 1993; and Klein and Ozmucur, 2007). This model embodies a constant effort to improve forecasts by
combining results from different methods, namely the expenditure side model, income side model, and the principal components model of an economy. It combines data at different frequencies to enable use of all available information. High-frequency forecasts are useful not only for studying the short-term developments of the economy but also for adjusting lower-frequency macroeconometric models so that they are solved from up-to-date initial conditions. The University of Pennsylvania Current Quarter Model has generated a great deal of interest in high-frequency macroeconometric models. Klein has authored or advised the building of similar models for Russia and China (see Klein and Mak, 2005) and he is in the process of contributing to building a model for India. There are also efforts, mostly by Klein's students, to build high-frequency models for other countries such as Japan, Mexico, Hong Kong, France and the European Union.

Klein's efforts to improve forecasting accuracy also have moved in the related direction of building models that include survey results (households, investors, and managers: see Klein and Ozmucur, 2007). And his constant attempt to answer pressing substantive issues has led to recent applied and technical papers on using input–output tables with econometric models (Klein, 2003; on information technology and productivity, see Klein, Duggal and Saltzman, 1999; 2003; 2004; on estimating China's economic growth rate, Klein and Ozmucur, 2002/2003; and on financial crises’ challenges and cures, see Klein, Mariano and Ozmucur, 2007; and Klein and Shabbir, 2007).

In addition to the academic activities that this article has focused on, Klein has been active throughout his career in non-academic pursuits as well. He chaired the economic task force of Jimmy Carter in the US presidential election campaign in 1976. He served on the Finance Committee of the National Academy of Sciences and on the Board of Directors of W.P. Carey Co. He found time to contribute journalistic pieces about economic affairs to the Los Angeles Times, Manchester Guardian, and Banker's Magazine; and to be a founding officer and active moving force of the Economists Allied for Arms Reduction (ECAAR), now Economists for Peace and Security (EPS). All these activities have produced an illustrious line-up of students and colleagues who have benefited from their collegial training and/or collaboration with Klein. Many of them are in the highest levels in major academic institutions, leading companies in the private sector, multinational organizations and government agencies all over the world. Klein has developed and moulded macroeconometric models for over six decades in his own inimitable way, addressing the soundness of the theoretical basis for the model specification, using empirical evidence and data and appropriate methodology to estimate and validate and apply the model for the purposes that drove its creation. Over the years, these models have evolved in terms of complexity, breadth, and new econometric methodologies. And these models have been constructed and applied to address a wide variety of issues such as post-war economic policy formation in the 1940s (his mission at the Cowles Commission), the oil price shocks and the ensuing stagflation in the United States in the 1970s, impact and policy implications of the financial crisis in the 1990s, impact of tariff and non-tariff barriers on regional trade flows, policy analysis of regional trade groupings and various international agreements (for example, Uruguay Round, NAFTA, APEC, WTO), capital flows, economic development all over the world, and explaining endogenous exchange rates after the demise of Bretton Woods parities.

Though Klein had the benefit of Tinbergen's early work as well as the post-war effort at the Central Planning Bureau in the Netherlands, Klein's modelling work was akin to the original model T Ford out of which many other models developed in different parts of the world. Klein's own work has shaped developments in the field quite uniquely and has influenced model builders on a worldwide scale.
'His principal achievement has been in pioneering an activity in the field of economic model building which has required foresight, persistence and great technical skill and which has been translated into a paradigm of research activity that has spread wherever statistical economics is taught and wherever models are built' (Ball, 1981, p. 92). Undoubtedly, he continues to inspire, teach, lead, explore and push the intellectual and academic frontiers of the pursuits that continue to define his lifetime of pioneering work.

Knapp, Georg Friedrich (1842–1926)

B. Schefold

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
capitalism; feudalism; gold standard; hereditary bondage; Knapp, G. F.; monetary theory; money; Mortality; paper money; peasants; state theory of money

Article

Knapp was born in Giessen, the son of a professor of technological chemistry who was also temporarily director of the Königliche Porzellanmanufaktur. Justus von Liebig, the famous chemist, was his uncle. Knapp studied in Munich, Berlin and Göttingen, and in 1867 became head of the statistical office of the municipality of Leipzig, in 1869 extraordinary professor of economics in Leipzig and in 1874 professor in Strassburg. He was one of the leading German ‘Kathedersozialisten’ (socialists of the chair), and cofounder of the Verein für Socialpolitik.

At the beginning of his career he carried out some important work in statistics: he was the first to develop a systematic theory of mortality measurement (1868), and he applied mathematical methods to demographical problems (1874). After his appointment to Strassburg in 1874, his research shifted to German agricultural history. He compared the economic organization of agriculture in the different parts of Germany (1925–7, vol. 1, ch. 3), his special interest being focused on the agrarian conditions in the German East. In a work now regarded as classic (1925–7, vols 2 and 3), Knapp described the peasant liberation and the rise of a class of rural workers in the long-settled provinces of Prussia. Around the turn of the 19th century, property relations in the rural parts of Eastern Prussia were dominated by the estate economy (Gutsherrschaft), which had arisen out of medieval landlordship (Grundherrschaft). It was characteristic of the estate economy that the peasants, who could own land, were obliged to do compulsory service on the land of the Junker, and remained in hereditary bondage (Erbunterthänigkeit). In Knapp's view, the latter had to be distinguished from slavery/serfdom and was not medieval at all, but inherently modern. Knapp perceived the estate economies as the first large capitalist enterprises and regarded hereditary bondage as the earliest capitalist labour constitution, a very controversial view. Thus Knapp emphasized that the origins of capitalism should be sought in agriculture (1925–7, vol. 1, ch. 2, pp. 91–106).
This system was to be changed by the reforms under Stein and Hardenberg (1925–7, vol. 1, ch. 2, pp. 107–23), which aimed at the abolition of hereditary bondage. However, under the pressure of the Junker, who were interested in maintaining an abundant labour supply for their estates, only wealthy peasants were allowed to own landed property; the others were transformed into wage labourers working on the Junker estates. Compensation payments for the Junker allowed them to absorb many peasant holdings. This implied a loss of the former feudal protection of the labourers. Thus the Prussian agrarian reforms resulted in a restructuring of the organization of agriculture, which worsened the social situation of large parts of the peasantry and strengthened the position of the Junker as the dominant class of Prussia and later of Imperial Germany. In order to avoid such failures for the future, in order to curb profit interests and prevent the harmful effects of class struggle, Knapp advocated strong state intervention and a typical German solution to the problem: a state ruled by civil servants (Beamtenstaat) (1925–7, vol. 1, p. 122).

At a later stage in his career Knapp became interested in monetary theory. His *Staatliche Theorie des Geldes* (State Theory of Money) (1905, ch. 4) was the counter-revolution against the traditional classical and neoclassical theories of money. These theories regarded it as a logical necessity for money to consist of (or to be ‘covered’ by) a commodity, generally gold, silver, or both, whose exchange value or purchasing power would then determine the exchange value or purchasing power of money. Knapp defined money independently of its material value as the creation of the legal order of the state. Consequently, he was able to explain theoretically the existence of ‘paper money’. Contrary to many of his followers, this did not lead Knapp to oppose the gold standard. He generally refrained from discussing monetary policy and tried to concentrate on the conceptual problems of monetary theory. In fact, the state theory of money did not really constitute a monetary theory, but was rather an analysis of the legal and historical aspects of money. In this sense it was supposed to be a precondition of monetary theory.

Knapp’s approach aroused stormy controversies. It was extremely popular among those German economists who associated the gold standard with the international supremacy of the London money market. More importantly, both Knapp’s institutional approach and his rejection of the quantity theory of money, his theoretical assessment of price increases being independent of the quantity of money and determined by ‘real’ phenomena such as wages and incomes (1905, pp. 436–48), constituted a first step towards the later theories of Keynes and his school.

Karl Knies was born in Marburg, the son of a police employee. He studied history and political science in Marburg, and in 1846 was appointed university lecturer. In 1855, after a break in his career due to political problems, he was appointed professor in Freiburg. He transferred to Heidelberg in 1865, where he taught until 1896.

Knies was a progressive liberal with an outstanding sense of political integrity. His refusal to sign a declaration of loyalty to a reactionary state minister prevented his appointment to a professorship after the failure of the revolution of 1848, and compelled him to emigrate to Switzerland. From 1861 to 1865 he was a member of the Diet of Baden, where he actively opposed the control of the school system by the Catholic Church.

Knies, who had a profound influence on Max Weber, was one of the most important economists of the German ‘older’ historical school. He favoured the inductive method (1853, pp. 321–55), regarding facts derived from experience as more important than logical postulates. Strongly opposed to any ‘absolutism of theory’, to any theoretical assessments that claimed to be valid for all times and all people, Knies rejected the existence of general economic laws (1853, pp. 235–49), and strongly objected both to the abstract deductive reasoning of Ricardo and to the mathematical approach of Walras. Political economy has to do with the permanently changing habits and behaviour of human beings. Therefore economic analysis has to be oriented towards practical life, taking account of the peculiarities of different people and nations and different historical circumstances – Knies puts the emphasis on the historical relativism. By comparing economic relations of different countries and different historical times we may find laws of analogy, but certainly no laws of the same causal nexus. In his opposition to such laws Knies went further than other exponents of the older historical school such as Roscher.

Knies's main work on political economy (1853) was totally different from traditional textbooks. The
reader will look in vain for separate chapters on prices, wages and rents. Rather, he will find a treatise which is strongly history-oriented and focuses on the impact of history and geography on the characteristics of different people and economies, and on problems of method. Knies attacked the classical notion of self-interest as the central regulating mechanism of economic behaviour and emphasized the equal importance of the sense of membership in a community, justice and fairness (1853, pp. 147–68). He was interested in the interdependence of economics with general cultural and political life and therefore objected to an isolated study of political economy. He focused closely on the national character, and on the peculiarities and uniquenesses of different peoples, nations and races (pp. 57–70).

He also provided an analysis of money, capital, credit and interest (1873; 1879). He outlined a concept for a world currency as an international means of payment (1874). However, his analysis followed conventional methodological patterns; he did not succeed in applying the historical method to the analysis of concrete economic problems.

Knies was one of the rare bourgeois economists of 19th-century Germany who discussed Marx. He took special interest in the Marxian labour theory of value, which he opposed because of its neglect of the centrality of use value (1873, pp. 117–43).

Knies had a flexible approach towards state interventionism, which he regarded as necessary in certain cases. On the tariff question he took a stance similar to List: for an industrializing country tariffs are necessary to protect its young industry against the competition of more advanced foreign industries.

Knies was also concerned with the economic and cultural implications of railroad transportation and with new systems of communication.

In an outstanding contribution to statistics Knies (1850) attempted to develop statistics as an independent discipline based on exact mathematical methods.

Knight, Frank Hyneman (1885–1962)

George J. Stigler
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A founder of the Chicago School, Frank Knight in his 1921 classic text *Risk, Uncertainty and Profit* defined perfect competition and distinguished risk from uncertainty in that under uncertainty the probability of events was unknowable. He criticized Pigou's proposal that increasing-cost industries should be taxed. His work on capital theory refuted Böhm-Bawerk's use of the period of production concept. Yet he conceived of economics as applying to only a small part of human activity; he criticized competitive enterprise as intrinsically unethical and unfair and debasing in practice, and feared freedom would be undermined by increasing monopoly and income inequality.

Article

Knight was born in McLean County, Illinois, on 7 November 1885, the first of eleven children of Winton Cyrus Knight and Julia Ann Hyneman Knight, farmers of Irish descent residing in southern Illinois. Two of Frank Knight's brothers, Melvin Moses and Bruce Winton, also became economists. Bruce once recounted an episode characteristic of his oldest brother. Under the suasion of their deeply religious parents, the children signed pledges at church to attend church the rest of their lives. Returning home, Frank (then 14 or 15) gathered the children behind the barn, built a fire, and said, ‘Burn these things because pledges and promises made under duress are not binding.’
Knight pursued his education through a series of schools and small colleges in the Midwest (see Dewey, 1986). His academic work was unfailingly marked by hard work, high intelligence and excellent grades, and one suspects that he was unfair to both himself and the poverty of his family when he once remarked that it would have been difficult to have chosen these institutions more unwisely. This preparatory period ended with two years at the University of Tennessee, and in 1913 Knight went to Cornell University, first to study philosophy and a year later (with the eager assistance of the philosophy department) he transferred to economics. His main teachers were Alvin S. Johnson and Allyn A. Young. He wrote a dissertation, ‘A Theory of Business Profit’ (1916), which displayed an astonishing depth and breadth of knowledge of the theory of value and distribution to have been acquired so quickly. With significant revision, the thesis appeared in 1921 as the classic Risk, Uncertainty and Profit.

Knight's subsequent academic career is easily summarized. After a year of teaching at Cornell and two (1917–19) at the University of Chicago, he went to the University of Iowa where he was an associate and then a full professor for eight years. In 1927 he returned to the University of Chicago, where he taught until 1958 and remained for the rest of his life. (Cornell in 1928 and Harvard in 1929 unsuccessfully attempted to lure him away.) The main courses he taught were in value and distribution and the history of economic thought, although occasionally he offered different topics (the present writer was one of a small number of students in a seminar on Max Weber in the mid-thirties). He was clearly the dominant intellectual influence upon economics students at Chicago in the 1930s (on his teaching, see Patinkin, 1973 and Stigler, in Journal of Political Economy, 1973).

He received the major honours that his profession could give him: the presidency of the American Economic Association in 1950, after he refused to be nominated in 1936 and 1937; and the Association's highest award, the Walker Medal, in 1957.

In 1911 he married a classmate at Milligan College, Minerva O. Shelburne, and they had three daughters and a son. They were divorced in 1928. In 1930 Knight married Ethel Verry, a social worker who was for many years the director of the Chicago Child Care Society, and they had two sons, Frank Bardsley, a mathematician, and Charles Alfred, a geologist. Knight died in Chicago on 15 April 1972.

The economist

Knight's dissertation, ‘A Theory of Business Profit’ was presented to Cornell University in June 1916. This was a short two years after he transferred to economics from philosophy, although evidently his interest in economics had begun earlier. (In 1913 he was already purchasing Marxist, Fabian and syndicalist pamphlets on a visit to London.) One can find much of Knight's mature thought in the thesis, which was completed when he was almost 31 years old.

The revisions of the thesis which appeared as Risk, Uncertainty and Profit in 1921 were substantial but not radical. Allyn Young reviewed the manuscript for the book and repeatedly asked him to ‘avoid the appearance of bumptiousness’ (Knight Papers, Box 54, folder 14), but the suggestions went unheeded. The three chapters in the thesis on the nature of perfect competition under stationary conditions became the four chapters of Part II of Risk, Uncertainty and Profit (hereafter RUP) with significant additions: the famous Knightian curves of diminishing returns (RUP, pp. 96ff.) made their first appearance, and the essence of the theory of the dominant firm was now mentioned (p. 193n). This section continued to present a clear, succinct statement of neoclassical price theory, and one can readily understand why
Knight, Frank Hyneman (1885–1962) : The New Palgrave Dictionary of Economics

Lionel Robbins made it a basic text at the London School of Economics.

Knight said in this thesis that ‘The definition of perfect competition … is our principal task in this essay’ (p. 8), and it was certainly an enormously influential part of the book. Knight's conditions must have seemed extraordinarily severe to his readers: he required infinite numbers of independent traders, free and instantaneous mobility of resources and communication of knowledge, perfect knowledge and fore-knowledge, and infinite divisibility of traded goods (RUP, pp. 76ff.). Even today we do not normally find it useful to postulate such extreme simplicity in the economy, so that even time and space are eliminated. Some of the subtle conditions, such as that the individual ‘must be free to social wants, prejudices, preferences, or repulsions’ (p. 78), are not developed sufficiently to reveal their relevance or implications.

The treatment of risk and uncertainty quickly became Knight's ‘contribution’. Risk was characterized by the reliability of the estimate of its probability and therefore the possibility of treating it as an insurable cost. The reliability of the estimate came from either knowledge of the theoretical law it obeyed or from stable empirical regularities:

The crux of the whole question of probability, whether pure or empirical, for purposes of economic theory, is that in so far as the probability can be numerically evaluated by either method, it can be eliminated and disregarded (Thesis, p. 186).

In economic life of course the empirical probabilities are the important ones.

True uncertainty is to be ‘radically distinguished’ from calculable risks: here ‘there is no valid basis of any kind for classifying instances’ (RUP, p. 225, his italics; also p. 231). Knight believed that uncertainty cannot be explicitly and exactly defined, but one could read Bayesian elements into his discussion of probability (compare Thesis, ch. 6, with RUP, ch. VII).

The latter part of both the thesis and the book lack substantive structure. There is fertile, unsystematic attention to the use of combination (of which one form is specialization) to reduce uncertainty as well as risk, despite the assertion just quoted that this cannot be done for uncertainty. Considerable emphasis is placed upon intuitive knowledge in dealing with uncertainty: ‘knowledge of men's capacities to know [how to deal with uncertainty] turns out to be more accurate than direct knowledge of things’ (RUP, p. 298). Pure profit and pure ‘rent’ (his term for an accurately imputed income) are never found in real life: every income contains elements of both. Moral hazard makes an explicit and potentially major appearance (RUP, pp. 249–54) but then surprisingly vanishes from the subsequent discussion.

Several characteristics of Knight's writing were already well established in the first book:

1. (1) He looked upon received theory with a strongly sceptical eye. For example, the traditional distinctions between capital and labour are vigorously – and properly – criticized (RUP, pp. 126ff.). He was equally critical of both Clark's concept of the stationary economy (RUP, pp. 32ff.) and of Marshall's treatment of time periods in production (RUP, pp. 142ff.). He had already re-thought a large part of standard value theory by 1916.

2. (2) He was extremely dogmatic in his empirical generalizations – all without a trace of proof. Here are a few examples: ‘The normal rate of interest is one-half to two-thirds of the normal rate of return in fairly successful businesses’ (Thesis, p. 333). ‘There is little question that in fact speculators in land make on the whole less than the competitive rate of return on their investment’; but he has the rare qualm to add, ‘though this is difficult to prove conclusively’ (RUP, p. 337). ‘… Laborers show themselves ready to engage in hazardous
enterprises at their own risk for an increase in wages which is a fraction of an adequate compensation for the chances they take' \( RUP, \) p. 301).

3. (3) He recurred time and time again to the same central thoughts. Once he defended the practice by quoting Herbert Spencer: ‘Only by varied iteration can alien conceptions be forced on reluctant minds.’ A lasting, and important, example of the tenacity of his beliefs is the view that a competitive enterprise system inherently leads to a cumulative increase in the inequality of the distribution of income. In later years at countless lunches this was challenged on both analytical and empirical grounds by Milton Friedman, each time leading Knight to make temporary concessions, only to return to his standard position by the next lunch. Knight must have felt that luncheons are doubly unfree.

A rather modest part of Knight's later writings fall within contemporary economic theory: chiefly two important articles in price theory and the series of articles on capital theory. The first article, ‘Cost of Production and Price over Long and Short Periods’ (1921; reprinted in The Ethics of Competition \( EOC \)), offers an emendation of Marshall's analysis of time periods. Knight distinguishes a ‘momentary’ price which represents the supply and demand for a commodity in a speculative market: it is essentially an analysis of the prices of stocks of goods. His second, closely related period is that within which the supply of a commodity is (initially) fixed, perhaps the pricing of a given periodic crop during the crop year. Knight's third period, long run normal price, is a merging of Marshall's short and long run normal prices, a distinction which is criticized as an unnecessarily rigid classification of what is truly a continuum of time periods. The neglect of external economies will be explained shortly. There cannot be many articles in price theory that read so well after sixty-five years. The second great article in price theory was ‘Fallacies in the Interpretation of Social Cost’ (1924; reprinted in \( EOC \)). The article contains an attack upon Pigou's celebrated error in wishing to tax increasing cost industries and upon Frank Graham's criticisms of the doctrine of comparative costs. (For a discussion of Knight's criticisms of the latter's work, see Viner, 1937, pp. 475–82.) Knight gave a lucid analysis of the role of intra-marginal transfers (rents) in achieving an efficient use of resources. It was in this article that Knight explicitly dismissed external economies: ‘External economies in one business unit are internal economies in some other, within the industry’ \( EOC, \) p. 229). The last three words of this dismissal are inappropriate: the activities subject to increasing returns may fall in separate industries. Even if these activities subject to increasing returns are monopolized, that need not prevent the buyers of their products or services from experiencing external economies.

The major later work in theory was the series of articles on capital theory, directed against both the time preference theorists (‘Professor Fisher's Interest Theory: A Case in Point’, 1931) and, in a round dozen additional articles, the Austrian theory of capital. The chief of these are ‘Capital, Time, and the Interest Rate’ (1934), ‘The Quantity of Capital and the Rate of Interest’ (1936), and ‘Diminishing Returns from Investment’ (1944).

The first major theme of these articles is that the Böhm-Bawerkian theory of capital and interest is fatally flawed. In that theory labour joins with natural resources to produce capital goods (in the Wicksell extension of Böhm-Bawerk, sustenance for labourers and landlords). The process of producing further goods is time-consuming, and as a fundamental empirical law, the longer the production period, the larger the product. Knight denies the existence of any ‘primary’ factors of production which contain no capital, and equally he denies the possibility of measuring the period of production of a society or an
industry, although he would concede the possibility of measuring the period of construction or investment of a specific capital good. It is fair to claim victory for Knight over his adversaries (including Hayek, Machlup, Lange and Kaldor) on this score: the period of production concept, which had never been fertile in real applications of capital theory, has virtually vanished from the literature.

On the constructive side, Knight placed much emphasis on the correct treatment of dimensionality, with particular attention to the differences in magnitude of the stock of capital and its growth (savings) in a period such as a year. Knight believed that the long run substitution possibilities of capital for labour or for any specific form of capital such as land were immense, so diminishing marginal returns to capital either did not exist or acted extremely weakly. Accordingly, no truly long run equilibrium (such as received so much attention in classical economics) might exist:

The peculiarity of the capital market, viewing capital service as a commodity, and the interest rate as its price, is twofold: (a) the stock of the commodity is enormously large in comparison with reasonably possible additions or subtractions in any moderate interval of time and (b) under anything like normal conditions in the real world the price is definitely above any theoretical equilibrium level (as proved by the fact that the supply does increase), and the very possibility of such a level is so problematic that it really has no interpretative value whatever (JPE, 1935, p. 813).

This work encountered much more criticism (see, for example, F. Lutz, The Theory of Interest, 1966, ch. 8, and Paul Samuelson, 1943).

Throughout his career at Chicago, Knight taught a highly idiosyncratic course on the history of economics, and it is suitably represented by the famous article ‘The Ricardian Theory of Production and Distribution’ (1935). Knight's interest in intellectual history is not in the process by which it evolves but rather in the lessons it has for modern scholars; for example,

The classical theory of wages and profits contrasts with that of rent in that it continued to be controversial, while the rent doctrine was, from the beginning, accepted as definitive. This, at least, is a good sign, for the theory sheds no light whatever on the economic principles of distribution and is an amazing tissue of inconsistency and irrelevance. These reasonings are interesting and important, not merely because they illustrate the workings of the best minds in one of the most important fields of thought and have, needless to say, some relation to facts and to real problems, but especially because they serve to warn against types of fallacy which seem to be perennially natural to minds not trained to be on guard against them (History and Method of Economics [HME], 1956, p. 75).

If Knight was quite unhistorical in treating with Dogmengeschichte, he was unusually widely read and perceptive in his rare appearances as an economic historian. ‘Historical and Theoretical Issues in the Problem of Modern Capitalism’ (1928) is a fascinating commentary on Werner Sombart and the related literature on capitalism, and Knight was also the translator of Max Weber's General Economic History (1927).

This is perhaps as appropriate a place as any to point out the unceasing intellectual curiosity Knight
displayed throughout his life. He was an inveterate and usually disappointed attendant at a vast number of lectures at the university. His wide-ranging reading never ceased. On our voyage to the first meeting of the Mt Pelerin Society in 1947, a voyage made in astonishingly powerful and persistent storms, he spent the whole time in his berth re-reading Jacob Burkhardt. It was a fundamental element of his character that his intellectual explorations were directed to the question of how ‘right’ the subject of these explorations was.

The philosopher

For most present-day economists, the primary purpose of their study is to increase our knowledge of the workings of the enterprise and other economic systems. For Knight, the primary role of economic theory is rather different: it is to contribute to the understanding of how by consensus based upon rational discussion we can fashion liberal society in which individual freedom is preserved and a satisfactory economic performance achieved. This vast social undertaking allows only a small role for the economist, and that role requires only a correct understanding of the central core of value theory. That is why the larger part of Knight's writings are outside of technical economics; indeed, that is why Knight did not return to the subjects constituting the main contributions of Risk, Uncertainty and Profit.

Economic theory prescribes the efficient ways of achieving given ends: this to Knight was a pathetically small part of human activity. The effects of acts often diverge grotesquely from the desires which led to them. Wants themselves are highly unstable, and it is their essential nature to change and grow. ‘The chief thing which the common-sense individual actually wants is not satisfactions for the wants he had, but more, and better wants’ (EOC, p. 22). So man is an explorer and experimenter, a seeker for unknown and perhaps unknowable truths, a creature better understood thought the study of literature than by scientific method.

It is easy, then, for Knight to castigate the competitive enterprise economy as essentially amoral, as he does in the famous essay ‘The Ethics of Competition’ (1923). Knight does not specify the nature of the ethical principles on which he bases his severe criticisms of a competitive economic system, beyond saying they are ‘the common-sense ideals of absolute ethics in modern Christendom’ (EOC, p. 44). That is a surprising criterion for him to employ, partly because he believed that ‘the Christian conception of goodness is the antithesis of competitive’ (EOC, p. 72) but also because he believed that Christian ethics had undergone great changes over time.

In the event, he bases his criticisms of those who praise the competitive system on three general grounds. The first ground is that the defence assumes perfect competition, which is certainly not even closely approximated in real life, and indeed the competitive economy instils in people crass and vulgar tastes (including placing a ‘premium on deceit and corruption’; EOC, p. 50). The second ground is that, viewed as a game, which is what business actually is in good part, the competitive system lacks most elements of fairness (EOC, p. 60). Finally, a competitive system is triply damned because competition itself is not ethically admirable (EOC, p. 64).

Knight's argument is subject to severe limitations. Because he avoids almost all questions of quantity, he often bases his argument on polar cases. Most of men's wants, for example, are stable, and at most only a small part of men's activities are devoted to the search for new wants or the exercise of curiosity. Again, he judges actual competitive enterprise by the criterion of perfect competition, yet this would be an incongruous criterion to judge other types of economic systems. (I offer some additional comments in
Yet he was even-handed in his criticisms, and when the historians criticize the competitive organization of economic life he laments their ignorance:

Few critics of capitalism see clearly enough that the entrepreneur in his ‘control’ of production is relatively helpless as to what he shall produce, and where and when and by what instrumentalities and methods – and in particular as to what he shall pay for labour . . . . If one considers the range within which the manager can actually choose arbitrarily and remain in business, and averages out over a reasonable area and time period, it is evident that impersonal competition is after all overwhelmingly dominant (HME, p. 92).

The exploratory nature of man's goals, the infinite variety and changeability of tastes, and the mutuality of the relationship between scientist and subject in the social sciences, all led Knight to believe that positivism and behaviourism were grossly inappropriate to the study of man. (See, for example, ‘What Is “Truth” in Economics?’, 1940, reprinted in Freedom and Reform [FR], and the temperate reply of T. Hutchison, Journal of Political Economy, 1941, pp. 732–50.) The communication between individuals introduced a dimension wholly absent from the physical sciences, so the root fallacy ‘is to believe that social science should or can be a science in the same sense as in natural science’ (FR, p. 226).

On the basis of Knight's assignment of a narrow role to science in the study, let alone the control, of human behaviour, and of Knight's ethical axiom that one person should influence another only by rational discourse, he launched a series of powerful attacks on important exponents of social planning. Knight was a pungent writer and a skillful phrase maker. Instructive examples of these attacks are ‘The Newer Economics and the Control of Economic Activity’ (1932, Journal of Political Economy, pp. 433–76), ‘Bertrand Russell on Power’ (1939), Ethics, 253–85), and ‘Salvation by Science: The Gospel According to Professor Lundberg’ (1947, HME).

Although the main principles of economics are obvious, ‘even insultingly obvious’ (FR, 325), Knight despaired that they would ever be (or even could be) recognized in political life. A parable he contrived in an unpublished lecture presents this fatalistic outlook in a typical manner:

As for telling the truth in political matters – well there is a popular story of a small boy who told the truth. Not George and the cherry tree story, but the equally famous boy who made the simple observation that an emperor had no clothes on. Scientifically, there is one fault in that story; it is unfinished. I think the author was a kindly, sensitive soul, and hadn't the heart. In the story, as a story, it is of course a merit. But in a scientific lecture if should be finished, and will only take a few sentences: That evening the people awoke to the realization that they had no emperor and the wise men were anxiously discussing what to do. You can't imagine a man as emperor after he had solemnly paraded the streets as his bare self, can you? The wise men couldn't agree, of course, and the next day there was a war. And in a year a prosperous, happy nation had been destroyed and a civilization reduced to barbarism. All because a child made an innocent remark about a plain matter of fact. And back of that, because the emperor was fool enough to let people see the human being inside an emperor's togs – which certainly everyone knew was there. Truth in society is like strychnine in the individual body, medicinal in special conditions and
minute doses; otherwise and in general, a deadly poison. …

And yet, Knight did not believe that the age of liberalism was doomed by man's incapacity to engage in and abide by rational discourse in the formation of social policy. Time and again he returned to the two forces which made liberalism intolerable: the cumulative growth of monopoly and increasing inequality of income (e.g., *EOC*, pp. 291, 310; *FR*, p. 31n). Perhaps there is no paradox here: perhaps a master of theory must become a servant of casual empiricism.

Kondratieff cycles

S.N. Solomou
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Kondratieff cycles are defined as regular variations in economic growth and price movements with a periodicity of 50 to 60 years. Although the balance of the evidence suggests that such regular cycles probably do not exist, this conclusion does not amount to a dismissal of the idea of long-term cyclicality. In fact, it is quite clear that various forms of long-term cycles are an observed empirical phenomenon.

Article

Kondratieff cycles are defined as regular variations in economic growth and price movements with a periodicity of 50 to 60 years. Over time the Kondratieff cycle has also been referred to as, inter alia, major cycle, long wave, long cycle, trend cycle, secular trend, secondary secular movement, secondary deviation, trend period and mouvements de longue durée. Kondratieff (1925) argued that the pre-1920 data he analysed imply that prices move pro-cyclically with output changes; periods of inflation were associated with rapid economic growth and periods of deflation with slow economic growth. Although Kondratieff was one of the first economists to provide a thorough statistical analysis of the long cycle, he was not the first to recognize its existence. The Russian Marxist Alexandre Helphand, writing under the pseudonym of Parvus, pointed to the existence of a long cycle as early as 1901. He drew on Marx's notion of sturm-und-drang periode of capital accumulation within a long-wave perspective. In 1913 the Dutch Marxist Van Gelderen, writing under the pseudonym of J. Fedder, gave an outline of ‘springtide’ and ‘ebbtide’ long cycle phases in the socialist monthly, De Nieuwe Tijd. A
long cycle in prices was also observed in the work of Wicksell (1898), Aftalion (1913), Lenoir (1913) and Tugan-Baranovsky (1894). In *Capital* Marx referred to ‘fluctuations extending over very long periods’ and implicitly related them to investment in buildings and other fixed capital with a low turnover period. In fact, as early as 1847 Hyde Clarke referred to a 54-year economic cycle associated with astronomical and meteorological variations.

In his first study of long cycles, Kondratieff (1922) referred exclusively to literature dealing with price movements. However, in his later work Kondratieff attempted to study long cycles as a more generalized phenomenon, observed in both nominal and real variables. Kondratieff's 1925 study is the most well known in the English-speaking world, having been first translated into English in 1935. The study is mainly an empirical exercise to test for the existence of long cycles. Kondratieff fitted ordinary least squares trend lines to per capita data and then used a nine-year moving average of the deviations in an attempt to eliminate the Juglar trade cycle. These filtered deviations were used to describe the historical time profile of long cycles. The statistical methodology employed is an application of Kondratieff's 1924 paper on static and dynamic equilibrium, which distinguished between reversible (wavelike movements) and non-reversible (trend) processes: ‘The wavelike fluctuations are processes of alternating disturbances of the equilibrium of the capitalistic system; they are increasing or decreasing deviations from the equilibrium levels’ (Garvy, 1943, p. 207).

Such a methodology implies that the equilibrium structure of capitalist economies remained unchanged over the period covered by his empirical work (c. 1780–1920). The periodization developed in Kondratieff (1925) is as follows:

1st long wave: upswing 1780s – 1810/17  
downswing 1810/17 – 1844/51

2nd long wave: upswing 1844/51 – 1870/75  
downswing 1870/75 – 1890/96

3rd long wave: upswing 1890/96 – 1914/20  
downswing 1914/20 – ?

Kondratieff's early work had little to say about the generating processes for long waves; the emphasis was on describing five stylized facts:

1. During the upswing phase years of prosperity are more numerous, whereas years of depression predominate during the downswing phases.
2. The problems of agriculture are particularly severe during long wave downswings.
3. Innovations (what he called inventions) cluster during the downswing phases, and their large-scale application during the next long upswing.
4. Gold production increases during the beginning of the long upswing, and the world market for goods is generally enlarged by the assimilation of new and especially of colonial countries.
5. Wars and revolutions occur during upswing phases.

All of these five aspects of long cycles are part of an endogenous process and not exogenous causal explanations. Even war is part of an endogenous long cycle; wars originate from the ‘increased tension"
Kondratieff cycles: The New Palgrave Dictionary of Economics

of economic life, in the heightened economic struggle for markets and raw materials’ (Kondratieff, 1925, p. 539). The waves are supposed to reflect the development path of the capitalist world economy:

The long cycles of the very important elements of life established above are international in nature and for the European capitalist countries the periods of these cycles are almost coincident in time. Based on the information given above, we conjecture that the same applies in the USA. (Kondratieff, 1926, translated in Makasheva, Samuels and Barnett, 1998, vol. 1, p. 38)

Kondratieff’s theory of the generating process for long waves was developed in a paper read before the Economic Institute in Moscow in 1926. The theory was a long duration investment cycle, similar to Marx’s ten-year investment cycle:

… it may be asserted that the material basis for long cycles is the deterioration, replacement and extension of the main capital goods, with long production times and vast production costs. The replacement and extension of the stock of these items is not a smooth process but a discontinuous one, which also finds expression in long cycles of conjuncture. (Kondratieff, 1926, translated in Makasheva, Samuels and Barnett, 1998, vol. 1, p. 56)

To explain the discontinuities in re-investment, Kondratieff introduced Tugan-Baranovsky’s (1894) theory of free loanable funds. Lumpy investments require large amounts of loanable capital and, therefore, the following preconditions are needed for the upswing: (a) a high propensity to save; (b) a large supply of loan capital at low rates of interest; (c) the accumulation of loan capital at the disposal of powerful entrepreneurial and financial groups; and (d) a low price level to induce saving. The expansion has its limits in the increased interest rate and the resulting capital shortage. Thus, Kondratieff has a monetary over-investment theory of the upper turning point, similar to that of Spiethoff (1925). The lower turning point was not explained (Garvy, 1943). Kondratieff’s generating process for the long wave is similar to that of De Wolff (1924), who perceived the long wave as an echo wave, caused by the replacement of capital goods of a long lifetime, averaging 38 years. The replacement cycle was seen to be endogenous once set in motion by the Industrial Revolution of the 18th century.

Schumpeter (1939) diffused Kondratieff’s ideas in the English-speaking world and significantly refined the explanatory framework. A major refinement was to view the Kondratieff cycle in a four-phase schema of prosperity, recession, depression and recovery around an equilibrium path. With respect to the price long cycle, the classification of the four phases can be interpreted using modern economic terminology. However, since Schumpeter worked within the Austrian theoretical economic framework, the pattern of real economic growth differs significantly from that postulated by Kondratieff (Solomou, 1987, pp. 6–8). In Schumpeter the economy is modelled as consisting of two sectors (producer goods and consumer goods); during the prosperity phase of the cycle output growth remains unchanged – only the structure of production changes, with the producer goods sector expanding relative to the consumer goods sector. Aggregate output expands only during the recession phase as the gestation of the new...
investment generates increased productivity. Thus, over time, because of the impact of technical progress in a competitive environment, the price long wave is centred along a deflationary trend while output growth follows discrete upward steps.

The Schumpeterian long wave is an innovation-induced cycle. Schumpeter saw long cycles as resulting from the effects of lumpy, long gestation investments. Such investment was made possible by clusters of major innovations, such as railway and electricity networks. Many recent studies have developed Schumpeter's theory of long waves by linking the concept of product life cycles to the Schumpeterian idea of innovation clusters. For example, Mensch (1979) provides a modern restatement of Schumpeter's ideas. Mensch describes economic growth as being characterized by a series of intermittent innovative impulses that take the form of ‘S’-shaped growth trajectories. He postulates a metamorphosis model, depicting long periods of stable economic growth and relatively shorter intervals of economic turbulence. He begins with the following working hypothesis of basic innovations:

A technological event is a technological basic innovation when the newly discovered material or newly developed technique is being put into regular production for the first time, or when an organised market for the new product is first created. (Mensch, 1979, p. 123)

Mensch argues that there is limited interest in implementing basic innovation during prosperous phases of growth; in such periods only minor improvements are introduced. In contrast, during major depression phases, when the old technologies have outlived their usefulness in sustaining profitability and economic growth, there is greater pressure for introducing basic innovations induced by low profit rates on the old technology and high potential profitability on new technology.

The empirical validity of Mensch's framework is dependent on proving the existence of regularly recurring clusters in basic innovations. Mensch rationalizes innovation clusters in terms of the pressures on profitability during periods of major depressions. However, without the assumption of the long wave pattern of major depressions as a macroeconomic conditioning factor, it is difficult to see why basic innovations should cluster in the interval of a regular 50-year cycle. The explanation for regular clusters has remained a major theoretical problem in the long wave literature (Garvy 1943; Kuznets, 1940; Rosenberg and Frischtak, 1983).

Do Kondratieff cycles exist?

Most economists find the empirical evidence for Kondratieff cycles to be weak. Garvy (1943) concluded that the waves identified by Kondratieff are, in part at least, statistical artefacts resulting from the techniques he employed to analyse long-run time-series data. Lewis (1978) concluded that long waves in production are not observed for the four major industrial economies (Britain, France, Germany and the United States) or for the weighted sum of these economies. Using spectral analysis (which is a statistical technique for analysing the existence of cycles of different durations), Van Ewijk (1981) found no evidence for the existence of a Kondratieff cycle in aggregate production. Beenstock (1983) examined Kondratieff's original data with the technique of spectral analysis and found no evidence of long cycles in either nominal or real variables.
Kondratieff mainly analysed price and production data from Britain and France. The focus of recent research has been on the major industrial countries of the period. In the case of Britain, most quantitative studies fail to find a pattern of Kondratieff long waves since 1850. Matthews, Feinstein and Odling-Smee (1982) recognized that British economic growth has shown long-run variations but did not observe Kondratieff cycles. Others (Van Duijn, 1983; Kleinknecht, 1987; Solomou, 1987) found a similar result. Lewis (1978) analysed industrial production trends over the period 1850–1913 and failed to find evidence of a Kondratieff cycle growth pattern.

Most studies have also failed to find evidence of Kondratieff cycles in the production trends of the US economy. Lewis (1978) focused on the period 1860–1913 and failed to find a long wave in industrial production. Solomou (1987) analysed data for the period 1870–1973 and failed to find a Kondratieff cycle in GDP growth: the most significant long-run growth variations are associated with the growth stagnation of the 1930s and the resurgence of growth in the 1940s. More recent examinations of economic growth in the USA point to one ‘big wave’ over the century after c.1870 (Gordon, 1999). Studies that have used the Kondratieff cycle to model the path of US economic growth have done so under restrictive assumptions: Bieshaar and Kleinknecht (1986) found a Kondratieff cycle in US GDP growth after 1890. A fast growth phase during 1890–1913 or 1890–1929 gives way to stagnation in the 1930s and is followed by a strong revival of economic growth after 1940. Metz (1992) also found a Kondratieff cycle over the period 1889–1979; however, this result is dependent on excluding the world war shocks and neglecting the available evidence for the 1870s and 1880s; with the war years included, the period of the long cycle is reduced significantly to the Kuznets swing periodicity. Given the importance of historical shocks to the growth process, it is difficult to justify a procedure that interpolates the war years. Similarly, neglecting the information on the 1870s and 1880s leads to a distorted picture of the US growth process during the period 1870–1913. Taking both sets of information into account results in the conventional picture that the US economy manifested a Kuznets swing growth process both during the classical gold standard period (Abramovitz, 1968) and in the period since 1913 (Hickman, 1974; Solomou, 1987). Although there are interesting long-term cyclical features, they are much longer than the Kondratieff wave period.

Similar results have been reported for France and Germany. During the period 1850–1938 the dominant long fluctuation in both economies is a Kuznets swing pattern of 20–25 year cycles (Lévy-Leboyer, 1978; Solomou, 1987; Van Duijn, 1983; Metz, 1992). Only after the Second World War is there evidence of Kondratieff-type trend periods.

Van Duijn (1983) has argued a case for the existence of Kondratieff waves in the world economy. Van Duijn found that, although the evidence for long cycles is weak, when we examine the growth path of individual countries there is stronger evidence for long cycles in the growth path of the world economy:

Great Britain, the USA, Germany and France each have their own histories, in which the S-shaped life cycle of economic development may be more conspicuous than long wave fluctuations. The industrialized world as a whole, or even the four core countries taken together, moves forward along a long wave path. (Van Duijn, 1983, p. 154)

The production trends of the world economy provide some support to this view. The long-run growth
Kondratieff cycles: The New Palgrave Dictionary of Economics

pattern in Maddison's (1982; 1995) world GDP series (a weighted average of GDP in the 16 major economies) suggests a pattern of long-run economic growth that is consistent with Kondratieff cycles since 1870. World exports show a similar pattern to world production trends (Lewis, 1981). It is important to emphasize, however, that this evidence cannot prove the existence of a propagation mechanism that generates long cycles as an endogenous economic process in the world economy. A number of shocks have played an important role in generating the phases of upswing and downswing in world economic performance. Solomou (1986) accounted for the upswing in world economic growth during 1890–1913 as the outcome of two main influences. First, countries were growing at differential rates during 1870–1913. Thus, while GDP in Britain and France grew at two per cent or less annually, the German rate averaged three per cent and the US rate four per cent. As the weight of the fast-growing economies increased over time, the world economy saw a stepping up of long-run economic growth. Second, many smaller countries started growing at a higher rate after 1890. Thus, to understand the ‘upswing’ of 1890–1913 we need to understand why countries industrialize when they do rather than why economic growth follows a long cycle. Both these effects are outcomes of one-off historical processes rather than being part of a cyclical structure in world economic growth, generated by technological developments. A similar historical perspective can be argued as explanations for the episodes of growth of the inter-war period and the post-war golden age.

Based on the evidence considered, Kondratieff cycles of a regular period probably do not exist. In reaching this conclusion it is important to stress that this is not a dismissal of the idea of long-term cyclicality. In fact, it is quite clear that various forms of long-term cycles are an observed empirical phenomenon. The idea that technological change is an important determinant of modern economic growth is a general truth among economists. However, determining the details of this hypothesis raises important questions for the long-cycle literature. One hypothesis is the idea that the path of major technological change is depicted as a series of general purpose technologies (GPTs). This idea has its roots in Schumpeter's theory of Kondratieff cycles – because in Schumpeter major innovation is clustered in time, the effects of clustering are at the heart of growth swings. Although the idea that there are regular 50-year Kondratieff cycles, resulting from major innovation clusters, remains a questionable empirical hypothesis, the characterization of technological change as a series of GPTs that appear episodically and have a profound effect on the growth process has received much attention in the literature on economic growth since the 1990s. Much of this work has been theoretical in nature, informing us of possible outcomes but offering no insights on actual historical economic growth. A number of macroeconomic growth hypotheses that work with fairly simple prototype models of GPTs have been accepted in the literature. For example, much of the literature argues that the diffusion of a new GPT will be correlated with a productivity slowdown in the early diffusion stage and, with long lags, will be followed by a productivity acceleration or bonus. Studies that have seen modern economic history as displaying a sequence of GPTs have used this idea as a basis of a theory for long cycles of the type that Kondratieff discussed (Freeman and Louçã, 2001). However, such models are, at present, simple thought experiments and have serious limitations when used to capture historical paths. For example, Lipsey, Bekar and Carlaw (2005, p. 384) argue that all models to date share the common problem that they deal with a complex historical economic system inappropriately, seeing economic growth as the outcome of a single GPT. In reality, at any point in historical time the growth process is the outcome of different GPTs at different stages of their life cycles, and as such the link between a new GPT and economic growth is not uniquely determined. Hence, although episodic long cycles are a
feasible historical outcome, we cannot assume that they will give rise to 50-year cycles. However, the concept of episodic and ‘stochastic’ long cycles may end up being a useful tool in understanding long-run economic growth and economic cycles more broadly understood.

Article

Kondratieff (also transliterated Kondrat'ev) was born in Russia on 4 March 1892. At the age of 13 he joined the Socialist Revolutionary Party. In 1915 he graduated from St Petersburg University with a First Class degree, having followed courses given by, among others, Tugan-Baranowsky. In the Soviet Union he established his reputation with his studies of the domestic economy, particularly agriculture. In October 1917, at the age of 25, he was appointed Deputy Minister for Food in the provisional (Kerensky) government, although this appointment lasted for only a few days. Kondratieff’s professional career was associated with the Moscow Conjuncture Institute, which he founded and directed between 1920 and 1928.

Much of Kondratieff’s work at the Conjuncture Institute consisted of obtaining accurate statistical information on the agricultural sector, including the sectoral terms of trade faced by farmers, the so-called ‘peasant indices’. These indices provided disaggregated information about the prices faced and received by the farming sector, and were calculated for the Soviet Union as a whole and for regions with different types of farming. The indices allowed Kondratieff to address the ‘scissors crisis’ by showing that the prices of farm products, relative to the cost of goods purchased by farmers, had declined during the 1920s. During 1923–5 his detailed knowledge of the agricultural sector allowed Kondratieff to prepare the first Five Year Plan for agriculture, proposing policies that did not place undue burdens on farmers. As a proponent of the New Economic Policy (NEP), he advocated a development strategy that emphasized the primacy of agriculture and the consumer goods sectors over the development of heavy industry. The abandonment of the NEP and the power struggles in the Communist Party saw Kondratieff’s influence decline and in 1928 he was removed from the directorship of the Conjuncture Institute, which was closed in 1929. He was arrested in July 1930, accused of heading the ‘Working
Peasants’ Party’ and given an eight-year prison sentence. Kondratieff’s daughter, Elena Kondratieva, has confirmed that his arrest in 1930 came after he had organized a meeting of ‘dissidents’ in his home (Makasheva, Samuels and Barnett, 1998, p. xiv). At the end of this sentence he was tried again and sentenced to be executed. In fact, as early as August 1930 Stalin wrote a letter to Molotov asking that Kondratieff be executed (Barnett, 1995, p. 437).

In the West, Kondratieff is mainly known as an applied economist working on long cycles. The Kondratieff cycle became an aspect of Joseph Schumpeter’s three-cycle schema, whereby the economic system was seen to display a short nine-year Juglar cycle, a medium-term Kuznets swing of 20 years and a long Kondratieff cycle of 55 years. Over the interwar period Kondratieff became a respected economist in the West, and his ideas on long cycles generated discussion from leading economists, including Schumpeter, Kuznets, Frisch and Tinbergen. Respect for his work is shown by the fact that Kondratieff became one of the founding Fellows of the Econometric Society in 1933 (Freeman and Loucã, 2001).

Kondratieff worked on long waves between 1919 and 1928. His interest in long waves may have been inspired by Tugan-Baranovsky, whom Kondratieff regarded as the ‘greatest Russian economist of all time’ (Jasny, 1972, p. 159). Kondratieff first outlined his theory of long waves in 1922. The manuscript was ‘lost’ by its Soviet publisher in 1921 but was rewritten from notes. The evidence was drawn exclusively from price trends and the conclusions were tentative: ‘We consider the long cycles in the capitalistic economy only as probable’ (1922, p. 255). A fuller analysis of long waves was offered in ‘The Major Economic Cycles’, which first appeared in 1925. In this paper Kondratieff analysed both price and production trends in Britain, France and Germany, and concluded that long waves are ‘at least very probable’. This paper was purely descriptive and did not offer a theory to explain the cycle. The explanation for long cycles, in terms of reinvestment cycles of capital goods with a long lifetime, was given in a paper read before the Economic Institute in Moscow in 1926 and published in 1928.

Soon after Kondratieff was removed from the Conjuncture Institute, the official Soviet Encyclopaedia (Bolshaya Sovetskaya Entsiklopediya) referred to his theory on the major cycle in a single sentence: ‘This theory is wrong and reactionary.’ This claim to knowledge is clearly unscientific. Kondratieff was an applied economist who used historical evidence to pose questions that remain as relevant today as they were in the interwar period.

Article

T.C. Koopmans was born in 1910 at ‘s-Graveland, The Netherlands, and died in 1985 at New Haven, USA. His MA was from Utrecht in 1933 in mathematics and theoretical physics, and his Ph.D. was from Leiden in 1936 in mathematical statistics with applications to economics. His career was rather peripatetic for eight years: the Netherlands School of Economics, the League of Nations in Geneva, Princeton University, New York University, the Penn Mutual Life Insurance Company, and the Combined Shipping Adjustment Board in Washington (where he worked on the problem of optimizing the allocation of ships during the Second World War). Then in 1944 he joined the Cowles Commission for Research in Economics at the University of Chicago, where he remained until 1955 when the entire Cowles group moved to Yale. He retired from Yale in 1981. He was Research Director of the Cowles Commission at Chicago from 1948 to 1954, and of the Cowles Foundation at Yale from 1961 to 1967. He was a member of the economics faculty at Chicago from 1946 to 1955, and at Yale from 1955 to 1981.

His work earned him great honours. He was elected President of the Econometric Society in 1950, Distinguished Fellow of the American Economic Association in 1971, and its President in 1978. He received the Nobel Prize in economics jointly with Leonid Kantorovich in 1975.

He was a gentle and quiet man. His avocations were chess and music, both composing and playing the piano and the violin. He was dedicated to the search for knowledge, so much so that in the late 1960s, when the American Economic Association asked him to be its President, he declined on the ground that he had too much research he wanted to do. It was only after his friend and colleague Jacob Marschak died while president-elect that Koopmans accepted the association's second call to its presidency.

He was a theorist by nature, but a theorist interested in real problems. He made fundamental contributions not to just one but to three areas of economics: econometric methods, activity analysis (including linear programming), and the theory of optimization over time (including optimizing the use of energy and natural resources). His work was marked by precise statements of postulates and theorems, with rigorous proofs.
His doctoral dissertation (1937), now a classic, foreshadowed the style of his important later contributions to econometric methods. In it he brought the insight of Frisch and the rigour of R.A. Fisher to linear regression when all variables are subject to errors of measurement. He postulated that these errors are serially independent, and jointly normally distributed with a covariance matrix $\sigma^2\varepsilon$. He derived maximum likelihood estimators of $\sigma^2$ and of the equation's coefficients, but showed that they depend upon $\varepsilon$, which in general cannot be estimated. Hence, if an incorrect $\varepsilon$ is used in place of $\varepsilon$ an ‘error of weighting’ results which does not go to zero as the sample size increases. He then showed (inter alia) that under favourable conditions this error is confined to an easily calculated region: If $\varepsilon$ is diagonal (that is, if the errors of measurement are independent not only across time but across variables), and if the elementary regressions (each obtained by minimizing parallel to a coordinate axis) agree as to the signs of the coefficients, then the weighted regression vector based on any diagonal $e$ must lie in the closed space angle that is defined by the elementary regressions and that includes the orthogonal regression vector.

Koopmans later turned to the simultaneous-equations case, assuming that each equation contains a stochastic disturbance, but that variables are measured without error. He and his co-workers made a fundamental contribution to econometric methods by solving two closely related problems that arise in such models. The identification problem concerns conditions under which simultaneous equations can be estimated at all. The estimation problem concerns how to avoid the bias inherent in least squares estimators of simultaneous equations, and obtain good estimators.

Economists had struggled with these problems for decades, with varying degrees of success or generality. Then Mann and Wald (1943) and Haavelmo (1943; 1944) in seminal pieces laid the foundations for the solution, by formulating an explicit stochastic simultaneous-equations model and considering the joint distribution of the jointly dependent variables as a function of the stochastic disturbances and the predetermined variables.

Koopmans, Rubin and Leipnik (1950c) worked out the solution to both the identification and the estimation problems in a long and technically difficult paper, which was first presented at a conference at the Cowles Commission in 1945. Much more readable papers about it are Koopmans (1945) and (1949c). Related pieces are Koopmans (1950b) and Koopmans and Hood (1953b).

An equation is said to be identified if, sampling variation aside, a unique vector of values for its parameters (up to multiplication by a nonzero constant) can be deduced from data for the variables in the model to which the equation belongs. Otherwise it is unidentified. A familiar example of unidentified equations occurs in a two-variable price-quantity model of supply and demand, where data for price and quantity allow one to estimate the intersection point of the supply and demand equations, but not the slope or intercept of either equation.

Koopmans and his colleagues considered a linear simultaneous-equations system of $G$ equations in $G$ jointly dependent variables, with $T$ observations. In modern notation it can be written as

$$\forall T + XB = E \quad \text{or} \quad ZA = E$$  

(1)

Here $Y$ and $X$ are matrices of data for jointly dependent and predetermined variables, of order $T \times G$ and $T \times K$, respectively. $E$ is a $T \times G$ matrix of unobservable stochastic disturbances, serially independent, with mean zero and $G \times G$ unknown covariance matrix $\Sigma$. $\Gamma$ and $B$ are matrices of unknown parameters, $G \times G$ and $K \times G$ respectively. $Z$ is $(YX)$ and $A$ is $(\Gamma' B')'$. Necessary and sufficient conditions were derived for the identifiability of the parameters $\Gamma$ and $B$, that is, of $A$. Consider first the simple case where the only a priori information about $A$ and $\Sigma$ consists in the knowledge that certain elements of $A$ are zero (meaning that certain variables do not appear in certain equations). Then a necessary and sufficient condition for the identification of the $i$th equation in the system (called the rank condition) is that the rank of a certain criterion matrix be equal to $G - 1$. This criterion matrix is obtained from $A$ by omitting just those rows of $A$ in which the element in the $i$th column is not required to be zero. Thus the criterion matrix can never have rank greater than $G - 1$, because its $i$th column is zero. Hence a necessary condition for the identification of the $i$th equation (called the order condition) is that its criterion matrix have at least $G - 1$ rows, that is, that at least $G - 1$ of the model's variables be excluded from it. In practice, if an equation satisfies the order condition, it is likely to satisfy the rank condition as well.

Koopmans and his colleagues also derived identifiability conditions for a type of a priori restriction that deals with two or more elements of $A$ which may be in the same or different equations of the model.

In general, least squares estimators of simultaneous equations are biased if their expectations exist at all, and are inconsistent. Koopmans and his co-authors defined the reduced form of the model (1) as its algebraic solution for the jointly dependent variables,

$$\gamma = -XB\Gamma^{-1} + E\Gamma^{-1} \equiv X\Pi + V$$

(2)

where the reduced form’s coefficients and disturbances $\Pi$ and $V$ are defined by the last equality in (2). Then the covariance matrix of $V$ is $\Gamma^{-1}, \Sigma^{-1}$, denoted by $\Omega$. They showed under their assumptions that the reduced form parameters $\Pi$ and $\Omega$ are identified, and that when the disturbances are normally distributed, least squares estimators are maximum likelihood estimators and are consistent.

They also derived maximum likelihood estimators of the model’s identified parameters $\Gamma$, $B$, and $\Sigma$, and showed that they are consistent. This was done as follows. The likelihood function of the normally distributed reduced-form disturbances $V$ is

$$(2\pi)^{-GT/2}\det^{-T/2}\Omega\exp\left[-(1/2)\text{tr}(\Omega^{-1}V')\right].$$

(3)

By substituting for $V$ from the reduced form (2), and subsequently substituting for $\Pi$ and $\Omega$ from (2), this is transformed in two steps to

$$= (2\pi)^{-GT/2}\det^{-T/2}\Omega\exp\left[-(1/2)\text{tr}(\gamma - X\Pi)\Omega^{-1}(\gamma' - \Pi'X')\right] = (2\pi)^{-GT/2}\det^{-T/2}(\Gamma^{-1}, \Sigma^{-1}) \times \exp\left[-(1/2)\text{tr}(\gamma + XB)\Sigma^{-1}(\gamma' + B'X')\right].$$

(4)

Then the logarithm of this likelihood function is maximized with respect to the parameters $B$, $\Gamma$, and $\Sigma$, subject to the identifying restrictions. The result is the full-information maximum likelihood estimator of $B$, $\Gamma$, and $\Sigma$.

These developments created a revolution in the theory and practice of econometrics. Subsequent work by associates of Koopmans led to the limited information maximum likelihood estimator, which is much simpler than the computationally demanding full-information estimator. Later work by Theil, Zellner, and many others led to the still simpler two-stage least squares estimator and related estimators such as three-stage least squares. Koopmans can fairly be said to be the father of simultaneous-equations econometric methods, though it is clear that there were grandfathers and great-grandfathers too.

In addition to econometrics, Koopmans made outstanding contributions in several areas of economic analysis, both theoretical and applied. The extent to which the two aspects complement each other is particularly striking in his work in activity analysis and linear programming. On the applied side, Koopmans’s interest in this area seems to stem from an investigation into tanker freight rates and tankship building (1939). The book on this subject, apparently his earliest published
work in economic (as distinct from econometric) analysis, has the subtitle *An Analysis of Cyclical Fluctuations*, and is indicative of his interest in the major macroeconomic issue of the 1930s, the business cycle. Other contributions dealing with business cycles appear in the early 1940s (1940; 1941; 1949b), although mainly concerned with econometric orientation. Subsequently Koopmans's macroeconomic interests shifted to the prevention of threatened post-Second World War inflation, a concern prevalent in the early 1940s (1942a; 1943). But his responsibilities with the Combined Shipping Adjustment Board pushed him in the direction of efficient resource allocation problems, applied to Allied freight shipping during the Second World War period. A memorandum (1942b), published for the first time in the *Scientific Papers of T.C. Koopmans* (1970), lays the foundation for what subsequently would be called activity analysis and linear programming. More specifically, the 1942 memo and more elaborate treatment (1949a) presented in 1947 at the International Statistical Conference deal with efficient utilization of transportation systems, a problem treated again (jointly with Reiter) in a more general setting in a paper presented at a memorable conference held in Chicago at the Cowles Commission in 1949 (1951). Koopmans' 1942 work on the transportation problem was done without awareness of the earlier (1941) study by Hitchcock and of the contributions due to Kantorovich (1939; 1942), von Neumann (1935), and Dantzig (1951a; 1951b; 1951c). The product of their insights and analyses, named *activity analysis*, is a model of production involving not only commodities (inputs and outputs), but also explicit recognition of the processes used in the course of production. With each process is associated a non-negative (scalar) variable, called the level of activity representing that process. Let $x_k$ denote the level of $k$th activity (from among $K$ possible ones), and let $y_n$ be the net output of the $n$th commodity (from among $N$ commodities present), with a negative value corresponding to an input. Technological information defines relations specifying the net outputs as a function of activity levels, say

\[ y_{nk} = f_{nk}(x_k), \quad n = 1, \ldots, N; \quad k = 1, \ldots, K. \]  

(5)

Thus for a given level $x_k$ of the $k$th activity, the function $f_{nk}$ specifies the amount of $y_{nk}$ of resulting net output (positive, negative, or zero) of the $n$th commodity. The equation system (5) allows for non-linear production relations, but most early work postulates linearity, in the sense that the ratio of net output to activity level is independent of the level of that activity. So (5) is specialized to

\[ y_{nk} = a_{nk}x_k, \quad n = 1, \ldots, N; \quad k = 1, \ldots, K \]

(6)

where $a_{nk}$ is a constant independent of $x_k$. Furthermore, as was already implicit in our notation, when several processes are carried on simultaneously, it is assumed that they do not interfere with each other. Hence the aggregate output, say $y_n$, of the $n$th commodity is formed additively from the amounts contributed by the simultaneous activities, and so

\[ y_n = \sum_{k=1}^{K} y_{nk} = \sum_{k=1}^{K} a_{nk}x_k, \quad n = 1, \ldots, N. \]

(7)
In this setting a number of problems have been studied. Optimization calls for maximization or minimization of a function, say $g(x_1, \ldots, x_k)$ of the activity levels. In linear programming models this function (like the technological relations (6)) is linear so that

$$g(x_1, \ldots, x_k) \equiv \sum_{k=1}^{K} c_k x_k.$$  

Formally, then, we have the problem of maximizing

$$\sum_{k=1}^{K} c_k x_k$$

with respect to the non-negative variables $x_k \geq 0$, subject to the technological relations (7), as well the resource constraints

$$\forall n \geq -\eta_n, \ n = 1, \ldots, N,$$

where $\eta_n$ is the amount of the $n$-th good initially available. The most important technique for solving such a linear programming problem, known as the simplex method, is due to Dantzig. Dantzig's pioneering contributions in formulating the model itself were repeatedly stressed by Koopmans, who felt that Dantzig should have shared in the Nobel prize. This recognition in no way detracts from Koopmans's own role in formulating and developing the activity analysis model and analysing its properties. Most importantly, he built a bridge between activity analysis and the conceptual framework of classical economics. This involved distinguishing between primary, intermediate, and final commodities, the analysis of the efficiency concept, and the role of prices and profits. In the latter areas, again, Koopmans was careful to recognize the relationship of his analysis to the earlier contributions, especially those of Lange (1938) and Lerner (1944). In particular, Koopmans dealt with efficiency in production by defining it in terms of the vectorial ordering in the commodity space as follows.

A commodity vector $\mathcal{V} = (\mathcal{V}_1, \ldots, \mathcal{V}_N)$ is called possible if it satisfies the technological constraints, without taking into account the limitations due to resource availability. Then a possible point $y$ is called efficient if there is no other possible point $y'$ such that $y'$ vectorially dominates $y$, that is, such that $\forall' r \geq \forall r$ for all $n = 1$ and $\forall' r \geq \forall r$ for some $r$.

An important contribution of Koopmans is the characterization of efficient points with the help of ‘accounting’ (also called ‘shadow’) prices, the condition being that no activity permits a positive profit and that the profit on activities actually carried out to be zero. The relationship of these conditions to those for
competitive profit maximization under constant returns to scale is evident. Indeed, Koopmans formulated a resource allocation ‘game’ whose equilibria would be efficient when ‘players’ follow specified behaviour rules, with activity managers expanding profitable activities, avoiding activities yielding losses, and keeping constant levels for activities yielding zero profit. Other participants for this ‘game’ are ‘commodity custodians’, whose function is to adjust prices according to the difference between demand and supply, and a ‘helmsman’, choosing prices of final goods according to specified objectives (tastes). As Koopmans pointed out, only static properties of the game follow from the rules.

Of particular significance is Koopmans’s emphasis on the informational decentralization of this ‘game’: a manager only needs to know the technology of his own process; a custodian needs only to know the availability and demand for the commodity he is in charge of. Koopmans stressed the applicability of the model both in a competitive economy (where the role of the ‘helmsman’ would be played by the consumers’ competitive bidding) and in planned economies (where prices are an accounting rather than market phenomenon).

Koopmans’ contribution in the area of activity analysis are of significance not only for their content, but also for their form and style. Their rigour and clarity became a standard, or at least an ideal, for later mathematical economics with emphasis on explicit definitions, postulates, and theorem formulations. His meticulous attention to (and acknowledgement of the work of) predecessors as well as generosity in evaluation of the contributions of others invite emulation.

In a brief article, it is impossible to do justice to Koopmans’ own accomplishments. His expository talents are particularly striking in the first of his *Three Essays* [1957], which is a model for exposition of classical welfare economics, making particularly clear which propositions depend on which assumptions – for example, absence of convexity postulates in proving the Pareto optimality of competitive equilibria.

Perhaps the most important of Koopmans’s theoretical contributions are those dealing with problems involving infinite horizon economies. A number of papers deal with optimal economic growth (for example, 1965a; 1965b, jointly with Beals; and 1973). But of particular interest are the papers (1960a, and 1964, jointly with Diamond and Williamson) concerning preferences and their representation by numerical (real-valued) utility functions over infinite horizons. Koopmans formalized the concept of impatience (introduced by Böhm-Bawerk into the theory of the rate of interest) and showed, surprisingly, that impatience is a necessary logical consequence of a set of postulates concerning utilities over infinite time horizons. Among the postulates are those of continuity and stationarity (that is, independence of calendar time).

An additional postulate is required to imply the discounted form of the utility function,

\[
U(x_1, x_2, \ldots) = \sum_{t=1}^{\infty} a^{t-1} u(x_t)
\]

where \(0 < a < 1\) and \(U(\cdot)\) is the utility function for the infinite programme \((x_1, x_2, \ldots)\). Here \(x_t\) denotes the choice \(x_t\) at time \(t\), and \(u(x_t)\) is the instantaneous ‘felicity’ experienced at time \(t\). For instance, \(x_t\) may be the consumption vector, \(x_t = (x_{1t}, \ldots, x_{lt})\), in an \(l\)-dimensional commodity space. More generally, all the \(x_t\) are assumed to be drawn from the fixed choice space \(X\), a connected subset of \(n\)-dimensional Euclidean space.

Koopmans returned to the problem of utility representation of preferences over infinite programmes in two papers (1972a; 1972b), differing from the earlier work by its formulation of the underlying postulates in terms of the preference relations rather than of a utility representation, whose existence was assumed previously in the hypotheses. In the later work, it is the preferences that are assumed to be continuous and stationary as well as to satisfy a condition of independence over time. Under these postulates the utility function of an infinite programme is shown to have certain additivity properties. A stronger conclusion is obtained, for the space of all programmes that are ‘bounded in utility.’ [A programme \(x = (x_1, \ldots)\), \(x_t \in X\) in the choice space \(X\), is said to be bounded in utility if there exist vectors \(x^*\) and \(x**\) in \(X\) such that \(x** \succeq x_t \succeq x^*\) for all \(t = 1, 2, \ldots\), where the symbol \(\succeq\) represents the (weak, that is, reflexive) preference relation. (We may note that ‘bounded in preference’ would have been a better term, since numerical utility is not involved in the definition.)] On the
space of all programmes bounded in utility preferences can again be represented by the discounted from

\[ U(x_1, x_2, \ldots) = \sum_{t=1}^{\infty} a^{t-1} u(x_t), \quad 0 < a < 1. \]

Among other contributions involving the infinite time horizon, we shall only mention Koopmans’s work on exhaustible resources, in particular the problem, of such interest in the 1970s and early 1980s, of transition from exhaustible to renewable resources. Closely related to this area of interest was Koopmans’s work on the modelling of alternative energy futures reflected in (1980) and the guidance he provided as chairman of the Modeling Resources Group of the Committee on Nuclear and Alternative Energy Systems (CONAES) of the National Academy of Sciences (1975–8).

The latter study exploited Koopmans’ lifelong interest in the relationship between economics and physical sciences. His first published papers were in physics, and his presidential (American Economic Association) address in 1978 was entitled ‘Economics among the Sciences’ (1979).

This talk was in part based on observations made in the course of the energy modelling study and dealt with the difficulties in communication between physical scientists, engineers, and economists, illustrated by several examples, including the problems of discounting future costs and benefits. The address also pointed to the university procedures for academic appointment and promotion as barriers to interdisciplinary contacts.

While concerned about the relationship to physical sciences, Koopmans did not neglect the ethical issues implicit in the various criteria of optimal growth, especially the problems of balancing the consumption levels of successive generations (1967a; 1967b). Technically, the problem arises because an ‘optimal’ solution may fail to exist in an infinite horizon setting. When future enjoyments are discounted but the discount factor falls below a critical value, it turns out that a further postponement of some future consumption raises the utility of the overall programme. Since, with an infinite horizon, a postponement is always conceivable, no programme is ‘best’. Koopmans’ conclusion was that ‘one cannot adopt ethical principles without regard to the anticipated population growth and to the anticipated technological possibilities’, and that ‘ethical principles … need mathematical screening to determine whether in given circumstances they are capable of implementation.’

In some models, given the discount rate, the existence of an optimum depends on the shape of the instantaneous ‘felicity’ function \(u(\cdot)\), and so does the shape of the optimal path when existence conditions are satisfied. Koopmans regards as debatable whether the choice of the felicity function \(u(\cdot)\) is an empirical or ethical question. He points out the paucity of empirical evidence concerning the asymptotic elasticity of marginal felicity at high consumption levels which is critical for the existence of an optimum. He then expresses concurrence with a remark due to Malinvaud that ethical judgments may be easier to base on comparison of optimal paths generated by alternative felicity assumptions than on ‘direct and aprioristic’ comparisons of the felicity functions themselves.

The depth and breadth of his scientific contributions as well as his influence on others (including these writers) amply justify the judgment of the Nobel Committee, as well as Scarf’s (1985) characterization of Koopmans as the ‘leader of a scientific revolution’, a revolution ranging over econometrics and economic analysis.

Abstract

The study of economics in Korea is a modern development, starting around the turn of the 20th century, influenced by the West, at first through Japan and since the end of the Second World War mainly through the United States. Over time, it has become a clone of economics in the USA, with an overriding concern for mathematization and econometrics. Even so, the Korean term for economics, kyung-je-hak, which derives from a classical Chinese expression for good governance, reveals the prevailing conflation of science and governing techniques.

Keywords

classical economics; German Historical School; Japan, economics in; Korea, economics in; Korean Economic Association; marginal economics; Marxist economics; neoclassical synthesis; protectionism; United States, economics in (after 1945)

Article

The 19th century

Before the turn of the 20th century, there was not much economic analysis to speak of in Korea. Of course, as a country settled continuously over 2,000 years, Koreans had a variety of administrative techniques concerning tax collection, budgeting, coinage, government monopolies and so forth. But there was hardly an attempt to organize observations on economic matters along general principles. The situation in Korea was not very different from that in most pre-industrial economies.

In the 18th century, in the aftermath of a series of foreign invasions from Japan and Manchu, a group of reform-minded thinkers, Shil-Hak-Pa, wrote pamphlets proposing measures to ameliorate economic devastation and social instability. But there was no economic analysis beyond the simplest form of common sense; and the school was subsequently suppressed as subversive. At the end of the 19th
century, when Korea was encircled by imperialist powers and its independent status became precarious, a few Korean students were sent to Japan to study the secrets of a ‘prosperous nation and strong army’. Some thereby encountered classical economics and viewed free competition as a means of creating a prosperous nation. The attempts to learn from the West and reform the country, however, came too late; Korea became a Japanese colony in 1910.

**The Japanese colonial period**

During this period, Korean economists, mostly trained in Japan, were few in number and predominantly Marxists, doing economic history from a Marxian perspective. The reasons had to do with contemporary economics in Japan and what many colonial people took Marxism to be at the time. Earlier, in the mid-19th century, classical economics was studied in Japan. From the 1880s, however, the German Historical School, critical of classical economics and providing a rationale for protectionism and nationalism, became the vogue among Japanese economists. (Note that economists in the United States were also heavily influenced by the Historical School, giving rise ultimately to American Institutionalism.) Another import from Germany was Marxism. By the 1920s, Marxism and the Historical School had become the dominant traditions in Japan. Protectionism and Keynesianism were later introduced, but they had a limited influence on the Japanese during this time. Broadly speaking, Korean students had to choose between the two dominant traditions in Japanese economics. As the Historical School was seen as providing a rationale for Japanese fascism, most Korean students of economics were attracted to Marxism, which represented anti-imperialism and anti-capitalism. As the Japanese did not appoint Koreans to faculty posts in Japanese universities (not even those located in Korea), Korean economists taught at a handful of private colleges founded by Koreans. However, from the early 1940s the Japanese repression of Korean nationalism and communism meant that most Korean academics were imprisoned and students sent either to the front line or to armaments factories. The surrender of Japan at the end of the Second World War and the liberation of Korea abruptly ended this state of affairs.

**Post-Second World War to the Korean War**

In the liberated Korea Marxist economists were restored and became dominant, as in Japan. Korea was partitioned and occupied by the two victors of the Second World War, the northern half by the USSR and the southern half by the United States. Ideological conflicts ensued as the occupiers delegated power to the locals and Korean Marxists abandoned all academic pretensions. During the subsequent internecine Korean War (1950–3), Marxists and their sympathizers were completely eradicated from South Korea; they all moved to Communist North Korea, where they were subsequently purged. What was left in South Korea at the end of the war, therefore, was only a handful of non-Marxist Korean economists who had been trained in Japan.

**Post-Korean War to the present**

Since the post-war era economics in South Korea has by and large become Americanized. Although a
worldwide phenomenon, this is particularly pronounced in Korea, since the country became completely dependent on US military and economic aid after the destructive war. In the late 1950s and the early 1960s the US government and UN organizations sent advisers, many of whom were New Dealers and/or Keynesians. During this period some Korean economists formerly trained in Japan visited American universities, or received additional training there. The first fruit of the initial contacts with the United States was a flurry of translations of economic literature, ranging from classical, neoclassical and Keynesian economics to development economics. In the 1970s there was a noticeable slowdown in translations and the concomitant publication of a number of popular economics textbooks in Korean, which closely resembled the then popular American economics textbooks in the tradition of the neoclassical–Keynesian synthesis. From the late 1980s, popular American textbooks began to be used, untranslated, in elite Korean universities. Since the 1980s translations of scholarly books in economics have become popular again, but not to the same degree as in the late 1950s. This in part reflects the rapid increase in the number of American-trained economists who can directly access economic literature in English. The paucity of translations also reflects the shallow roots of economics in Korea. From the late 1960s, Koreans with doctorates in economics from American universities began to return to Korea in significant numbers, increasing from the 1970s and peaking in 1990, when the figure reached over 60. In 1993, the Korean Economic Association had over 1,800 members with a Ph.D. in economics. Of these, 55 per cent had a Ph.D. from a foreign university and 43 per cent from an American university. The proportion alone understates the impact of Americanization, as the US-trained economists have come to occupy a disproportionately large share of key positions in academia, research institutes and central government in Seoul. For example, in 1993 at the top three Korean universities, the proportion of American-trained economists in the economics faculty reached over 70 per cent. In one of them, all but one had an economics Ph.D. from the United States. The process of Americanization was greatly aided by the job market for economists in Korea, which can best be characterized by institutional inbreeding and credentialism. The former is the practice of hiring graduates of one's own department, a legacy of the Japanese colonial period, and the latter the practice of hiring based on the quality of credentials. Initially, the custom of obtaining an academic post in Korea was first to get a BA (or even an MA) at an economics department in an elite Korean university, and then get an American Ph.D. Competition for credentials has become more intense. In the 1960s, an American Ph.D. was sufficient to gain an academic post. As the number of American Ph.D.s increased over time, the prestige of the school awarding the degree became significant. As more and more Koreans get their Ph.D.s from elite American universities, some teaching experience in the United States and even publications in English-language journals have become crucial for employment prospects. Economics in Korea, through the process of competition for better credentials, has come to reflect the prevalent practices of the economics department at elite American universities, with the overriding concern for publication in top journals, which necessarily implies emphasis on mathematical economics, model building, and econometrics. From the late 1980s, increasing competition for credentials has extended the period of scientific endeavours well beyond graduate school, and a few Korean economists have managed to gain mobility across the national border. Yet there is no great man in economics in Korea. Of course, there have been economists who have been celebrated on account of their contributions in the popular media, or economists who have authored
popular economic textbooks, or commanded much respect on account of having taught many able students. But no economist in Korea has attained eminence in economic science as one might have expected from the investment of so many resources. The reason is only in part that economics in Korea is essentially a post-Korean War development, or that many Korean economists decided not to return to Korea after their graduate training. The main reason is the pragmatic orientation of the majority of Korean economists (which has only very recently begun to shift).

Economics in Korea gained its prestige under the economic dirigisme of President Park (1961–79). The administration and legitimization of planning development programmes required the services of economists, which many were eager to supply. For aspiring economic advisors or policymakers, the primary concern is political expediency; during the period 1961–79, it was as if Korean economists entertained scientific concerns only while their credentials were being established, that is, during their graduate training in the United States. Afterwards, even as they taught students what they had learned in the USA, the majority of them ended up taking on diverse extra-curricular activities, including extra teaching, consulting for government bureaux and cultivating political connections. This pragmatic approach to economics has produced an army of economists who are very competent in importing techniques, but quickly cease to be members of the scientific community. The pragmatism of Korean economists is reflected in the absence of doctrinal disputes or distinctive schools of thought. Academic fashions have come and gone, largely reflecting, if with a time lag, debates that took place in the United States during students’ graduate training.

One exception has been doctrinaire Marxists whose number has increased in South Korea since the late 1980s, precisely when Marxism was being discarded elsewhere. This surprising development against the worldwide trend has been an outgrowth of reactions to the authoritarian rules of Presidents Park and Chun, in which anti-authoritarianism, pro-democracy, socialism, Marxism and nationalism had been all conflated. There is little debate between Marxists and non-Marxists, however. Marxists are more than willing to be engaged in doctrinal debate, though their concern largely focuses on who has a more faithful reading of the canon. Non-Marxist economists, the majority of Korean economists who are either US-trained or trained by other US-trained Korean economists, are pragmatists in their teaching and advice, generally seconding the popular preference for a welfare state of the European variety.

Outwardly, economics in Korea has become fully internationalized. Over 50 per cent of Korean economists with a Ph.D. have been trained overseas, the overwhelming majority in the United States. Most are competent in the techniques of modern economics, familiar with the relevant literature, an increasing number of them are publishing in international journals, and a few have even gained international job mobility. Yet if economics in Korea is to progress beyond the stage of competently importing the latest academic trends and techniques, more Korean economists will have to become less pragmatic and begin to examine basic questions.

Irving Kravis is best known for his pioneering empirical estimates of country purchasing power parities (PPPs) and real products based on detailed price and expenditure comparisons. This research began in the early 1950s at the Organisation for European Economic Co-operation (OEEC, now OECD) in collaboration with Milton Gilbert. It was continued on a world scale when he jointly directed the United Nations International Comparison Project from 1968 to 1982. However, these contributions were just the most notable in a career that included yeoman service to the University of Pennsylvania: in building up the Department of Economics, in serving as Associate Dean of the Wharton School and chair of the University Senate, and in active participation in many important committees of the School of Arts and Sciences and the university.

With the exception of the Second World War, Kravis's career was all at the University of Pennsylvania, where he studied as both undergraduate and postgraduate and to which he returned as a faculty member in 1947. His mentor at Penn was Simon Kuznets, whose influence on Kravis's work shows in many ways, including the strong belief in and practice of making research replicable. Like many of his generation with economic and statistical training, he worked for the War Production Board during the Second World War, but only partly in Washington. Raymond Bye at Penn and Kravis wrote *Economic Problems of War* in 1942. Kravis also served in Kunming, China, as a logistics officer and worked with Claire Chenault's Flying Tigers involved in tracking supply missions.

Kravis joined the Bureau of Labor Statistics (BLS) prior to returning to Penn. With Irwin Friend of Wharton's finance department, Kravis directed an 18-volume BLS–Wharton Study of Consumer
Expenditures culminating in a major conference in 1959. As part of this research Kravis explored facets of income distribution, which remained one of his long-term intellectual interests.

Kravis maintained a long collaboration with Robert Lipsey, focusing on international price competitiveness. Their 1985 article ‘Towards an Explanation of National Price Levels’ continues to be influential in making clear the many frictions that lead to persistent divergence of both levels and changes in the relationship between purchasing power parities and exchange rates. The law of one price is a fundamental insight in spatial economics, but, as Kravis and Lipsey make clear in much of their joint work, the flaw of one price is that, in the world in which we live, the exceptions are frequent, persistent and often systematic.

Kravis had very broad interests in the global economy, including contributions to productivity comparisons, the role of multinationals in international trade and the construction of export and import price indexes. His important 1970 article ‘Trade as a Handmaiden to Growth’ sets forth his view that expanded international trade is better viewed as accompanying rather than causing economic growth. This article continues to capture the attention of economic historians and development economists.

Kravis began his work on PPPs at the OEEC in collaboration with Milton Gilbert, Director of Economics and Statistics, and other staff members including Angus Maddison. They undertook systematic binary purchasing power comparisons between the United States and the four largest European economies, comparing prices of items with written specifications for consumption and investment. These were combined with indirect estimates of government expenditure to make international real product comparisons at the GDP level. Gilbert and Kravis concentrated on binary comparisons with the United States that produced both Paasche and Laspeyeres indexes, as was sometimes done for price indexes at the time. The spreads in these indexes were much larger than had been anticipated, especially for Italy; but it turned out to be a characteristic of such comparisons that was even more pronounced as the range of countries compared increased.

Parallel purchasing power studies were being carried out in the 1950s by the then Economic and Social Commission of Latin America, the European Economic Commission, and the Council for Mutual Economic Assistance (CMEA). These purchasing power studies were important landmarks leading to the establishment of the International Comparison Programme (ICP) of the United Nations in 1968, where Kravis served as a joint director, based at Penn, with a counterpart at the UN Statistical Office. Under his direction benchmark comparisons were carried out for 1970 for 10 and 16 countries, and for 34 countries in 1975, all involving monographs by Kravis and others. In these studies multilateral methods for purchasing power comparisons were worked out, including the country-product dummy (CPD) method of Robert Summers, which has been extended widely in recent BLS and ICP work. An extension of the benchmark work to a total of 100 countries was published in 1978; it became the basis for the current Penn World Table of Alan Heston, Robert Summers and Bettina Aten.

Acceptance of the results of the ICP was slow in coming, but by the late 1980s many economics textbooks were using PPP comparisons. After the 1975 benchmarks responsibility for this work became international, and the European Union and the OECD now routinely carry out comparisons for their 50 member and associate countries. Currently the World Bank is coordinating a global 2005 ICP benchmark comparison involving about 150 countries, a major legacy of Kravis's leadership. While the methods used in the initial ICP work are being modified, the basic multilateral framework pioneered by Kravis remains in place. During a heated debate on methods following presentation of the results of the first ICP benchmark, the late Nancy Ruggles observed that the important thing was not which method...
was used but rather that a multilateral PPP comparison was actually completed. It took the focus, patience, wisdom and good humour of Kravis to produce these initial multilateral PPP comparisons in a timely manner and of a quality that has led to their adoption on a global basis.

Kuznets swings refer to variations in economic growth with an average cyclical period of 20 years. The evidence suggests that for the period before the First World War long swings were a dominant and pervasive aspect of national economic growth. Abramovitz (1968) argued that Kuznets swings were a feature only of the pre-1913 era, partly because the migration restrictions introduced in the New World during the interwar period changed the causal process. We consider this idea and argue that, although the features of long swings are time-varying, the idea of a ‘passing of the Kuznets cycle’ needs to be re-evaluated.

Article

Kuznets swings refer to variations in economic growth with an average cyclical period of 20 years. The average period of the swings found varies depending on the specific smoothing and trend elimination techniques employed (Bird et al., 1965). Kuznets (1958), Abramovitz (1959) and Lewis and O’Leary (1955) found mean swings of 22, 14 and 19 years respectively. The existing historical evidence suggests that for the period before the First World War long swings were a pervasive aspect of national economic growth, being observed in a wide set of economies, including the United States, Argentina, Australia, Brazil, Britain, Canada, France and Germany (Solomou, 1987). Similar results have been reported for Japan (Ohkawa and Rosovsky, 1973; Ohkawa, 1979; Shinohara, 1962).

Long swings have often been explained as the outcome of the pre-1913 economic structure, with population-sensitive investments playing a central role. The emphasis has been on the Anglo-American
Kuznets swings: The New Palgrave Dictionary of Economics

economies, with the aim of explaining the economic impact of international migration. Kuznets (1958) suggested that internal and international migration responded to development opportunities in the American economy, inducing multiplier–accelerator effects via the building sector. Abramovitz (1959; 1961) and Easterlin (1968) have offered similar explanations. Working from the migration perspective, Thomas (1973) attempted to explain migration and aggregate long swings in terms of the framework of the ‘Atlantic Economy’ (of Britain and America). The high degree of economic integration in the Atlantic economy implies that the availability of factors of production was a constraint on economic growth within the region. An increase of investment in one region was assumed to result in a decrease of investment in the other region. Since construction activity was greatly influenced by population changes, which, in turn, were influenced by migration movements, migration was seen to be the main force generating inverse swings in output and investment in the Atlantic economy.

That exogenous migration movements can generate macroeconomic swings is theoretically plausible. However, to the extent that migration patterns are influenced by economic considerations, Thomas's (1973) model is misleading; the description of endogenous economic processes has been confused with an exogenous explanation of economic change. Moreover, the emphasis on migration as the causal variable has led to a neglect of other important determinants of long swings in economic growth. Cairncross (1953) focused on the variation of the international sectoral terms of trade between manufacturing and agriculture in the world economy. Britain, France and Germany were representative of industrial economies producing manufactured commodities while much of the rest of the world was taken to represent the primary-producing sector. Investment flows in the international economy were determined by the relative profitability of these two sectors. Migration flows were not an exogenous force generating long swings but were merely a response to these underlying economic variations. In Cairncross's framework, sectoral terms of trade changes reflected long-run sectoral imbalances in the world economy:

One would expect to find, therefore, that during, or immediately after, a fairly long period in which the terms of trade were relatively unfavourable to Britain there would be heavy investment in the countries supplying her with imports … On the other hand, when capital goods were expensive and foodstuffs were in over-supply, the continuance of a rapid opening up of agricultural countries would be distinctly surprising. (Cairncross, 1953, p. 189)

Cairncross argued that a similar experience is also observed for the other major capital exporters. All these early studies of pre-1913 long swings emphasize monocausality, partly due to the limited macroeconomic and sectoral data available to the early researchers. Solomou (1987) has shown that long swings were observed for, inter alia, aggregate investment, profitability, output, productivity, agricultural output, construction output, weather variables, monetary growth, sectoral terms of trade and migration flows. The swings also have international dimensions; they are observed for overseas investment, international terms of trade and international relative profitability movements, and the balance of trade. Such evidence raises strong doubts about the simple migration and terms of trade explanations for these swings – instead, these variables are best seen as part of a broader causal structure for the observed swings.

Abramovitz (1968) argued that Kuznets swings were a feature only of the pre-1913 era, partly because the migration restrictions introduced in the New World during the interwar period changed the causal process for long swings. However, in arguing the case for 'the passing of the Kuznets swing' Abramovitz is relying on the validity of the prior hypothesis that growth swings of this duration were the outcome of international migration swings. As argued above, this offers a partial perspective on pre-1913 growth swings. Abramovitz's idea of the passing of the Kuznets swing is inconsistent with evidence on historical economic growth that suggests that long swings were observed after 1913, implying that a much broader causal framework is needed. For example, in the US economy the long-swing pattern of macroeconomic growth continues into the interwar and post-war eras (Hickman, 1974), with domestic migration swings playing an important role in the period after 1914 (Easterlin, 1968; Hickman, 1963). In Japan long swings of growth are observed throughout the period before the Second World War (Shinohara, 1962; Solomou and Shimazaki, 2007), accounted for by a broader causal structure than is emphasized in the traditional long-swing literature. This suggests that seeking an explanation for change in the features of long swings is more useful than seeking an explanation for a unique 'passing'.

After surveying American long swings in the period 1840–1914, Abramovitz (1959, p. 462) concluded,

> It is not yet known whether they are the result of some stable mechanism inherent in the structure of the US economy, or whether they are set in motion by the episodic occurrence of wars, financial panics, or other unsystematic disturbances.

What Abramovitz seems to have had in mind is that the question of endogeneity is an open one. A useful general perspective on long swings is to view the features of this cycle as being a product of the specific policy framework. During the rules-based policy framework of the gold standard, a necessary outcome was the need for cyclical adjustment. This type of adjustment was manifested in a number of ways. In the case of the core industrial countries before the First World War, they were able to sustain the gold standard rule as their policy framework and were able to use migration, capital flow, trade and real exchange rate adjustment to cope with a changing and stochastic economic environment (Catão and Solomou, 2005). The slow-relaxing nature of these variables meant that most of the cyclical movement is observed in the long-swing frequency rather than the shorter business-cycle frequency. To this extent Abramovitz is right to say that interwar swings were of a different nature from previous ones; however, this does not constitute a passing of the cycle. In fact, we could argue that during the interwar period, as the conventional adjustment processes of the gold standard epoch disintegrated, discretionary policy became a new adjustment tool determining growth outcomes.

This analysis of Kuznets swings suggests that an understanding of the observed swings requires us to understand the episodic changes that have been observed in different historical periods. This emphasis on policy framework suggests that Kuznets swings could become of increasing relevance in the future. As different policy blocs attempt to establish fixed exchange-rate regimes and single currency areas, the adjustment to shocks in the future will once again become policy-constrained. For example, Europe's commitment to a single currency under economic and monetary union must imply that a number of adjustment mechanisms (such as migration and capital flows) will have to be activated as equilibrating mechanisms to national-specific shocks if we are not to observe persistent divergence across different
countries. Such flows could generate economic–demographic interactions on the cyclical process, which has clear homologies with the gold-standard pattern of international adjustments.

Article

Kuznets was born in Pinsk, Russia, on 30 April 1901 and died in Cambridge, Massachusetts, on 9 July 1985. After a brief period as youthful head of a statistical office in the Ukraine under the early Soviet regime, Kuznets emigrated to the United States, where he received his BA in 1923, MA in 1924, and Ph. D. in economics in 1926, all from Columbia University. He was a member of the research staff of the National Bureau of Economic Research in New York from 1927 to 1961, and held professorial appointments in economics at the University of Pennsylvania (1930–54), Johns Hopkins University (1954–60), and Harvard University (1960–71). After his retirement, Kuznets continued an active research career for another decade. During the Second World War he was associate director from 1942 to 1944 of the Bureau of Planning and Statistics of the US War Production Board. Kuznets was elected president of the American Economic Association in 1954 and the American Statistical Association in 1949, and was the 1971 recipient of the Nobel prize in economics.

Kuznets's foremost contribution, for which he received the Nobel prize, is an empirically founded comparative study of the economic growth of nations. In this work Kuznets identifies, documents and analyses the emergence of a new epoch in economic history, which he calls 'modern economic growth' (Kuznets, 1966). Modern economic growth first makes its appearance in north-western Europe in the latter half of the 18th century. In the course of the 19th century it diffuses southward and eastward throughout Europe, and by the end of the century its beginnings can be identified in Russia and Japan. Mirroring the diffusion pattern within Europe is a somewhat parallel development in overseas areas settled by Europeans. Modern economic growth appears first in areas initially settled by migrants from north-western Europe – the United States in the first part of the 19th century, followed by Canada, Australia, and New Zealand – and subsequently in parts of Latin America where migration from
southern and eastern Europe was especially important. In the 20th century, especially since the Second
World War, the initial signs of modern economic growth have become more widespread in parts of Asia,
and, to a lesser extent, Africa.

Three conditions especially set off the epoch of modern economic growth from prior forms of economic
organizations – the growth rate of real per capita income, the industrial and occupational distribution of
the labour force, and the form of population settlement. In economies experiencing modern economic
growth the rate of increase of real per capita income has typically averaged around 15 per cent or more
per decade over periods of a century or more. In this epoch, there may be shorter or longer fluctuations
in the growth rate (such as business cycles, Kuznets cycles, or Kondratieff cycles) but there is no clear
evidence of systematic long-term retardation or acceleration. A sustained growth rate of 15 per cent or
more per decade is unprecedented in economic history.

In prior epochs of economic organization, economic activity was concentrated in the primary, extractive,
sector of the economy, and took the form of agriculture, or, at an earlier time, hunting, gathering and
fishing. The era of modern economic growth has witnessed a vast diversification and proliferation of
industries and occupations. In today's developed economies, extractive pursuits often account for as little
as five per cent or less of the labour force; the secondary sector, chiefly manufacturing and construction,
may account for around another third; and the tertiary service sector for the remainder. Within the
service sector, a sizeable share of the labour force, approaching the importance of manufacturing in
magnitude, is employed in the transportation and distribution of goods, while the remainder is engaged
in activities such as personal and professional services, and government. On the occupational side, white
collar jobs (managerial, clerical, professional, and sales), of small importance in prior epochs, grow
significantly in proportion to blue collar (manual) labour.

Associated with the shift out of agriculture is a major transformation in place of residence of the
population. In prior epochs nomadic or village life was the overwhelming form; in contrast, the epoch of
modern economic growth has seen the emergence and dominance of spatial concentration, in cities and
surrounding suburbs. As a consequence, in many developed economies rural depopulation has been a
pervasive phenomenon.

Underlying the acceleration in the growth rate of real per capita incomes and associated reallocation of
resources by industry, occupation and location has been a technological revolution, most easily
identified by the increased flow since the 18th century of inventions and innovations in economic
activity. At bottom, this new technology stems from the emergence of modern science in the 16th and
17th centuries and the empirical outlook to which it gave rise. Modern technology is distinct from the
technology of prior epochs in its reliance on inanimate sources of power, the growth in importance of
minerals relative to fibres as raw material, the spread of mechanization and an associated increase in
optimum scale of manufacturing production leading to replacement of artisanal by factory organization,
and new forms of transportation and communication.

To some the epoch of modern economic growth is identified with industrialization and capitalism, but in
Kuznets's view this is a misconception. ‘Industrial’ work in the sense of manufacturing and construction,
accounts, as has been noted, for a minority share of economic activity in presently developed countries,
and, in some of these countries, modern economic growth has been based primarily on the
commercialization and technological modernization of agriculture rather than on industry. Moreover, the
phenomenon of modern economic growth transcends specific institutional forms such as capitalism,
socialism or communism. As Kuznets demonstrated in numerous works, the dramatic rise in the growth
rate of real per capita income, the immense reallocation of resources among economic activities, the spatial concentration of population, the adoption of a common modern technology, and many other features of contemporary economic development have been essentially similar in the United States and the Soviet Union, western and eastern Europe, and, in incipient stages today, China, India and Brazil. The analysis of modern economic growth was the logical culmination of Kuznets's earlier work. The organizing framework for his comparative study was national income and its components, in whose conceptualization and measurement Kuznets was the foremost pioneer. Indeed, so great are his accomplishments in the measurement of national income and so close the identification of national income with his name that American economists frequently cite this work as the basis for his Nobel award. Certainly, there is no doubt that this work too is a landmark in the evolution of economic science. Today figures of gross national product (GNP) are taken for granted, but before the First World War there was almost total ignorance of such elementary facts of the economy's size and structure. Kuznets was not the first to seek to close this gap, but his work on national income and product was so distinctive and comprehensive that it became the benchmark in the field. It encompassed estimates of total output and income by final product, industry of origin, and type of income; capital formation and savings; and the distribution of income between rich and poor. This work, coinciding with the new demands for economic information generated, first, by the Great Depression of the 1930s and then by the mobilization requirements of the Second World War, laid the foundation for the establishment of official estimates of total GNP and its components by the federal government, a task in which Kuznets played a leading role. As mentioned, it also provided the basis for Kuznets's subsequent programme of research on economic growth, which was built upon historical series of national income and product for as many countries as possible.

Kuznets's work on national income played a crucial role in the transition of economics from a deductive to a quantitative science. This transition required a union of theory, economic measurement and statistical methodology. In the 1930s the new macroeconomic theories of John Maynard Keynes had aroused much interest because of their relevance to the worldwide economic crisis. Kuznets's concurrent and independent effort to develop measures of the consumption, savings, and investment components of national income provided the empirical counterparts of the Keynesian concepts. This advance in economic measurement and its concordance with new theoretical formulations was a key step in the development of econometrics, the statistical techniques for systematic quantitative modelling of the economic system pioneered by Ragnar Frisch and Jan Tinbergen.

In one of his earliest works, on secular movements in production and prices, Kuznets identified fluctuations of 15–25 years’ duration in a number of economic time series in the United States. Subsequently he returned to this subject several times, widening the range of observation to other developed countries and incorporating demographic as well as economic time series. These movements, although still somewhat controversial, are commonly referred to today as ‘Kuznets cycles’, in recognition of his pioneering contribution.

In the history of economic thought, Kuznets stands in a line of descent tracing back through the American institutional school to the German historical school and thence to Karl Marx. The common thread is a search for laws or generalizations about long-term economic development based on comparative study of historical experience. The unique feature of Kuznets's work, which endows it with the prospect of more enduring success, is its foundation in quantitative measurement. In using national income as the key organizing principle of his comparative studies, Kuznets made possible the replication
and extension of his work by others and thus the cumulation of a body of systematic knowledge about economic development forming the basis for tested generalizations.

Although Kuznets identified modern economic growth as a distinctive epoch in economic organization, he did not extend his empirical approach to the study of earlier epochs. In this respect, Kuznets was much like Marx and Joseph Schumpeter, in that he focused his attention on the study of a single, contemporary stage of economic evolution, although, unlike them, he did not see this stage as confined to the boundaries of capitalism.

Kuznets's approach to economics and to economic research may best be understood in terms of his intellectual heritage. Although Kuznets' convictions about the importance of quantitative measurement and knowledge of economic history antedated his emigration to the United States, they received strong reinforcement from his mentor at Columbia, Wesley C. Mitchell. Mitchell's scepticism about the reliance of economics on deductive economic theory and his belief in the need for quantitative facts had been instrumental in the establishment in 1920 of the National Bureau of Economic Research, a non-profit research organization devoted to basic economic science, the first of its kind in America. Mitchell brought Kuznets into the NBER, where he conducted his national income studies and came to head the bureau's programme in that field. This project, and that on business cycles, headed by Mitchell and Arthur F. Burns, were the central pillars of the bureau's work, and the basis for the national and international reputation that the bureau established in the 1930s and 1940s. Two themes of the NBER's work – a respect for facts and the cumulation of economic knowledge through quantitative measurement – were key ingredients in Kuznets' research strategy.

The quintessential criticism of the NBER approach was captured in the title of Tjalling Koopmans' famed 'Measurement without Theory' review of the Burns–Mitchell treatise on business cycles (Koopmans, 1947). In Kuznets's view, however, measurement can never be divorced from economic theory, and is necessarily guided by theory. Indeed, in the late 1940s Kuznets broke with the official estimators of GNP, because he considered their increasing emphasis on 'social accounting' to be an abandonment of the fundamental Marshallian and Pigovian theoretical concept of national income as a measure of economic welfare. Throughout his career, Kuznets's monographs, although structured around tables of data, were infused with 'tentative' interpretations and explanations based on economic theory. Admittedly Kuznets was reserved in his use of economic theory and sceptical of formal mathematical and econometric models. This arose, however, not from a rejection of theory but from another feature of his approach that he shared in common with the historical school. This notion is the historical relativity of economic theory. To Kuznets, much economic writing and theorizing was geared to current conditions and claimed validity far beyond the limits that would be revealed by an empirical test. His reservations about economic theory also stemmed from what he felt was its limited coverage of social reality. Particularly in the study of economic growth was an expansion of disciplinary boundaries necessary. Much of Kuznets’ work on modern economic growth was carried out under the auspices of the Committee on Economic Growth of the Social Science Research Council. This committee, which Kuznets chaired and directed for the two decades of its life, included important representation from anthropology, sociology, and political science, and organized 16 interdisciplinary conferences. Some of Kuznets’ own research involved interdisciplinary cooperation, notably in his collaboration with the distinguished sociologist, Dorothy S. Thomas, in their study of population redistribution and economic growth in the United States.

Simon Kuznets was a devoted family man and warm with intimates. Perhaps his happiest moments,
however, were those frequent long mornings spent over a calculator, bending the diverse facts of reality to manageable size. A brief anecdote may capture the spirit of the man. Once, after his retirement, Kuznets was invited to prepare a paper for a forthcoming conference, and, in reply, he asked how long it would be before the conference proceedings were published. When his interrogator quipped, ‘Why, Simon, you’re not still interested in “publish or perish”, are you?’ he responded with a twinkle, ‘Well, in a sense, I am.’

Though one of the first Nobel prize winners in economics, Kuznets was in important respects a maverick. In a discipline where deductive analysis is the hallmark of accomplishment, Kuznets, though himself a creative and original thinker, was notable for his insistence on facts and measurement. In a field that prides itself as ‘queen of the social sciences’, Kuznets reached out to other disciplines both in teaching and research. And in a subject where sweeping ideological prescriptions for reform abound, Kuznets was in both words and example a passionate believer in the ultimate value of science.

Finn Kydland's contributions to economics science have changed the terms of the debate in two important and related counts: the theory of policymaking and of business cycles. In his Ph.D. dissertation, Finn showed that a complex ‘credibility problem’, inherent to the policymaking process, prevented the evaluation of economic policies with the optimal control theory techniques applied until then. His work with Edward Prescott on business cycles identified supply shocks as one of the primary causes of economic fluctuations, with the counter-intuitive and therefore resisted implication that the perfect smoothing of the business cycle may not be a sensible policy objective.

Article

Finn was born in Bjerkreim, Norway, in the southern tip of the country, and grew up in nearby Søyland with his mother Johanna, his five younger siblings, and his father Martin, who ran a family business that hauled milk and sheep.

Finn was the only one among his classmates to further his education beyond elementary school: at the early age of 15, he moved by himself to Bryne, 20 miles away from home, to be able to attend the nearest high school. His excellent grades there allowed him to apply to the Norwegian School of Economics and Business Administration (abbreviated NHH in Norwegian) at Bergen. He was at first rejected because the secondary school he had attended didn't have a business orientation. With his usual determination to fight adversity, Finn studied some more to acquire the necessary qualifications and
finally started his business degree at the NHH in August 1965. There, in the winter of 1968 he would be hit by a major real shock that would derail him for ever from a business career track. The source of the shock was Sten Thore, the professor of economics teaching a managerial sciences course, in which Finn wrote his first computer program (in FORTRAN) doing dynamic programming, a tool he would use repeatedly throughout his career. According to Sten Thore's testimony (2005), ‘Finn quickly established himself as the smartest kid in the class’. It became obvious to him that this low-key farmer boy with a scientific mind had not been born for the business world. Secretly hoping that Finn would find his true calling in life, in the winter of 1968 Sten asked Finn to be his research assistant, ‘grasping him in the nick of time after his graduation, before he had time to disappear into the commercial world’.

A few months later Sten was given the opportunity to spend a year as a visiting professor at the Graduate School of Industrial Administration (GSIA), at Carnegie-Mellon University, and asked Finn to accompany him as his research assistant. When Finn joined Sten in Pittsburgh in the summer of 1969, his fate was sealed.

In that exciting intellectual atmosphere, it didn't take Finn long to catch the economics bug, apply formally to the graduate programme, and be promptly admitted. There, in the following spring, while attending a course by young professor Robert Lucas, Finn would see unfold on the blackboard, as it was conceived, Lucas's seminal paper ‘Expectations and the Neutrality of Money’ (1972). Without either of them knowing it, two future Nobel prizewinners were tuning their minds in the same classroom.

Another fortuitous encounter took place in August 1971, when Finn ran into Edward Prescott, a newly hired professor who asked him what he was working on.

At that time, Finn had become interested in the so-called assignment problem. The problem, formulated in the context of the system-of-equation framework dominating macroeconomics at the time, was to determine the most effective policy instrument for targeting each of multiple, potentially conflicting policy objectives (such as maintaining low inflation and full employment).

Finn was taking an out-of-the-box approach, not in terms of the usual system-of-equations but of a game between the monetary and fiscal authorities. Prescott was curious because he had been doing related research with Robert Lucas. But he was taken aback by the discovery that Finn was about to make: that the outcome of the game was different, depending on whether the players were forced to make all their decisions for the entire future at the beginning of the planning period (the open-loop solution in the so-called sequence space) or allowed to choose their actions one period at a time (the feedback solution in the so-called policy space).

Engineers and physicists routinely using optimal control theory had not considered that possibility because, by Bellman's principle of optimality, both solutions are equivalent in their ‘mechanical’ world. Intuitively, the reason is that a mechanical device implements instructions exactly as written in the program currently fed into it, regardless of whether in the future it will be asked to implement a different program. Put differently, machines are incapable of conditioning current behaviour on the future. It was not surprising that economists at the time thought that the results from optimal control theory carried over automatically to economic policy questions. They had been trained in the system-of-equations tradition, which modelled the behaviour of economic agents as if they were machines in the sense that households and firms were allowed to make decisions using only information from the past, even if humans, unlike machines, can anticipate the future and therefore condition current actions on the economic programs (or policies) they expect to be implemented in the future. That artificial assumption
ensured the absence of feedback from the future to the present necessary for the principle of optimality to hold.

It is not by chance that Finn had his first Nobel-calibre insight at the GSIA and at that time. After all, it was there, in the spring of 1970, that he witnessed Lucas produce a path-breaking paper showing the serious shortcomings of evaluating alternative policies with the mechanical behavior of economic agents imbedded in the system-of-equations approach. However, in Lucas's 1972 paper the principle of optimality held because he could make his point about the constant money growth policies advocated by Milton Friedman, keeping intact the ‘single-player against nature’ structure underlying the system-of-equations approach with the policymaker – a random money growth process – instead of households behaving like a machine.

In his dissertation, Finn took Lucas's contribution one step further by assuming that the policymaker (a dominant fiscal authority) didn't behave mechanically but was forward-looking as well, picking policies strategically, depending on the reactions of the other optimizing agents (households or a follower monetary authority). With both participants in the policy game reacting strategically to each other's future decisions, the condition of no feedback from the future to the present required for the principle of optimality to hold was not met. As a consequence, decisions made one at a time are different from decisions made once and for the entire future.

That result had far-reaching consequences for the theory of policymaking. It implied that the reason governments around the world seemed to be unable to implement policies that were the best according to optimal control theory was not necessarily, as it was widely believed, myopic or incompetent policymakers. Rather, it was the inherently dynamic nature of the policymaking process, when there is feedback from the future to the present and societies lack commitment mechanisms to bind the decisions of not-yet-born policymakers. The profession at large would become fully aware of the importance of this revelation only later, after Finn joined forces with Ed Prescott to address the issue of optimal selection of policies in uncertain, dynamic environments that Prescott had been exploring earlier with Lucas.

But first Finn had to finish his degree, which he did in May 1973 with a gold medal. He then returned to Bergen as an assistant professor at the NHH, to fulfil the conditions of the fellowship he had received from that school. There he managed to publish the stunning discovery of his dissertation in a 1975 International Economic Review paper.

He also got Ed Prescott to visit the school for the 1974–5 academic year. In the spring of 1975 they came out with a paper with the provocative title ‘On the Inapplicability of Optimal Control for Policy Making’. The paper was received with the same scepticism as Finn's dissertation's first draft: everyone was expecting the principle of optimality to hold and trying to spot the error. Those difficulties persuaded Ed Prescott to add a conventional Phillips curve example to their paper before resubmitting it to the *Journal of Political Economy*, where it appeared in 1977.

Aware of the theoretical result in the paper, Finn was nevertheless surprised by the quantitative finding reported in it: that the time-consistent plan (the ‘decisions-one-period-at-a-time’ solution), arguably the one that governments will be most tempted to implement, represented a sizable loss of welfare relative to the optimal plan (the ‘decisions-for-the-entire-future’ solution). The theoretical contribution in his dissertation was not just an intellectual curiosity: it had concrete implications for the real world. This result surely accounts for the huge impact that the paper had in the profession and may help to explain the quantitative focus of Finn's subsequent research.
The rules-rather-than-discretion paper reopened the US market to Finn. In 1976–7 he spent the academic year as visiting faculty at the University of Minnesota. In 1978, the economics department at Carnegie-Mellon appointed Finn as associate professor at the GSIA, breaking an almost inviolable rule among US universities of not offering permanent faculty positions to their own Ph.D. graduates. Finn became full professor there in 1982.

That was also the year in which the other seminal contribution by Kydland and Prescott appeared in *Econometrica*. ‘Time-to-build and Aggregate Fluctuations’ is a testimony of the quantitative focus that the rules-rather-than-discretion paper impinged on Finn's research agenda. The question that the time-to-build paper set out to answer was: ‘If total factor productivity (or technology) shocks were the only source of impulse, what portion of business-cycle fluctuations could they account for?’ The answer was more than one-half, later raised to around 70 per cent.

That finding sent shockwaves throughout the profession because it undermined fundamental tenets of the monetarist and Keynesian rival schools of thought then dominating the profession. The monetarists couldn't come to terms with the finding that technology shocks, and not monetary shocks, were the most significant source of economic fluctuations. The Keynesians weren't amused either: they had been attributing economic fluctuations to demand-side shocks, and not to supply side shocks like the ones Kydland and Prescott had just unveiled.

Adding insult to injury, the time-to-build paper seriously challenged both schools’ long-held presumption that only models with nominal rigidities in prices and/or wages would be capable of producing fluctuations like the ones observed in the real world. Kydland and Prescott proved that presumption wrong: a neoclassical growth model with flexible prices fed with productivity shocks like the ones observed in the United States was perfectly capable of accounting for about two-thirds of that country's post-war cycles. Therein lay the methodological beauty and conceptual significance of the paper: it derived the quantitative business-cycle implications of well-established growth theory. It is hard to understand in retrospect why such a sensible research project ruffled so many feathers in the profession.

The answer lies in the policy implications: Kydland and Prescott's model, calibrated to US long-run economic growth features, suggests that that country's business-cycle fluctuations since the Second World War can be attributed mostly to the optimal responses of the private sector to exogenous (independent of economic policies) productivity shocks. Under that interpretation, the perfect smoothing of the business cycle that monetarists and Keynesians had been advocating not only is not a sensible policy objective, but can also result in large welfare losses. Neither camp has surrendered, but interestingly enough their subsequent attempts to overturn the finding of the time-to-build paper have preserved many of its distinctive features: money is not explicitly included in the analysis (as in Woodford's ‘cashless’ economy, 2003), agents exhibit forward-looking and optimizing behaviour and, more ironically, prices are a lot more flexible than in pre-1982 monetarist or Keynesian models. Unlike with the rules-rather-than-discretion paper, the controversy generated by the time-to-build paper rages on, eloquent testimony of the indelible mark it has left in the profession.

That paper was by no means Finn's last accomplishment. He has continued publishing consistently in the top journals of the profession, recruiting coauthors who share his methodological views and taste for quantitative questions motivated by anomalies and puzzles. For example, international economists have been trying to account for the ‘output-consumption correlation puzzle’ ever since he and coauthors David Backus and Patrick Kehoe uncovered it in a 1992 *Journal of Political Economy* paper.
Recognizing the calibre of his contributions, the Bank of Sweden awarded to Finn the Nobel Prize in Economics on 11 October 2004, jointly with another giant of the profession, his coauthor Edward Prescott. Shortly before, Finn had accepted the Jeffrey Henley Chair in Economics at the University of California at Santa Barbara. Shortly after, he married Tonya Engstler at their home in Vancouver, Canada.

Inevitably a busy scholar, Finn nevertheless finds time to see his four children from a previous marriage (Martin, Eirik, Camilla and Kari), listen to blues over beers with his colleagues, ride his Ducati, and watch or play soccer. In fact, no award exhibits him more unashamedly than the lifetime membership bestowed upon him in November 2004 by Club Atlético Boca Juniors, the Argentine soccer team he became an unruly fan of while watching, in my company, famous Diego Maradona play for that team in Buenos Aires the last game of his professional career.

The University of Chicago economist and home economist Hazel Kyrk was a pioneer in the study of consumption decisions and of the allocation of time in households. Born in Ashley, Ohio, Kyrk was the only child of Elmer Kyrk, a drayman, and Jane Benedict Kyrk, a homemaker who died while her daughter was a teenager. After finishing high school, Hazel Kyrk taught for three years before entering Ohio Wesleyan University in 1904, where she supported herself by working as a mother's helper in the household of Leon Carroll Marshall, an economics professor. When he was hired by the University of Chicago, Kyrk went with the family. She graduated from the University of Chicago in 1910 with a Ph.B. in economics and a Phi Beta Kappa key. After a year as an instructor in economics at Wellesley College, Kyrk returned to the University of Chicago to study for a Ph.D. in economics, writing her dissertation with the economic demographer James A. Field. From 1914, she also taught at Oberlin College, first as an instructor, then as an assistant professor. Taking leave from Oberlin in 1918–19 to work on her thesis, she followed her adviser to London, where she served as a statistician for the American Division of the Allied Maritime Transport Council. Her dissertation, accepted in 1920, was published as *A Theory of Consumption* (1923) and won the prestigious, thousand-dollar Hart, Schaffner and Marx Prize for economic research. In that book and in *The Economic Problems of the Family* (1929), Kyrk discussed how social psychology shapes consumer choice and how the economic role of the housewife was moving beyond household production to being a ‘director of consumption’.

Hazel Kyrk worked at the Food Research Institute of Stanford University in 1923–4, co-authoring a study of the American baking industry, and taught at Iowa State College (1924–5). From 1925 until her retirement in 1952, she taught at the University of Chicago, appointed to both the Departments of Economics and Home Economics, with promotion to full professor in 1941. She made the University of Chicago the leading centre of consumer and family economics, supervising many dissertations, notably...
Margaret Reid's *The Economics of Household Production* (1934). Reid, the first female Distinguished Fellow of the American Economic Association, returned from Iowa State to Chicago as a full professor of economics and home economics in 1951, a year before the retirement of her mentor, Kyrk. Active in consumer economics beyond the university, from 1938 to 1941 Kyrk spent the summers as principal economist in the Bureau of Home Economics of the Department of Agriculture, working on the 20-volume Consumer Purchases Study which, among other contributions, established base-year prices for the cost of living index. From 1943 she chaired the Consumer Advisory Committee of the wartime Office of Price Administration. In 1945–6, she returned to Washington to chair the Technical Advisory Committee of the Bureau of Labor Statistics, helping to create a ‘standard family budget’ and to revise the consumer price index. Kyrk was also active on the boards of the Chicago Women's Trade Union League and a consumer cooperative in Chicago's Hyde Park neighbourhood, and from 1922 to 1925 she taught at the Bryn Mawr Summer School for Women Workers. Never married, Kyrk took charge of bringing up and educating a teenage cousin.

The economic analysis of household time-allocation and production and consumption decisions by Kyrk and her Chicago students (most notably Reid) prefigured the later Chicago ‘new home economics’ of Gary Becker (see Reid, 1977). Kyrk's *Theory of Consumption* is also recognized as a landmark in the history of marketing thought (Zuckerman and Carsky, 1990).

Abstract

Small-scale financial markets have been studied in the laboratory for more than two decades. Typically, 6–20 human subjects buy and sell units of a single asset whose dividends extend over several periods and/or are uncertain. Such markets permit direct observation of informational efficiency, and allow sharp tests of theoretical predictions. They also provide test beds for policy initiatives, new market formats and automated trading strategies.

Article

Laboratory financial markets allow human subjects to trade assets under conditions controlled by the researcher. By varying the conditions – such as the trading format, or the timing and content of private information – the researcher can make direct and sharp inferences.

Such inferences are crucial to achieve insight into the ongoing debate about the importance of behavioural anomalies in financial markets (see behavioural finance). Efficient markets and related theories provide a satisfying explanation for many of the properties of modern financial markets, but they are hard to reconcile with well documented ‘market anomalies’ such as home bias, the large equity premium and excessive volatility. Should financial economists force a reconciliation, or should they embrace prospect theory and other behavioural theories?

These issues are not just academic. Since the collapse of the Soviet bloc around 1990, a dominant share of the world economy has relied on financial markets to choose its economic future. If the efficient markets theory is wrong, and asset prices do not necessarily reflect all available information, then major restructuring may be in order. Perhaps the global economy would be stronger with information disclosures that cater to our behavioural idiosyncrasies, or even with non-market allocation of investment.

Laboratory asset markets inform the debate by offering evidence that complements field data. The strength of experimental methodology is that the researcher can precisely control information, public and private, and can elicit beliefs as well as track offers, transactions and allocations. Thus, in a simplified setting, researchers can systematically dissect the process of asset price formation. In conjunction with theory and field empirical work, laboratory investigations help us understand how financial markets really work.

Early laboratory markets

Experimental economics cut its teeth on laboratory commodity markets. Reacting to Edward Chamberlin's casual classroom experiments, Vernon Smith pioneered the scientific study of markets in the laboratory. He refined the idea of induced value and cost: the experimenter promises to pay a subject the amount \( v \) if she buys a unit, and charges another subject the amount \( c \) if he sells a unit. If they transact at price \( p \), she earns \( v−p \) and he earns \( p−c \), generating surplus of \( v−c \). The payments are in cash and large enough for the subjects to take
Smith introduced stationary repetition – several consecutive trading periods with the same endowed values and costs but no carry-over from one period to the next, so that subjects have the opportunity to adapt to the trading environment. He also brought the continuous double auction (CDA) market (sometimes referred to as the double oral auction) format into the laboratory: traders can make public, committed offers to buy and to sell and can accept others’ offers at any time during a trading period. Variants of the CDA format predominate in modern financial markets, including the New York Stock Exchange (NYSE), NASDAQ, and the Chicago Mercantile Exchange.

Numerous laboratory studies, beginning with Smith (1962), show that CDA markets with only a few buyers and sellers (say, four of each) reliably produce highly efficient outcomes, where efficiency is defined as the fraction of potential surplus in the market that is captured by the buyers and sellers. Typically, over 95 per cent of total surplus is realized after a few periods of stationary repetition.

Such perishable commodity markets provide no interesting role for time or uncertainty, both important dimensions of financial assets. Laboratory financial markets should allow two-way traders who can both buy and sell, and who trade assets with a payout that is uncertain and/or carries over several periods. Experimenter at Caltech first introduced such markets in the early 1980s. For example, Plott and Sunder (1982) created a single period asset that was traded by six uninformed traders, who knew only that one of two states would occur with given probabilities independently each period, and six informed traders, who knew the realized state. Both informed and uninformed traders were distributed evenly across three types of state-contingent dividend schedules. Within a few periods, prices became highly efficient, and the trading patterns demonstrated that the market fully disseminated the private information. About the same time, several teams of researchers found very efficient asset prices in laboratory markets with assets paying individual- and state-contingent dividends over several trading periods. These and other early laboratory experiments demonstrated that futures and options contracts can speed convergence towards efficient asset prices. See Sunder (1995) for a thorough survey.

The main lesson from these studies is that financial markets can process information very efficiently. As Hayek (1945) conjectured, markets can fully aggregate and disseminate dispersed private information, and can do so quite rapidly. A few bids and asks in the CDA suffice to fully inform experienced traders, dealing appropriate assets, in moderately complex environments.

**Dissecting financial markets**

These positive early results encourage us to look more deeply at how financial markets process information. The process has several logical stages. Investors and other participants acquire relevant information from diverse sources, public and private. Individual investors incorporate the information into their beliefs about future asset prices. Acting on their beliefs, investors try to buy assets they expect to appreciate relatively rapidly and to sell assets that they expect to do less well. Their buy and sell orders in turn produce observable market outcomes such as asset price and trading volume. The market outcomes provide further public information for investors, other new information arrives from time to time, and so the process continues. We now know that the process can work quite well in favourable circumstances. But even the early laboratory studies show that it is sometimes fallible. When and where might it go wrong?

Each stage of the process can be examined in the laboratory and compared with theoretical predictions. Cognitive scientists focus on the first stage, the formation of beliefs given arriving information, and have documented many biases that might distort beliefs. Examples include overconfidence, the gambler’s fallacy (believing that a coin that has come up ‘heads’ many times in succession is the more likely to come up ‘tails’) and the hot-hand fallacy (believing that basketball players who have made ten free throws in succession are especially likely to make the next). In the next stage, investors may make decision errors when they buy and sell assets, even when their beliefs are realistic. There are numerous examples, including hyperbolic (or quasi-hyperbolic) discounting, the disposition effect, and the sunk-cost fallacy.

It is often tempting to explain financial market anomalies simply by pointing to one or more of these biases and errors. But such explanations are incomplete and potentially erroneous. One problem is that there are so many documented biases and errors; indeed, a complete list seems not to exist. Given any market anomaly A, a diligent student can always find some decision error or bias B that superficially seems connected, whether or not B really causes A. Even more important, investors’ biases and decision errors never translate directly into financial market imperfections. Asset prices are non-trivial functions of investors’ buy and sell orders, and they provide information that affects subsequent orders and prices. These later stages of the process depend on the market format, and they can attenuate or amplify investors’ biases and errors.

**Attenuating biases and errors**

Three different market forces can greatly attenuate the financial market impact of erratic investors. First, it is a powerful learning experience to lose money in a financial market, or even to see other investors do better when they have no informational advantage. Friedman (1998) and later studies demonstrate that people can overcome even the strongest biases and errors in a suitable learning environment. To the extent that a bias or error leads to clearly inferior performance, an investor will learn to do better over time. Subjects in most laboratory financial markets commit fewer errors and trade more efficiently in later periods than in earlier periods, and subjects with previous experience in a particular laboratory market do better yet.
Second, the market shares of investors with inferior trading strategies tend to shrink over time, reducing their influence on market performance. Blume and Easley (1992) demonstrate theoretically that wealth redistribution eventually eliminates all but the most effective investors. Laboratory studies routinely cancel out this force via stationary repetition, but it can easily be inferred by compounding relative profits across periods.

Third, persistent costly errors and biases create profit opportunities for entrepreneurs whose efforts attenuate (or even eliminate) the market impact. For example, yellow pages and speed dials help us overcome our cognitive limitations in remembering phone numbers. Similarly, mutual funds and a host of investor advisory services allow investors to sidestep their personal biases. Such entrepreneurs can create new problems but, as noted below, those problems also can be studied in the laboratory. Arbitrage is the most direct form of such entrepreneurship. If error-prone investors create an asset price discrepancy, this will attract profit-seeking arbitrageurs whose buy and sell orders tend to make it disappear. Laboratory studies, including those of Plott and Sunder (1982), confirm the power of arbitrage.

Amplifying biases and errors

There are also three strong forces that can amplify the market impact of errant investors. First, raw information is often gathered, analysed and released by individuals who have major personal stakes in the market reaction. Despite oversight by authorities such as the US Securities and Exchange Commission, these individuals may use their discretion to distort the market reaction. Bloomfield and O'Hara (1999) and subsequent laboratory studies confirm the possibility.

Second, professional fund managers typically are compensated (directly or indirectly, via competing job offers) for returns that rank highly relative to their peers. It is difficult to infer from field data whether such incentives have an impact, but inference is straightforward in the laboratory. James and Isaac (2000) find major distortions of laboratory asset prices when traders have rank-based performance incentives, and the distortions disappear in otherwise identical markets when traders are paid only their own realized returns.

Third, and most intriguingly, investors may go astray when they try to glean information from the trades of informed investors. Information mirages (for example, Camerer and Weigelt, 1991) can arise as follows. Uninformed trader A observes trader B attempting to buy (due to some slight cognitive bias, say) and mistakenly infers that B has favorable inside information. Then A tries to buy. Now trader C infers that A (or B) is an insider and tries to mimic their trades. Other traders follow, creating a price bubble.

Several research teams (including the author's) have occasionally observed such episodes in the laboratory. They cannot be produced consistently, because incurred losses teach traders to be cautious when they suspect the presence of better-informed traders. The lesson does not necessarily improve market efficiency, since excessive caution impedes information aggregation.

Price bubbles deserve longer discussion, as bubbles have produced important distortions in market prices. Asset prices seemed to disconnect from fundamental value in Japan in the late 1980s, in the dot.com bubble and crash of 1997–2002, and in a number of other episodes since the famous 17th and 18th century events now known as tulipmania and the South Sea bubble. Do such episodes indicate dysfunctional financial markets? Perhaps, but the field data also can be interpreted merely as unusual movements in fundamental value (Garber, 1989). By contrast, in the laboratory the experimenter can always observe (or more typically, control) the fundamental value, so bubbles can be detected and measured precisely.

Smith, Suchanek and Williams (1988) found large positive bubbles, and subsequent crashes, for long-lived laboratory assets and inexperienced traders. Figure 1 shows a representative example. The expected dividend is constant, so the fundamental value (the sum of expected remaining dividends) declines steadily over the 15 trading periods. Ask ('offer') and bid prices start low, but by the second period the transaction prices (indicated by lines connecting accepted bids and asks) rise above fundamental value. The bubble inflates rapidly until late in period 4. In period 9, prices crash below fundamental value.

Figure 1
A bubble and crash in the laboratory. Source: Smith, Suchanek and Williams (1988, Figure 9).
Keynes’s ‘greater fool’ theory provides a possible interpretation. Traders who themselves have no cognitive bias might be willing to buy at a price above fundamental value because they expect to sell later at even higher prices to other traders dazzled by rising prices. Subsequent studies confirm that such dazzled traders do exist, and that bubbles are more prevalent when traders are less experienced (individually and as a group), have larger cash endowments, and have less conclusive information.

Current frontiers: market formats, agents, and prediction markets

Which underlying biases and errors are most important? When does attenuation predominate, and when does amplification? Accumulating laboratory evidence inspires new theoretical and empirical field work as well as follow-up laboratory studies.

It is increasingly clear that answers hinge on the market format or institution – the rules that transform bids and asks into transactions. In particular, the CDA format allows all traders to observe other traders’ attempts to buy and sell in real time, and thereby encourages information dissemination. The CDA format attenuates the impact of erratic traders because the closing price is not set by the most biased trader or even by a random trader. The most optimistic traders buy (or already hold) and the most pessimistic traders sell (or never held) the asset, so the closing price reflects the moderate expectations of marginal traders (see Smith, Vernon).

Other traditional formats include the call market (CM), in which bids and asks (or limit orders) are gathered and executed simultaneously at a uniform price, and the posted offer (PO), in which one side (usually sellers) simultaneously announces prices and the other side (buyers) choose transaction quantities at the given prices. Many other formats and hybrids are possible in the Internet age. Which formats are most efficient? Which can attract market share from other formats? Work so far indicates that the CM format does relatively well.
for thinly traded assets and the PO format works best when the posting side is more concentrated; but the questions remain far from settled.

Related new work blurs the line between computer simulations and laboratory markets. Computer algorithms for artificial agents, or bots, incorporate specified cognitive limitations, and simulations examine the market level impact (for example, Arthur et al., 1997). Gode and Sunder (1993) showed that simple perishables CDA markets are quite efficient even when populated by zero intelligence (ZI) agents, bots that are constrained not to take losses but are otherwise quite random. Current work puts ZI and more intelligent bots into the same asset markets as human traders, and compares efficiency and the distribution of surplus. Such work should help inform regulators, reformers, and entrepreneurs creating new asset markets. Early published examples of policy-oriented research includes performance assessment of (a) trader privileges such as price posting and access to order flow information (for example, Friedman, 1993), and (b) transaction taxes, price change limits and trading suspensions intended (typically ineffectively) to mitigate price bubbles and panics (for example, Coursey and Dyl, 1990).

Prediction markets, which use the information-aggregation property of markets to forecast events such as election outcomes, are gaining increased attention. The Iowa Electronic Market, designed and operated by experimental economists (Berg et al., 2008), offers various assets that pay the holder ten dollars if (and only if) a specified event occurs by a specified date. Participants self-select, are not representative of the general public, and their trades exhibit partisan bias – for example, self-styled Democrats are more likely to buy assets that pay off when the Democratic Party candidates win. Nevertheless, political event asset prices have consistently outperformed opinion polls and all other available predictors. Prediction markets are a growing presence on the Internet, for example tradesports.com, and some corporations such as HP are beginning to rely on them when making business decisions. The line between laboratory and field financial markets is beginning to blur.

labour discipline

Peter Hans Matthews
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Although economists in different fields, or from different schools, use different words to describe the phenomenon, there is widespread agreement that workers can, and sometimes do, ‘contest’ the sale of their labour power to employers. The question of how employers maintain ‘labour discipline’ in such an environment has intrigued economists since at least Marx’s time.

Keywords

asymmetric information; capitalism; contested transactions; effort extraction problem; employment rent; Hobbes, T.; incentive compatibility; Kalecki, M.; labour discipline; labour market contracts; loyalty; Marx, K.; supervision; unemployment

Article

Because it is difficult to write and enforce complete contracts in labour markets, transactions are often ‘contested’ (Bowles and Gintis, 1993) and labour discipline must somehow be enforced. Recent formalizations of the ‘effort extraction problem’, for example, are premised on the notion that it is difficult for firms to monitor the effort levels of all workers at all times. How much effort workers expend will then depend on, among other things, the cost of job loss. It follows that, as the unemployment rate or, to be more precise, the expected duration of unemployment decreases, the wage at which workers will expend a particular effort level will increase. In many such models, the ‘employment rent’ consistent with near-full employment is not feasible, and it is equilibrium unemployment that ‘solves’ the labour discipline problem.

To fix ideas, consider a discrete time variant of the influential Shapiro and Stiglitz (1984) model. There are $N$ identical, infinite-lived and risk-neutral workers, each of whom maximizes the expected value of

$$
\sum_{i=0}^{\infty} \theta^i u(w_i, e_i),
$$

where:
labour discipline: The New Palgrave Dictionary of Economics

and where \(w_i\) and \(e_i\) are the real wage and effort level in period \(i\), \(\Theta\) is the common rate of time preference and \(\tilde{w}\) is an unemployment benefit, financed, for the sake of convenience, with a lump-sum tax on profits. Workers must choose one of two effort levels, 0 or \(\bar{e}\), each period, and there is some likelihood \(d\) that a worker who expends no effort in a particular period will be detected and then dismissed. Furthermore, at the end of each period a fraction \(q\) of all employed workers enters the jobless pool for other reasons.

In a stationary equilibrium, the lifetime utility, \(V_1\), of an employed worker who expends \(\bar{e}\) each period will be:

\[
V_1 = \frac{w - \bar{e} + q\Theta V_3}{1 - \Theta(1 - q)}
\]

where \(V_3\) is the lifetime utility of a worker who is currently unemployed. (The worker receives \(w - \bar{e} + \Theta V_3\) and \(w - \bar{e} + \Theta V_1\) with likelihoods \(q\) and \(1 - q\), respectively, which implies that \(V_1 = q(w - \bar{e} + \Theta V_3) + (1 - q)(w - \bar{e} + \Theta V_1)\).) In a similar vein, the lifetime utility, \(V_2\), of an employed worker who expends no effort each period will be:

\[
V_2 = \frac{w + (d + q(1 - d))\Theta V_3}{1 - \Theta(1 - q)(1 - d)}
\]

Workers will therefore not expend effort \(\bar{e}\) unless \(V_1 \geq V_2\) or, after substitution and simplification:

\[
w \geq \left(\frac{1 - \Theta(1 - q)(1 - d)}{\Theta(1 - q)d}\right)\bar{e} + (1 - \Theta)V_3
\]

Consistent with intuition, firms will find it more expensive to achieve labour discipline (that is, the
incentive-compatible wage will be higher) the costlier effort is to workers, whether this is because the required effort level $\bar{e}$ has increased or the disutility of such effort has. Discipline will also be more expensive when either the likelihood of detection $d$ or the discount rate $\theta$ is lower. When, for example, workers care less about the future, the prospect of eventual dismissal will be less salient. An increase in the separation rate $q$ also causes the threshold in (1) to rise: as labour markets become more turbulent, workers have less incentive, *ceteris paribus*, to invest in a particular employment relationship.

To understand the full implications of (1), however, the lifetime utility of unemployed workers must be further decomposed. If $a$ is the fraction of the jobless pool that is (re)hired at the start of each period in equilibrium, the value of $V_3$ will be:

$$V_3 = \frac{(1 - a)\bar{w} + aV_1}{1 - \theta(1 - a)}$$

when employed workers find it in their interest to expend effort. It is then tedious but not difficult to show that (1) can be written:

$$w \geq \bar{w} + \left(\frac{1 - \theta(1 - a)(1 - q)(1 - d)}{\theta(1 - a)(1 - q)d}\right)^{\bar{e}}$$

(2)

In a provocative choice of words, Shapiro and Stiglitz (1984) called this now familiar incentive constraint the ‘no shirking condition’. As the likelihood of rehire $a$ tends toward 1, labour discipline becomes impossible to achieve because the incentive-compatible real wage increases without limit. In more intuitive terms, workers are certain to ‘contest the exchange’ if the expected duration of unemployment, in this case $\frac{1 - a}{a}$, and therefore the punishment value of dismissal, are small.

This model and the dozens, perhaps hundreds, of subsequent variations are sometimes viewed as mainstream restatements of the radical position that persistent joblessness is a characteristic feature of capitalism. In Volume I of *Capital*, for example, Karl Marx (1867, p. 701) saw the ‘industrial reserve army of the unemployed’ as a ‘condition of existence of the capitalist mode of production’, one which ‘[held the] pretentions of the active labor army in check’ in ‘periods of over-production and paroxysm’. Writing almost 80 years later, at the dawn of the Keynesian Revolution, Michal Kalecki (1943, p. 326) would claim that capitalists were ‘consistently opposed to creating employment by subsidizing consumption’, even if meant a reduction in profits, so that ‘discipline in the factories’ could be preserved.

The similarities should not be overstated, however. For Bowles (1985), for example, the difference between ‘Marxian’ and ‘neo-Hobbesian’ models is the difference between those in which the nature of capitalist production is central and those in which simple ‘malfeasance’ is the issue. Furthermore, while
there is no doubt that Marx believed that the reserve army served to constrain the demands of workers, its existence owes more to the dynamics of accumulation and technological change than to asymmetric information. And, unlike Shapiro and Stiglitz, or for that matter Marx, Kalecki believed the impediments to full employment were largely political, not economic.

The enforcement of labour discipline involves more than reserve armies, however. Levine (1989), for example, extends the Shapiro–Stiglitz model to show that, when firms cannot be sure that low output is the result of low effort, dismissal policies will violate the just-cause principle, and that the (forced) adoption of this principle leads to more efficient outcomes. In other contributions to the literature, enforcement is more subtle. The slope of the representative wage-tenure profile, for example, which some labour economists believe is too steep to be explained in terms of human capital accumulation alone, could also reflect firms’ pursuit of labour discipline: in this case, deferred compensation mimics the properties of a performance bond, and so increases the cost of job loss for recently hired workers.

The substantial variation in the ratio of supervisory to production workers across otherwise similar economies (and over time, for that matter) hints that, in practice, firms can influence the likelihood of detection or, in broader terms, decide how much, and in what form, workers will be monitored. Furthermore, there is reason to believe that, from an efficiency standpoint, firms will spend too much on supervision: if the size of the employment rent were increased at the expense of supervision, the same output could be produced with fewer inputs.

Both the choice of technique and the search for new methods of production influence, and are influenced by, the enforcement of discipline. In some cases, the most salient characteristic of a particular innovation is its effect on effort extraction. As the historian E. P. Thompson (1967) reminds us, for example, the spread of reliable mechanical clocks in production more than two centuries ago represented a watershed in the evolution of enforcement mechanisms, in much the same sense, perhaps, that computerization has, whatever its other effects, forever altered the power to monitor.

Braverman (1974) and others follow this line even further, arguing, in effect, that the widespread adoption of methods of mass production – in particular, the routinization of labour – owed much to how these methods simplified the extraction of effort and reduced replacement costs for dismissed workers. Even if mainstream economists are sceptical, few doubt that the ‘rise of the factory’ involved ‘substantial investment in fixed capital with strict supervision and rigid discipline’ (Mokyr, 2002, p. 2).

Finally, recent advances in behavioural and experimental economics have revitalized interest in ‘bureaucratic control’ (Edwards, 1977) of the workplace, in which the means to achieve labour discipline are often more subtle. There is considerable experimental evidence, for example, to support the view that workers and firms sometimes exchange ‘gifts’ of effort and wages, and that this relationship is ‘socially embedded’ (Gachter and Fehr, 2002), one consequence of which is that intrinsic motivation (a sense of loyalty, for example) can also contribute to labour discipline.

Since Richard Freeman wrote labour economics for the first (1987) edition of *The New Palgrave: A Dictionary of Economics*, labour economics has become increasingly empirical, with less emphasis on theory. The most noticeable change in empirical work is an increased emphasis on the plausibility of identification assumptions such as the validity of instrumental variables. Among the areas growing or receiving the greatest attention are changes in the wage structure, the economics of education, social interactions and personnel economics. The range of topics studied by labour economists today has broadened far beyond those of traditional labour economics.

Article

When Richard Freeman wrote his excellent article labour economics for the first (1987) edition of *The New Palgrave: A Dictionary of Economics*, which is reproduced in the present edition, labour economics had changed dramatically with the development of the human capital paradigm and the use of large-scale data-sets. In many ways labour economics has continued along the trends Freeman discussed, but in other important ways its focus has shifted, in terms of both topics and interests. The goal of this article is to describe major trends in this dynamic field of applied microeconomics since the 1980s. We begin with an overview of methodological trends that are common to much of the field and then talk about specific research questions within labour economics. We will direct readers to the appropriate *New Palgrave* articles for a more complete discussion of those topics.
One important way in which labour economics has changed since Freeman's article is that it has become increasingly empirical. Presumably, this trend is due at least in part to improvements in large-scale computing and ease of access to data sources. Along with this trend has come a decreased emphasis on theory in all but a few areas. The decreased emphasis on institutional factors, discussed in labour economics, has certainly continued (even the study of labour unions has declined substantially). Along with the trend towards increased empirical work has come a much stronger emphasis on the plausibility of identification assumptions. In many labour contexts, there are substantial unexplained variation in the dependent variables being studied, leading to interest in strategies for dealing with sample selection and endogeneity. In the case of earnings regressions, for instance, the vast majority of the variation in earnings cannot be explained by observable worker characteristics. While the presence of important unmeasured factors does not invalidate a regression model, it raises a concern that the coefficients on the variables of interest may be biased if the substantial unexplained component is correlated with the variables of interest. In the earnings regression case, one worries that workers who are more able or motivated (in ways that are unmeasured by the analyst) may obtain more school, biasing estimates of the return to school upwards. Labour economists have increasingly focused on these selection or endogeneity issues and this emphasis has spilled over from labour economics into other fields in economics.

The most noticeable change in approach is much greater emphasis on the plausibility of identification strategies. The two most noticeable examples in this vein are an increased use of fixed effect approaches (including ‘difference in differences’) and much more attention being paid to the validity of instrumental variables. A classic example is Angrist's (1990) study of Vietnam veterans. Estimating the effect of veteran status on earnings is plagued by the classic sample selection problem. Angrist solves this problem by using the Vietnam draft lottery number as an instrument for veteran status. This number is mechanically related to veteran status, but since it is random it will be unrelated to earnings again by construction. Studies along these lines are typically referred to as experimental or natural-experiment studies (depending on whether the variation arises from an explicit randomized experiment or policy or institutional factors that are plausibly, but not explicitly, random).

Structural estimation has also received substantial attention since the 1980s, although in relative terms, substantially less than during the previous 20 years. Different people may define structural in different ways. For example, simple linear models estimated by ordinary least squares or two-stage least squares can be considered structural if the researcher is explicit about the interpretation of the parameters. We have witnessed a large increase in popularity of a more ambitious approach in which a researcher formally models an individual's decision process and estimates the underlying parameters of say the utility function or production process by choosing the parameters that minimize the difference between observed outcomes and those implied by the model. For instance, a young individual has the option to attend school, or work in a variety of jobs, or remain in the household sector in each year of his or her life. One structural approach would be to estimate an individual's value function from the terminal period backwards at each node on the decision tree by matching observed behaviours to those implied by utility maximization. Unobserved individual factors can be addressed by including them in the value functions and integrating them out when trying to match the data. This approach is computationally demanding. Substantial advances in computational methods for these models and improvements in computer technology have allowed researchers to estimate considerably richer models. This approach has benefited from the year-by-year extension of longitudinal (panel) data sets.
The literature on returns to schooling provides a nice example of the evolution of empirical approaches. The goal of this literature is to estimate the causal effect of schooling. Willis and Rosen (1979) is a classic paper in this literature and an excellent illustration of empirical approaches prior to 1987. These authors consider a model with two schooling choices, high school and college, in which students make decisions to maximize the present value of earnings. They allow for individual heterogeneity in college and high-school earnings, college and high-school earnings growth, and interest rates. Their empirical approach consists of a three-stage method in which the first stage is a reduced form probit for college attendance. The second stage is a series of wage regressions including inverse Mills ratios. The third is a ‘structural probit’ that allows one to estimate the effects of earnings on schooling choices. The key for semiparametric identification in models like this is a variable that affects schooling choices but does not affect earnings directly (see Roy model for discussion of semiparametric identification in this type of model). Willis and Rosen use family background as their exclusion restriction. Family background is relatively strongly related to schooling and might not directly affect earnings. However, subsequent researchers have been sceptical about this exclusion restriction. The biggest concern in using regression analysis is that schooling is probably related to unobservable ability, but for similar reasons one may expect family background to be related to unobserved ability. Either through genetics, parenting skills, or simply resources one might worry that children from privileged backgrounds have more unobserved ability than their less fortunate peers.

Since 1990 or so many papers have tried to develop more credible exclusion restrictions to estimate the return to schooling. One of the most well known is Angrist and Krueger (1991), who use quarter of birth as an instrument. They argue that a combination of truancy laws and school starting ages will lead students born late in a calendar year to obtain more education than a student born early in a year. To see why, suppose that the cut-off date for starting school is 1 January. As a result, an individual born on 31 December 1962 will begin school a year earlier than a student born a day later, on 1 January 1963. However, if both of these students drop out of high school as soon as the truancy law says that they can, say on their 16th birthday, then the student born in December will have attained an extra year of schooling. Unfortunately, data-sets are not sufficiently large to focus only on these two days, so Angrist and Krueger (1991) use quarter of birth instead. Furthermore, there is a fair amount of slippage in that neither truancy laws nor age cut-off dates are strictly adhered to. Note that this last feature does not invalidate the instrument but reduces its power. As an example of a fixed effect approach, Ashenfelter and Krueger (1994) collect data on both earnings and educational attainment of twins. By using family fixed effects they can obtain an estimate of the returns to schooling, differencing out genetic ability.

At the same time we have seen a large structural literature emerge that has generalized Willis and Rosen (1979) by allowing for more complex educational choices and selection. A classic example of this approach is Keane and Wolpin (1994), who estimate a dynamic model of labour-market decisions. They generalize Willis and Rosen (1979) by allowing for many more than two schooling choices (high school versus college), by allowing students to go back and forth from the labour market and school, and by allowing the payoff to schooling to be sector specific. Another example is Heckman, Lochner and Taber (1998a), which estimates a general equilibrium version of the Willis and Rosen (1979) model that estimates not just the pricing equation for schooling but the determinants of both the supply and demand for college. This additional structure included in these papers allows one to simulate substantially more
complicated policy experiments than one can perform with the Willis and Rosen (1979) framework. There are substantial disagreements over the relative merits of different empirical approaches, and a full discussion goes well beyond the scope of this article. With that in mind, some of the instrumental variable and difference in differences approaches have the benefit of placing identification and the source of identification at the forefront of the analysis. For example, the source of identification in the Angrist and Krueger (1991) case is transparent. Estimation of intricate structural models typically requires substantial assumptions, whose validity is frequently unclear, but because the underlying parameters of the problem (preferences, the technology and so on) can be estimated, it is frequently possible to evaluate a wide range of policies that are not represented in the data. For example, identification in Keane and Wolpin (1994) is much less transparent. While it may appear that the reduced-form, natural experiment approach requires fewer or weaker assumptions, work of this type usually implicitly makes a number of important assumptions, particularly if one wants to apply these results to some other context. For example, Heckman, Lochner and Taber (1998b) demonstrate that one can severely underestimate policy effects if one ignores general equilibrium (GE) effects in their model. When researchers ignore GE effects in drawing policy predictions from their work, they implicitly assume that the demand for educated workers is perfectly elastic. The work of Heckman, Lochner and Taber (1998b) suggests that this is a very strong assumption. It seems likely that a large variety of approaches will continue to be used and that results that are robust across a wide range of approaches will be most convincing.

As indicated, labour economics has become increasingly empirical as emphasis on identification has increased. Personnel economics, the study of incentives within firms, is a notable exception. This literature is discussed in more detail in personnel economics. Another exception is work on search and matching, which spans labour economics and macroeconomics and which tends to be more theoretical. Because it requires explicit statements of the decision problem, structural work tends to be more theoretical than reduced form work, although deriving explicit theoretical results is rarely the focus of such studies.

Another notable recent development in labour economics is that the scope of problems that labour economists address has broadened considerably since the 1980s. However one wants to define ‘labour economics’ – as the study of the determinants of individual earnings, the demand and supply for labour, and the functioning of labour markets or as whatever labour economists do – what is noteworthy is that much of the work being done by labour economists falls well outside a traditional definition of the field. Similarly, other fields have increasingly drawn on ideas developed in labour economics, and the lines between labour economics and closely related fields, including development, urban, and public economics, are blurring. To some extent this reflects the general applicability of traditional labour theory (for example, human capital, which has played an important role in growth economics) and to some extent it reflects the widespread applicability of the econometric techniques developed by labour economists.

One of the most influential areas in labour economics since the 1970s has been the changes in the wage structure (see wage inequality, changes in). Much of this work focuses on the increase in inequality and the increase in the returns to education in the United States. This literature has emphasized demand-side factors, and skill-biased technological change in particular, as the primary explanation for the recent trends. Most recent work on the demand-side of labour economics has been in this area. Whether it is a
result of this literature, or coincidental, the whole field has shifted towards trying to understand wage differentials and human capital accumulation.

Another increasingly active area in labour economics is the economics of education, which perhaps can be considered its own field rather than a subfield of labour. The increased interest in education probably has arisen both from the literature on the changing wage structure, which emphasizes human capital, and from the increasing attention to education in the policy world. Within labour economics, understanding the economic value of education is one of the most studied empirical questions (see returns to schooling for a summary of this literature). Economists have also moved from wanting a general understanding of the effects of education on wages to a more specific understanding of what aspects of school are most important in forming human capital. Specifically, researchers have tried to uncover these factors in the ‘education production function’ literature discussed in education production functions.

We have also seen increased research on private schools and school choice (see school choice and competition for a discussion of this literature). Another branch of this literature (which is really much more of a subfield of public economics rather than labour economics) studies the complicated system under which schools are financed and how changes in these schemes influence students (see educational finance for a description of this literature).

Empirically, race and gender are also important determinants of wages. There is a long literature in labour economics on the economics of discrimination, which tries to understand why these differences arise. The two most studied effects have been the male/female and black/white gap in the United States. While the raw log wage differentials are of similar magnitude (approximately 20 per cent), the effects are very different from each other. As more controls are included in the analysis the black–white gap declines substantially; see black–white labour market inequality in the United States. This has led researchers to focus on pre-market forces as the primary cause. By contrast, men and women look much more similar when they enter the labour market. Thus the difference seems to be related to post-market entry factors. women's work and wages discusses this literature.

The traditional field of labour supply has probably received less attention since the last Palgrave than in the decades preceding it. Much of the work on this subject has focused on the lower end of the earnings distribution. Perhaps most importantly, a large literature has arisen that attempts to measure the effects of transfer programmes on labour supply of low-income individuals, especially on single mothers. Another important policy area has focused on understanding the effects of minimum wages on employment. Related to the literature on the changing wage structure, there has also been a substantial literature studying labour-force participation among low-skilled workers who are likely to be close to the margin to work and whose wages have fallen considerably (in the case of the United States). While it is well known that labour-force participation among women has increased substantially, participation among men has declined (see for example, Juhn, Murphy and Topel, 2002). This literature is discussed more thoroughly in labour supply.

Drawing on research in sociology, labour economists have also become increasingly interested in how people are affected by the groups (for example, schools or neighbourhoods) to which they belong (see social interactions (empirics) and social interactions (theory)). Such studies span a number of the topics already discussed – how students’ educational outcomes (and other behaviours such as substance use) depend on those of their peers; or how labour market activity (for example, employment or welfare participation) depends on that of neighbours. Naive estimates indicate that people's behaviours and
outcomes are highly correlated with those of their groups, but researchers have been concerned that the
groups that people choose (or are ‘forced’ into) are similar to themselves. A substantial literature has
developed using quasi-experiments and explicit experiments to estimate the effect of groups on the
people who are in them controlling for the selection processes into groups. Estimates that control for the
selection processes are considerably lower than those that do not.
While individual characteristics are very important for wage determination, characteristics of the firm
may matter as well. There have been an increasing number of data-sets that allow researchers panels on
both firms and workers. These types of data-set allow one to use procedures such as estimating both firm
and worker fixed effects (see for example, Abowd, Kramarz and Margolis, 1999). These papers show
that firm effects are an important component of wages. The most obvious explanation for this type of
result is that there is some type of friction in the labour market. Perhaps as a result there has been an
increased interest in labour market friction and its importance in explaining inequality: see labour
market search for a discussion of this search literature and matching for a discussion of the matching
literature.
There has also been increased attention on the economics of the household, which lies at the intersection
of labour economics and other fields such as demography. This work includes studies of bargaining
between members of the household on intra-household resource allocations and the effect of household
behaviours on children's human capital. Related to these topics are marriage and fertility decisions and
household labour supply.
In recent years, the theoretical concepts and empirical methods of labour economics have proven useful
across a wide range of topics. Consequently, labour economics has influenced work in a wide variety of
other areas and the topics studied by labour economists have expanded considerably.

Article

Labour economics studies the demand and supply for the most important factor of production, human beings. Since the days of Marshall and indeed of Smith, if not earlier, economists have recognized that one cannot analyse the market for labour, without taking account of such issues as social relations of production, long-term contractual arrangements, problems of effort and motivation, as well as institutions like unions and internal labour markets, which differentiate the labour market from a bourse. For many years recognition of these factors made labour economics an area in which economic theory was applied sparingly and in which institutional analyses dominated. This is no longer the case. Sparked in part by theoretical advances and in part by the availability of computerized data-sets with observations on hundreds, (thousands, tens of thousands) of individuals, labour economics underwent a dramatic revolution beginning in the 1960s and accelerating thereafter. As a result modern labour economics diverges notably from its past in two respects: creative use of theory to cast light on the aforementioned aspects of reality and detailed empirical investigations of the behaviour of individuals using advanced econometrics. In addition, in contrast to earlier labour economics, which dealt largely with firms’ behaviour from a demand perspective, there has been a pronounced interest in labour supply issues in much of the modern work.
Conceptually the most important development in the rise of modern labour economics has been the ‘human capital’ revolution associated with Gary Becker and Jacob Mincer, among others. Human capital analyses concentrate on individual decision-making, particularly with respect to labour supply and related areas of behaviour often associated with sociology rather than economics. Prior to Becker’s *Human Capital*, many labour economists tended to regard labour supply decisions as being only loosely based on economic rationality and therefore as a poor subject area for rigorous theory and analysis. By putting decisions regarding education and other forms of improving skills in an investment framework and developing implications for wages, time worked, and diverse other forms of behaviour, the human capital analysis fundamentally changed the way in which economists see labour supply. The simple investment concept – that individuals, like enterprises, ‘invest’ early in life (through schooling, and on-the-job-training) and reap rewards later, thereby producing an upward tilt to the age-earnings profile – has proved valuable in interpreting wages, and in directing attention to lifetime considerations in labour supply (for example, use of deferred compensation to motivate workers). Equally important, the view that diverse forms of decision-making can be fruitfully analysed by economic models of rational behaviour has illuminated not only traditional areas of labour supply behaviour such as labour participation, hours worked, job search, career choice, and the like, but has also extended the boundary of analysis to issues ranging from crime to marriage, fertility, and health.

At roughly the same time that human capital theory directed attention at individual behaviour, *computerized data-sets* providing information on the economic and demographic characteristics of individuals became available to analysts. The conjunction of theory and data produced a massive outpouring of studies on the effect of individual as opposed to market or employer factors on wages, and on the supply decisions of individuals. As a result of these factors the labour economist of the 1980s differed substantively in his or her orientation and analytic approach from the labour economist of earlier decades. Whereas in the 1950s labour economists generally studied wages and mobility at the level of industry, area, or in some cases establishments, in the 1970s and 1980s they tended to focus on individuals, first with cross-sectional data comparing different people, then with longitudinal (or panel) data that follow the same person over time. Whereas in the 1950s labour economics was heavily concerned with case studies, in the 1970s and 1980s labour economics had become pre-eminently the field of applied econometrics and statistical analyses of large data types.

In addition to use of modern theoretical and econometric tools, labour economics had been intimately involved in development and analysis of ‘controlled experiments’ to explore labour supply responses to alternative tax or welfare systems. The most famous of these experiments, the New Jersey and Seattle–Denver experiments, used a control methodology to explore the potential effects of a negative income tax, finding labour supply elasticities that ranged from modest (men) to significant (women) and also uncovering some forms of behaviour relatively hard to explain by standard economics theories (notably in family behaviour). Despite problems with the experimental approach, it marks a striking advance in the set of tools which are employed to explore supply issues.

While there will be some disagreement among economists about the contribution of the human capital and human capital-inspired analysis to explanation of social phenomena, a reasonable assessment is that the analysis has done a good job in illuminating a broad area of social behaviour but at the same time has not explained most of what goes on in the labour market. Changes in behaviour and in structural
relations for reasons of tastes, technology, or whatever, create variation at a point in time and changes over time that are not readily explicable by standard models. For example, in the area of female labour participation, studies find that income effects (reflected in husband's income) and substitution effects (reflected in the wages of the woman) and various indicators of the shadow price of time, such as number of young children, have the sorts of impacts on participation one would expect, but that these factors cannot readily account for the magnitude of upward trends in participation or for cross-country differences in trends or levels. Similarly, while the magnitude and probability of punishment and rates of unemployment and related labour market factors affect crime, they do not account for the high rates of crime in the US relative to other countries not for the time series pattern of change in crime in the US. Even in terms of wage determination, while the variables associated with human capital enter equations with high significance, they are not the dominant factor in variations in wages among individuals: in a typical log-earnings equation, education may explain five per cent of the variation and education and years of experience may explain 15 per cent in total, with job tenure (whose effect is partly the outcome of on-the-job training and partly the result of institutional seniority rules) dominating the experience component; additional important contributors to wage variation include such factors as industry and firm (or establishment) of work that cannot be readily interpreted solely by supply-side factors.

**Labour demand**

The theoretical and empirical thrust of modern labour economics has had less impact on analyses and understanding of demand for labour and firms' behaviour than it has had on the supply of labour. One reason is that previous generations of scholars had devoted considerable effort to analysing the demand side, dealing with such issues as internal labour markets, hiring, promotion, and wage policies, and the structure of wages in various markets, yielding a body evidence on behaviour which has stood up to further analysis. Another reason is that cross-section and longitudinal data on firms and establishments comparable to that on individuals have not been readily available. The computerization of personnel records of firms provides the best potential for major empirical advances in analysis of their labour demand and personnel policy, but as yet work on these records has been rather sparse. The modern analysis of labour demand has taken the key facts established by the previous generation – that labour markets are far from ‘spot markets’ – and sought to develop a consistent theory of economic behaviour, in which the firm is viewed as choosing a particular wage and personnel policy to optimize its profits, given the likely response of workers to the policy. Since firms will do best if they offer a labour compensation package that workers desire (at a given cost), some analysts look upon the firm as implicitly maximizing the utility of workers. Others pay greater attention to areas of conflict between the two sides, dealing with issues of shirking, (which makes deferred compensation especially valuable) and effort.

Thus far, the success of this approach has been more on the theoretical than empirical front. Analysts have developed models for such phenomena as deferred compensation, piece rates and related ‘prize’ systems for rewarding workers, and for such policies as mandatory retirement, but the ability of these ‘stories’ to account for the bulk of observed variation has not been demonstrated. To take one example, these are unquestionable differences in pay among firms to local labour markets: some firms pay what appear to be ‘above-market’ rates, while others pay less than the going rate. One can tell efficiency wage stories (firms pay high wages to reduce turnover and shirking); rent-sharing stories (firms share their
economic rents with workers); or union-threat stories (firms pay to keep unions out) about such policies; but labour economics has yet to determine the relative empirical relevance of these stories. In that sense, progress beyond the work of the generation of the 1940s and 1950s that stressed the firms’ wage policies has been limited.

Another area of work on demand, more grounded in the neoclassical model of the firm, has examined the magnitude of elasticities and cross-elasticities of labour demand for workers of different skills and the effect of administered wages (minimum wages) on employment. Since the basic parameters in labour demand analysis are elasticities of demand one would hope that empirical work would pin down their magnitude with some certainty. Such has not always been the case. In the US most studies, including those focused on the minimum wage, yield relatively modest elasticities for low-wage workers and manufacturing labour, usually considerably below unity. Analysis of demand for women workers in Australia, exploiting an exogeneous change in female wages due to comparable-worth-type rulings, has also found relatively moderate demand responses. Work on the UK and some European countries, by contrast, has yielded larger estimates of elasticities, which is puzzling given the widespread belief that the United States has a more flexible labour market with employers able to adjust employment more freely than in Europe.

Analyses of elasticities of substitution (which measure the effect of changes in relative wages on changes in relative employment) and of elasticities of complementarity (which measure the effect of changes in relative employment on relative wages) for narrowly defined skill, age, or education groups tend to find higher elasticities, implying that a large exogenous increase in the relative number of persons in a group can significantly affect the relative wages. Two cases in point are the 1970s increased number of young workers (‘baby boomers’) and of young college graduates in the United States, which greatly reduced the earnings of those groups relative to older and less educated groups.

As a general rule, shifts in demand schedules tend to account for more observed changes in employment than do movements along demand schedules. Work on factors shifting demand for labour (technology, changes in consumer tastes, income elasticities for the goods produced by particular groups of workers) has, however, been rather limited. One body of work has focused on relative demand for minorities, where the development of specific programmes to raise demand provides the same sort of exogeneous shift in the curve as minimum wages provide movements along the curves. The available evidence here suggests that affirmative action and similar programmes have played a role in raising demand for minority labour in the United States, though here as elsewhere changes in the market cannot be solely attributed to one demand-shift factor. Another body of work, associated more with governmental agencies than with academic economists, has projected future labour ‘requirements’ in an input–output framework.

Comparing the theoretical and empirical work on demand, one is struck by the failure of the empirical analysis to take appropriate account of the potential importance of the long-term employment arrangements and internal labour markets stressed in the theory. A major cause of the difficulty is a data problem: until analysts of labour demand have available detailed longitudinal data on employment by establishment or firm, and on firms’ personnel and wage policies, it is exceedingly difficult to marry the advances in theory to the data.

The contrast with the supply side, where theory and data came together, highlights the complementarity of the two ‘blades’ of the research scissors for a field to develop rapidly.
Institutions

In the area of institutions labour economics has tended to focus on unions as the major worker institution in modern capitalist economies. A massive body of work has examined the effects of unions on wages, beginning first with comparisons of wages in union and non-union sectors of the economy (industries, occupations across cities, and so forth), and then moving on to analysis of the computerized data-sets with information on individuals, classified by union status. While the question that motivates this work is ‘what do unions do to the economy?’ the empirical analyses have, of necessity, been devoted to measuring differences between union and non-union workers (firms).

Following a massive outburst of work on union–non-union wage differentials, labour economists turned to a wide variety of behaviour by individuals and firms likely to be affected by unions. Analysts found quits to be lower and job tenure higher under unionism; temporary layoffs (which occur when workers are laid off for short periods of time, then recalled) to be largely a union sector phenomenon; and the dispersion of wages to be lower in union plants, as well as finding effects of unions on profitability and productivity. This work has paralleled the human capital analysis by continually expanding the set of outcome variables under study and the labour demand analysis by focusing on issues dealt with by the earlier generation of labour economists.

On the theoretical front the thrust of modern work on unions has explored the idea of ‘efficient contracts’ in which unions and management eliminate potential inefficiencies due to monopoly through joint wage and employment determination. Efforts have also been made to develop models of unions as maximizing institutions, following the path laid out by Dunlop in the 1940s, in which unions are concerned with both wages and membership or job security.

Markets

Demand, supply and institutions interact in market settings, and labour economics contains numerous studies of the operation of labour markets for various types of labour. Attention has shifted from markets for blue-collar labour to markets for white-collar labour, and from case studied to more econometric investigations of wage, employment, and unemployment.

One strand of work, closely related to human capital analysis, has been to investigate markets for highly educated workers, where the time period of ‘production’ (college takes four years) allows one to differentiate supply and demand forces in the market. The first generation of such models used relatively simple cobweb structures; a later generation examined more complex rational expectations market-clearing models. The general tone of the results has been sufficiently successful to change the issue from whether markets follow readily understandable economic principles to which type of model best explains patterns of change. Even so, here as elsewhere in economics, the models have not done an especially good job in forecasting, in large because of our inability to project shifts in demand schedules, noted earlier.

Another stream of market analysis had dealt with such topics as geographic and industrial mobility, and unemployment and related wage patterns. Observed patterns of wages and mobility make it clear that in the United States decentralized wage setting across a huge geographic area produces separate local labour markets which experience different patterns of change, with costs of mobility sufficiently large as to produce significant ‘losses’ to some (particularly older) displaced workers. An important empirical
finding has been that high-wage cities tend to have high unemployment, providing some support for ‘job search’ as a factor in unemployment. Across industries, the United States evidence shows falling dispersion in wages in periods of economic boom (as low-wage employers raise pay while high-wage employers do not) and also an upward trend in dispersion of wages among industries. Other countries do not appear to have experienced such a trend over time, possibly because of centralized wage setting.

The question of whether unemployment is a long-term or transitory phenomenon has been analysed in the context of models which differentiate between completed and uncompleted spells and between the duration and incidence of unemployment. Perhaps the most important finding, which appears to hold for a large number of countries, is that the bulk of unemployment at any one time is due to a small number of people who are unemployed for long periods, rather than to short-term unemployed people.

Finally, an important area of labour research which diverges substantively from the micro-orientation of much of modern labour economics has involved analysis of macro-change in wages, employment and unemployment over time within a country and across countries. To some extent, labour economics has played a ‘devil’s advocate’ role with respect to proposed macro-explanations of problems like unemployment and wage inflation. Macroeconomists have suggested that unemployment is due to such factors as rigid wages associated with three-year contract cycles, intertemporal substitution of time, shocks that require mobility across sectors; labour economists have tested and, in general, rejected these models in a macro-context.

In addition, however, studies suggest that different labour market institutions in different countries may affect macro-outcomes as well. An important hypothesis has been that ‘corporatist’ or centralized free-market economies have an advantage in adjusting to stagflation because all workers can jointly agree to lower rates of increases in wages, avoiding Prisoner's Dilemma problems. Another hypothesis has been that ‘flexibility’ in labour markets is the key to the differential performances of the European and the American economy in employment generation in the 1970s and through the mid-1980s. In the area of theory the notion that ‘a share economy’ (where workers are paid in part via profit or revenue sharing) may produce less unemployment than a ‘wage economy’ has directed attention at alternative modes of paying workers, particularly over the business cycle. Whether comparative analysis focusing on different wage-setting mechanisms across countries becomes a major part of the field, however, remains to be seen.

Another area of comparative labour market studies that proliferated in the 1960s and 1970s focused on labour markets in developing countries. The Harris–Todaro model, which interpreted urban unemployment in terms of migration to cities and queuing for high-wage jobs, directed attention at mobility issues and institutional forces causing ‘dual labour markets’. A variety of studies dealing with the effect of education and human capital on earnings and behaviour revealed patterns similar to those in developed lands, suggesting that some aspects of markets function similarly across levels of development.

Conclusion

In the span of two decades labour economics has moved from a largely institutional field into the mainstream of economics, while maintaining its empirical bent. It has widened the subject of discourse, particularly on the supply side, and struggled to synthesize the ‘facts’ of the labour market with economic principles. It is the interplay of detailed micro data and economic analysis which currently is
the hallmark of the field, differentiating it from more abstract theoretical and less factually based parts of the discipline.

labour market institutions

Richard B. Freeman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Labour market institutions – unions, collective bargaining, government regulations – that help determine wages and working conditions differ greatly across countries. Advanced European countries rely extensively on institutions while the United States relies more on market forces. Labour institutions reduce the dispersion of pay and income inequality but have problematic effects on other aggregate economic outcomes, such as unemployment. The weak or inconclusive link between institutions and outcomes beyond wage dispersion could reflect different institutional effects under different economic conditions; efficient bargaining that balances the adverse and positive effects of institutions on those outcomes, or weaknesses in data and modelling.

Article

Labour market institutions – the organizations and procedures through which workers, firms, and the government affect wages, employment and working conditions – vary widely across countries and among firms and industries within a country. In some countries or settings within a country, trade unions, employer federations, personnel and human resource departments of firms and various forms of collective bargaining, or government regulations greatly affect how firms and workers interact at work places and help determine the hours, wages, occupational health and safety conditions, rules for promotion, and other conditions of work life. In other settings and countries these institutions have little impact. In those situations the market rules.
Once a minor tributary of economic analysis, the study of labour market institutions moved to the mainstream of discourse in the 1990s and 2000s as economists focused on differences in labour institutions as a possible cause of the varying economic performances among countries that had roughly similar macro-economic policies. The Organisation for Economic Co-operation and Development's influential 1994 Jobs Study (OECD, 1994a; 1994b) spurred research in advanced countries with its claim that many institutional interventions in the labour market reduced employment and that OECD countries should deregulate labour markets and weaken welfare state protections to achieve full employment. Ensuing analyses questioned the evidentiary basis for this diagnosis, producing a wide-ranging debate about how labour institutions affect advanced market economies. In developing countries, the analogous claim has been that institutionally determined wages and rules of work in the formal sector of economies reduce job creation in that sector and thus contribute to a dual labour market that harms economic growth and worsens the distribution of income. This also has generated considerable debate, pitting analysts who see institutions largely as creating distortions in competitive markets against those who see them as mechanisms for resolving market failures and shifting income distribution to workers.

Institutional differences

The starting fact for the debate is the wide variation of institutional arrangements in both advanced countries and developing countries. Table 1 summarizes the institutional architecture of the labour market in the United States and in advanced European countries – defined as European Union (EU) countries exclusive of the United Kingdom and Ireland, whose institutions are often closer to those of the United States than to the rest of the advanced Europe (Freeman, Boxall and Haynes, 2007) and inclusive of Norway and Switzerland, which are outside the European Union. The exhibit shows that the percentage of workers in unions is three times greater in the advanced European countries than in the United States. It notes a large difference in the organization of firms into employer associations. In advanced Europe many firms join employer associations that negotiate with unions, whereas in the United States employers negotiate separately with unions or with individual employees in the absence of collective bargaining. In addition, many advanced European governments extend the terms of a contract between an employer federation or major employer to all firms and workers in a sector, including those who were not party to the agreement, on the grounds that collective bargaining should produce a single wage just as supply and demand should produce a single wage in a competitive labour market. As a result of mandatory extension of contracts, the rate of collective bargaining coverage in advanced Europe (80 per cent in the table) exceeds the rate of unionization (38 per cent in the table); whereas the rates of union density and collective bargaining coverage are about the same in the United States. As a result, the gap in coverage between the United States and advanced Europe exceeds that in union density. The effect of mandatory extension on wage setting is most dramatic for France, where approximately 90 per cent of workers are covered by collective bargaining even though union density is six per cent or so – the lowest among advanced countries.

Source: Union density from Visser (2006), OECD (2004, Table 3.3; 2004, Table 2.A2.4, version 2; 2006a, Table 3.2; 2006b, Figure GE1.2, p 41), Gwartney, Lawson and Gartzke (2005), and Freeman and Chor (2005).

At the enterprise level, all countries in the European Union require that firms above a specified size introduce a works council of democratically elected employee representatives and that the firm consult with the council on key decisions that affect workers. In Germany firms must reach agreement with the council on some issues or go to arbitration to resolve disagreements. By contrast, the United States outlaws non-union employee organizations at the workplace for fear that they will become company-dominated barriers to independent unions. Many US firms set up employee involvement committees to deal with issues regarding workplace productivity, but these committees cannot legally represent workers’ interests to management. Going beyond enterprises, the EU relies extensively on social dialogue among employer federations, unions, and in many cases, governments to determine labour and other economic policies. Social dialogue produced Ireland’s 1987 Solidarity Wage Agreement in which the government agreed to lower taxes on workers, unions agreed to moderate wage demands, and employers agreed to seek to increase employment. The ensuing economic boom in Ireland suggested to some that the social pact contributed positively to Irish economic performance.
There are also large country differences in hiring and firing practices. Firms in the United States operate largely by employment at will, which means that the firm can replace workers for any business or other (non-discriminatory) reason. By contrast, many EU countries have employment protection legislation that requires firms to give substantial severance pay to laid off workers and to negotiate ‘social contracts’ with works councils to help laid off workers obtain training and new employment. In addition, European welfare states pay higher unemployment insurance in relation to wages for longer periods of time than does the United States, and provide national health insurance that US firms and workers must fund for themselves. These policies produce higher government social expenditures as a share of national income in the EU countries than in the United States, and commensurately higher taxes as a share of national income to pay for the benefits.

Taking these and related differences in the labour market together, analysts have created aggregate thermometer style indices of the institutional versus market orientation of country labour markets, in which higher scores reflect greater reliance on markets than on institutions. The Fraser Institute – a conservative think tank that produces an index of economic freedom based on metrics for ‘personal choice, voluntary exchange, freedom to compete, and protection of person and property’ (Gwartney, Lawson and Gartzke, 2005, p. 5) – codes countries that have extensive legal protection of labour and high levels of collective bargaining as having less economic freedom than those without these institutions. The Global Labor Survey has created a comparable index by asking union leaders, labour relations professors and other experts to report on the actual situation of labour in their country (Chor and Freeman, 2005). The difference in ideological persuasion between the Fraser Institute and most respondents to the Global Labor Survey notwithstanding, the two indices tell a similar story about cross-country differences. They give the United States and the other English-speaking advanced countries higher scores in using markets than European Union economies, and give the Scandinavian countries, which rely extensively on collective bargaining to determine pay and working conditions, particularly low scores in reliance on markets. While analyses of labour institutions in developing countries are less plentiful, the Fraser Economic Freedom Index and Global Labor Survey show a similar wide variation in the institutional framework for those countries. Botero et al. (2004) provide additional information on labour institutions across countries in terms of their labour laws. The indices of labour laws measure de jure labour institutions, whose impact on the labour market depends on the extent to which countries enforce their laws.

Institutions and outcomes

To see how institutions affect economic outcomes, analysts compare the economic outcomes for firms and workers within countries whose pay and work conditions are set by unions or regulations with the outcomes of firms and workers whose pay and conditions are set by market forces; compare the outcomes when institutional rules change (for instance, through an increase in minimum wages); and when the workers or firms move from market determination of wages and conditions of work to having an institution determine wages and conditions, or vice versa (for instance from moving from union to non-union status or non-union status to union status). To analyse how differences in institutions affect outcomes across countries, analysts contrast labour market outcomes between countries that rely more on institutions and those that rely more on markets; and compare outcomes before and after a country
changes its institutions with outcomes in countries that maintain their institutions over the same time period. The goal is to use the experiences of countries that do not change institutions as a counterfactual to predict what might have happened to countries that change institutions, and, conversely, to use the experience of the country that changed institutions to predict what might have happened in countries with stable institutions if they were to change.

Constructing a counterfactual to assess the impacts of institutions is difficult. One difficulty is that changes in institutional arrangements can affect the behaviour and outcomes for the group that is not covered by the changes as well as the covered group. A decline in union density, for example, might lower the wages of union and non-union workers equally, so that the differential between them was constant, which an analyst could misinterpret as implying no change in the wages of union workers. Another reason is that persons involved with institutions learn from past experiences, so that they may respond differently in the future to a given change in conditions than they might have done in the past. British unions made different decisions in the 1990s from those they made in the 1970s, in part because of their experiences in the earlier period. Finally, to the extent that one institutional rule affects another, a counterfactual analysis of a change in a single institution can be misleading if it does not allow for how the change interacts with other regulations and rules. When Spain enacted a law permitting firms to hire workers on temporary contracts, there was a huge increase in the proportion of workers hired under these contracts. When Germany enacted such a law, firms continue to hire apprentices for permanent jobs.

Difficulties of developing a valid counterfactual notwithstanding, virtually all analyses find that labour institutions reduce the dispersion of hourly earnings and the inequality of income (which depends on hours worked, and streams of income outside of work in addition to hourly pay) compared to market-pay setting. Studies that compare the distribution of earnings and incomes across countries find, for example, that the pay of persons in the 90th percentile of wages and salaries in relation to the pay of persons in the 10th percentile is lower in the advanced European countries that rely more on collective bargaining than in the market-driven United States and other English-speaking countries; and that the Gini coefficient of inequality for total income is also markedly lower in countries where labour institutions dominate wage-setting (Table 2). The US has the largest 90/10 earnings ratio of wages and the largest Gini coefficient for total income among advanced countries. By contrast, the Nordic countries, where collective bargaining sets wages for the vast majority of workers, have the lowest dispersion of pay and low Gini coefficients. Other advanced European countries and Japan also have relatively low pay dispersion and Gini coefficients. Centralized collective bargaining arrangements are sufficiently effective to narrow pay gaps even though most centralized agreements allow for ‘wage drift’ – higher or lower wages for some firms and workers than the negotiated central agreement due to variations in local market conditions.

Looking at earnings when country institutions change, increased reliance on institutions narrows the distribution of earnings while increased reliance on market-wage setting widens the distribution. Declines in collective bargaining coverage in the United States, Canada, United Kingdom and New Zealand contributed to greater inequality in those countries. Similarly, the decline in the real value of the US minimum wage added to inequality, while the introduction of the minimum wage in the United Kingdom limited the rise of inequality in that country. The breakdown of centralized negotiations between the major union federation and major employer association in Sweden raised inequality modestly in that country. But perhaps the most compelling evidence comes from the rise and fall of Italy's Scala Mobile mode of pay setting. The Scala Mobile was a national agreement that gave larger percentage increases in pay to low-wage workers than to high-wage workers. When the Scala Mobile determined wages, the dispersion of earnings in Italy fell sharply – towards Scandinavian levels. When Italy abandoned this mode of pay setting, in part because the distribution of pay seemed to have narrowed wage differentials beyond what made economic sense, the dispersion of earnings increased (Erickson and Iquino, 1995; Manacorda, 2004).

Studies within countries that contrast the inequality of pay among workers whose pay is set by institutions and those whose pay is set by markets also find that institutions are associated with lower dispersion of pay. Dispersion is less among unionized workers than among otherwise comparable non-union workers and less among government employees than among private sector employees whose pay is market-determined. Moreover, although the wage differential between union and non-union workers raises inequality between organized and non-organized workers, the net effect of unions on earnings is to reduce inequality. The overall distribution of earnings is dominated by the compression of wages within the union sector and by difference the reduced earnings between management and other high-paid non-union workers and union workers within firms. Consistent with this, studies that contrast the inequality of pay among workers who shift from non-union jobs to union jobs or the converse find that dispersion among a group of job changers falls when workers enter the union sector and rises when they leave the unionized setting (Freeman, 1984).

Is the institution-induced reduction in the dispersion of pay good or bad for the economy? To the extent that real world labour markets perform largely as ideal competitive markets, the reduced dispersion of pay distorts economic decisions on both the supply and demand sides of the market. By contrast, to the extent that real-world labour markets fall short of the competitive ideal, institutions can improve the efficiency of markets. There are plausible arguments and evidentiary support for both interpretations of what institutions do.
The claim that labour institutions adversely affect economic performance begins with the assumption that in the absence of institutional interventions, real labour markets produce wage, employment, and working conditions that approach those of an ideal competitive labour market. In this case, institutions can only distort incentives and reduce the efficient allocation of resources. For instance, union-induced wages above the market rate induce unionized firms to reduce employment, which reallocates labour to lower paid less productive activities. The following statement from the World Bank expresses the view that institutions distort the demand for labour in developing countries and slow down the shift of labour from agriculture and informal sector work to more highly productive and better-paid formal sector jobs:

Labor market policies – minimum wages, job security regulations, and social security – are usually intended to raise welfare or reduce exploitation. But they actually work to raise the cost of labor in the formal sector and reduce labor demand … increase the supply of labor to the rural and urban informal sectors, and thus depress labor incomes where most of the poor are found. (World Bank, 1990, p. 63)

The arguments against labour institutions in advanced countries are similar. On the demand side, institutionally driven increases in wages for the low-paid raise their cost to employers, which lowers their employment, and distort the allocation of the workforce among sectors, squeezing in particular low wage service industries. On the supply side, institutionally driven reductions in earnings inequality reduce pecuniary incentives to make efficient economic decisions. All else the same, reductions in the earnings premium paid to more-skilled workers will reduce investments in skills. And high unemployment insurance benefits will induce laid off workers to raise the reservation wage at which they will accept a new job and to search less intensely for jobs, producing longer spells of joblessness and higher rates of unemployment. In addition, the reduction in job search will lessen supply side pressures towards modest wage settlements that help job creation.

The magnitude of the distortions depends on the responsiveness of decision-makers to the institutionally determined incentives. In the standard ‘welfare triangle’ analysis, the economic loss from raising a wage above the market rate depends on the magnitude of the wage change and the elasticity of demand, which determines the magnitude of the distortion in the allocation of labour. (The formula for a welfare loss is \( \frac{1}{2} \times (\text{change in wages}) \times (\text{change in employment}) \), where the change in employment is the elasticity of demand times the change in wages.) The higher the elasticity of demand, the greater will be the welfare loss from wages above the market rate. Similarly, on the supply side, the higher the elasticity of supply to the returns to skills, the greater will be the welfare loss from decisions to forgo investments in skill due to the compression of wages, and the higher the elasticity of supply to unemployment benefits, the greater will be the welfare loss, due to the decision to search less intensely for a new job due to unemployment insurance.

Finally, institutional determination of labour outcomes can impose two additional costs on the economy. The first is the political lobbying and related resources that labour and management spend to affect labour regulations and the rules governing union and employer interactions. These are sometimes pejoratively labelled as the costs of rent seeking, though if institutions help to solve economic problems they could just as well be called the costs of problem-solving. The second are the resources involved in implementing institutional arrangements. These range from establishment of union and employer
labour market institutions: The New Palgrave Dictionary of Economics

federations, time spent in negotiations and dialogue at the workplace and at national levels. Discussion reduces the speed of decision-making, so that institutionally driven systems are likely to respond more slowly to economic changes than market-driven systems.

On the other side of the debate, the argument that labour institutions improve economic performance begins with the belief that real labour markets fall short of competitive equilibrium. Analysts view the high dispersion of pay for workers with observationally equivalent skills as reflecting the failure of the market to establish a single price of labour for similar workers. If this is a correct reading of the data, institutionally determined reductions in dispersion could create outcomes closer to the competitive ideal just as institutionally determined increases in wages can induce firms that are monopsonies to raise employment to competitive levels. Looking at the dynamics of wage changes, in an ideal competitive system, improvements in productivity in a given sector are supposed to show up in lower prices to consumers, not in higher wages (Salter, 1960; Council of Economic Advisors, 1962); while changes in the prices of products due to changes in demand are supposed to induce firms to change output and employment but not to change wages. The reason wages are not expected to respond to these shocks is that the competitive model posits that firms face a perfectly elastic supply of labour at the market wage rate. In fact, changes in wages are highly related to changes in productivity and prices among industries in the United States but not in the Nordic and other countries where institutions determine wages (Holmlund and Zetterberg, 1991; Teulings and Hartog, 2002). At the national level, some analysts argue that the union and employer federations that negotiate national wage agreements adjust wages more rapidly to macroeconomic developments such as balance of payments or inflation than local labour markets that respond to the macroeconomy less directly.

Finally, inside firms, labour institutions can facilitate the flow of information from workers to management and from management to workers. Workers are more likely to provide information to management when they can influence how management uses the information. Regulations or union pressure that force management to open its books to workers gives them or their representative access to the same information that guides management. Increasing the flow of information and communication can in turn lead management and workers to make better decisions. Workers will be more likely to give wage concessions when the firm is truly in crisis and avoid being snookered when the firm cries ‘wolf’ while continuing to earn profits (Freeman and Lazear, 1995). In addition, workers who have an institutional voice for dealing with problems are less likely to quit their employer and more likely to invest in firm-specific skills and seek to resolve problems by bringing them to the attention of management.

Evidence

The OECD Jobs Study contains two volumes of research and references to research that buttressed its claim that labour institutions explained some of the job market problems of OECD countries. Since the Jobs Study many other analysts have examined the link between those institutions and outcomes, generally using cross-country time series data that the OECD provides. Each year the OECD reviews the latest findings on particular issues regarding the impact of labour institutions in its Employment Outlook. As economists inside and outside the OECD have critically examined the data and models that link outcomes to institutions, they have moved to a more cautious stance about the evidentiary support for
the Jobs Study conclusions. Assessing the time series models that the OECD and others used in their analyses, Baker et al. (2005) found that the estimated coefficients on labour institutions were not robust to changes in specification. They found that models that covered more years, additional countries or used different measures of the institutions than the early studies ‘provide little support for those who advocate comprehensive deregulation of OECD labour markets’ (2005, p. 106). Baker et al. conclude that there is a ‘yawning gap between the confidence with which the case for labour market deregulation has been asserted and the evidence that the regulating institutions are the culprits’ (2005, p. 198). Assessing results in the mid-2000s, Howell et al. (2007) and Baccaro and Rei (2005) come to a similar conclusion.

For its part, the OECD has recognized that the evidence is more equivocal than first claimed. The 2004 OECD Employment Outlook noted that ‘the evidence of the role played by employment protection legislation (EPL) on aggregate employment and unemployment rates remains mixed’ (2004, p. 81). It argued for ‘the plausibility (my italics) of the Jobs Strategy diagnosis that excessively high aggregate wages and/or wage compression have been impediments’ to jobs, while admitting that ‘this evidence is somewhat fragile’. With respect to unionism, it summarized research as showing the effect of collective bargaining ‘to be contingent upon other institutional and policy factors that need to be clarified to provide robust policy advice’ (2004, p. 165). In a similar vein, the IMF (2003) reported that ‘Institutions … hardly account for the growing trend observed in most European countries and the dramatic fall in U. S. unemployment in the 1990s.’ German unemployment, for example, rose by about six percentage points in the 1990s while US unemployment fell, even though labour institutions were broadly unchanged in both countries. But the IMF still concluded that the route to full employment rested with deregulating labour markets. The strong priors and commitment to the case that institutions are the problem overrode the actual evidence.

The 2006 OECD Employment Outlook went a step further in assessing the impact of institutions on outcomes. It highlighted that countries with low unemployment had very different modes of wage-setting, ranging from some smaller European countries that relied on collective bargaining to the more market-determined United States and United Kingdom (2006a, Table 6.3). If different institutions can reach similar market outcomes, there may be no ‘peak’ form of labour market institutions to which each country should strive (Freeman, 2002). But this does not resolve the debate over the impact of institutions. In a study that took account of criticisms of the non-robust findings of earlier cross-country time series data, Bassanini and Duval (2006) found that changes in tax and labour policies explain about half the 1982–2003 changes in unemployment among countries, with changes in tax policies playing a particularly large role.

The potential effect of employment protection legislation on unemployment has attracted considerable attention. Countries pass these laws to reduce layoffs and raise job security for existing workers. But the laws make it more expensive to hire workers since firms must factor in the greater expense of laying them off if business dictates reductions of output. The net effect of employment protection laws on aggregate employment thus depends on the degree to which they reduce layoffs compared to the degree to which they reduce hires. An alternative perspective predicts that on net the employment protection laws should have little or no impact on aggregate employment or unemployment. If employers and unions bargain efficiently, then the Coase Theorem predicts that they should bargain so that the firm makes the efficient layoff regardless of the employment protection law. What differs is the division of the profits from the efficient choice. With employment protection the firm pays some of the profit from
a layoff to the worker to get the worker to leave. With employment at will, the firm gets all the profit from the decision. Studies of unemployment and employment between countries with greater or lesser employment protection are broadly consistent with this view. They show that the regulations have little effect on the overall rate of unemployment but shift unemployment from older workers to younger job-seekers (OECD, 2004). In developing countries as well, job security regulations appear to shift employment from the unskilled youth to the skilled and older workers protected by the legislation (Montenegro and Pages, 2003).

In summary, there is no clear consensus from the empirical analyses that labour institutions have adverse or positive effects on aggregate economic outcomes beyond their distributional effects on earnings or employment.

Alternative interpretations

There are three possible interpretations of the empirical evidence that institutions reduce the dispersion of earnings and income but do not have clear or easily identified effects on other aggregate economic outcomes.

The first interpretation is that extant measures of institutions and models of their impact are too crude to pin down the hypothesized effects on other outcomes. Better cross-section time series data on countries and more sophisticated statistical modelling might produce statistically significant impacts of institutions on outcomes beyond dispersion of pay. Most economists believe that disaggregated data that cover thousands of observations on individuals or firms has a greater likelihood of pinning down responses of individuals and firms to changes in labour policies and institutions than further analysis of short time series across countries. But these analyses are insufficient in themselves to capture what might happen when a country changes its institutions. What might better illuminate the impacts of institutions at the national level would be to combine estimated response parameters from microeconomic studies with artificial agent models that simulate labour markets under different institution.

The second interpretation is that the effects of institutions vary over time as the economic environment changes. Given that the labour market institutions in the United States and advanced Europe were largely unchanged between the 1960s and 1990s, the only way for institutional factors to explain lower European unemployment in the former period and higher European unemployment in the latter period would be that the impact of the institutions changed over time (Blanchard and Wolfers, 2000; Lundquist and Sargent, 1998; OECD, 2006). Perhaps EU institutions were well suited to produce low unemployment in the economic conditions of the 1960s–1980s while US institutions were better suited to produce low unemployment in the globalized digital economy of the 1990s and 2000s. This interpretation is appealing. But it is difficult to test since it makes great demands on data. Allowing institutions to affect outcomes differently in different time periods reduces the number of observations with which to test the hypothesized impact and risks creating epicycles of interactions to account for observed patterns.

The third interpretation is that in fact labour institutions have first-order effects on income distribution but only modest second-order effects on other outcomes. Perhaps the hypothesized adverse effects that institutions can have on economic efficiency are balanced by their hypothesized positive effects, giving a net effect around zero. This is consistent with efficient bargaining theory, in which parties strive to
reach efficient outcomes but battle over distribution. This interpretation is appealing. But there are enough situations in which unions, firms and governments do not reach efficient solutions to raise questions about it. As Sir John Hicks pointed out in *The Theory of Wages* (1934), efficient bargaining implies that strikes, which in most cases harm workers and firms, should vary randomly across industries, regions, firms and time as a result of random errors of judgment or communication. In fact strikes occur frequently in some sectors (for instance coal mining) and not in others, in some firms but not in others, and vary over the business cycle in ways that conflict with the efficient bargaining model. In conclusion, we need to learn much more about how labour institutions affect the economy and how they operate for us to resolve the debate over whether institutions are part of the problem facing economies or part of the solution, or, more likely, which institutions and issues fall more into the former category and which fall into the latter category under particular economic conditions.

labour market search

Dale Mortensen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Time and other resources are required in the process by which workers and jobs are matched: this process is referred to as labour market search. Models of the search process have made contributions to our understanding of unemployment incidence and duration, labour turnover, earnings growth and wage dispersion. These models, which are based on the assumption that agents act in their own best interest, are designed characterize market equilibria in environments complicated by imperfect information and uncertainty. Consequently, they are also useful in the analysis of labour market policy.

Article

Labour market search refers to the process by which workers and employers find and match with one another in the labour market. The theoretical models that have been developed to understand the process explicitly account for the fact that search and matching are time consuming activities. The models have been used to interpret empirical data on phenomena that include unemployment duration and incidence, unemployment fluctuations, labour turnover, earnings growth, and wage dispersion and discrimination. As with other equilibrium models in economics, these are based on the assumption that participants in the labour market act in their own self-interest and that the market phenomena observed are explained by outcomes of the market participant interaction. Hence, they can and are used to address the consequence of labour market policy on labour market statistics and on the welfare of labour market participants.

Equilibrium search theory extends the standard competitive model of the labour market. In spite of the
obvious usefulness and elegance of the competitive market equilibrium for the analysis of many questions, the framework in its simplest form excludes much of the phenomena of interest to a labour economist. To give but two examples, there is no unemployment in competitive equilibrium and workers with identical skills earn the same wage. Equilibrium labour market search theory was developed to explain these facts as well as other phenomena having to do with the dynamics of the employment and earning experiences of individual workers that cannot be accommodated in the standard model. More generally, the labour market search framework has proven to be a useful tool for thinking about markets with ‘friction’, those that function without the market clearing auctioneer invoked in the competitive market framework. How do the participants in such markets come together? How are prices and the quantities exchanged at these prices determined? Search theory attempts to answer these questions.

Modelling the fact that the labour market experiences of individual workers take place in real time is an essential ingredient of the labour market search approach. After workers leave school and enter the labour market, most spend time seeking a job. Once employed, young workers seem to ‘job-shop’ by trying several employers and occupations before settling down to an extended period of employment with one. Later, employment spells are punctuated by interruptions attributable to changes in the individual’s desire for employment, on the one hand, and the termination of the worker’s current job, on the other. It is fair to say that virtually all the recent theoretical treatments of these phenomena are based on labour market search theory, and that theory informs the interpretation of most empirical studies that focus on them.

Individual search behaviour

The reservation wage

Labour market search theory began as a model of how a worker might gather information about employment opportunities. In the real world, there are many sources of such information. Economists and sociologists distinguish between formal and informal search channels. Formal channels are information sources provided by market institutions such as newspaper advertisements, public employment services, private employment agents and the Internet. Informal channels include friends, relatives, and neighbours, anyone in the workers’ extended social network. It is well known that most workers find their jobs through these informal channels, a fact that underlines the decentralized nature of the labour market.

The first important paper in search theory, by George Stigler (1961), was an attempt to formalize the economic problem posed by the need to gather information about trading opportunities in a non-auction market where different prices for the same or close substitutes can coexist. He modelled the problem as one of choosing the size of a sample of prices drawn randomly from the available set. Given that the agent would purchase the good from the lowest-priced seller in the sample and must pay a fixed cost per price sample, how many quotes should the buyer seek?

Although this well-known problem in sampling theory provides some interesting insights, it does not serve well as a model of job search. In that context, it is the worker’s time rather than money that is the principal cost incurred. Furthermore, the length of time spent by an unemployed worker is an observable quantity that is measured in both survey and administrative data. The models focused on the duration of
search, which were simultaneously introduced by McCall (1970), Mortensen (1970), and Gronau (1971), became the basis for further work on the subject. The idea underlying these models is that the duration of job search by an individual worker is usefully viewed as a random variable with the length determined by the worker's decision to accept or refuse offers as they arrive. In other words, instead of gathering a sample of job opportunities and selecting the one most preferred as in Stigler's formulation, these authors argued that it was more realistic to think of the search process as sequential in time. Offers arrive one at a time and the unemployment period ends when the worker accepts one of them. As McCall (1970) pointed out, this is formally an optimal stopping problem in the theory of decisions under uncertainty. It is well known that a reservation strategy is optimal: accept the first offer above some critical value.

Formally, let $F(w)$ characterize the distribution of offers and suppose that the number of offers received in a time period of unit length is a Poisson random variable characterized by the arrival rate $\lambda$. Assume that the worker is a risk neutral with an indefinite future life span. When the distribution of wages is known, the optimal strategy is to accept the first wage offered above a reservation wage. In other words, the reservation wage, denoted as $R$, is the lower bound on the set of wages that are acceptable to the worker. Accepting employment at the reservation wage must just compensate for any income forgone by becoming employed, which one can think of an unemployment benefit denoted by $b$, plus the option of continued search. Formally, if the worker does not plan to search while employed, the reservation wage is the implicit solution to the indifference condition.

$$R = b + \lambda \int_{R}^{\bar{W}} \left( \frac{w - R}{r + \delta} \right) dF(w),$$

(1)

where $r$ is the rate at which worker's discount future income, $\delta$ is the rate at which the worker can expect to lose a job, and $\bar{W}$ is the upper support of the wage distribution (see Mortensen and Pissarides, 1999a; 1999b for a derivation of the equation). The second term, the option value of continued search, is the product of the offer arrival rate and the expected present value of the future gains in income attributable to the possibility of receiving an offer in the future.

**Empirical application**

Labour economists later exploited the empirical implications of the original stopping model. In one of the first such papers, Ehrenberg and Oaxaca (1976) pointed out that the expected duration of an unemployment spell and the expected post-spell wage were both increasing in unemployment insurance benefit. Specifically, since a spell ends only when an offer is received and it is found acceptable, the hazard rate of the unemployment duration distribution is the product $\lambda [1 - F(R)]$. Hence, the duration distribution is exponential with expectation equal to the inverse of the hazard that is increasing in $R$. As the post-spell distribution of wages is the distribution of offers truncated on the left by the reservation wage, the expected post-spell wage,
is increasing in $R$. Since the reservation wage, the solution to (1), is increasing in unemployment income $b$, the expected duration of an unemployment spell and the average wage earned once employed should both increase with the generosity of the unemployment benefit.

Subsequently, Kiefer and Neumann (1979) used the fact that the model specifies the form of the statistical likelihood function for the observed length of unemployment spells and accepted wages. Formally, for a sample of $n$ completed spells of unemployment followed by employment at an observable wage, a set of pairs denoted by $(t_i, w_i), i=1,\ldots, n$, the likelihood of the observed sample is given by

$$L = \prod_{i=1}^{n} \lambda [1 - F(R_i)] e^{-\lambda[1 - F(R_i)]} \frac{F'(w_i)}{1 - F(R_i)}$$

for a set of workers who all sample from the same wage offer distribution. In this equation, $R_i$ is the reservation wage of worker $i$ which varies with the entitled unemployment insurance payment as determined by eq. (4). Given observed values of $b_i$ one can estimate both the offer arrival rate parameter and the distribution of acceptable wage offers using this structure, at least in principle. For a review of the early empirical literature that uses the duration analysis approach to estimation and search theory to interpret the results see Devine and Kiefer (1991). Wolpin (1995) provides an excellent treatment of the structural approaches to estimation of decision theoretic search models.

**Equilibrium wage dispersion**

The wage dispersion assumed in the stopping formulation of the job search problem is obviously inconsistent with the ‘law of one price’ that characterizes competitive equilibrium. Idiosyncratic match productivity is the simplest way to justify the assumption that a worker's employment opportunities can be described by a distribution of alternative wages. Although this justification may be sufficient for the purpose, Rothschild (1973) asks the following question: are there reasonable conditions under which wage dispersion, different wages paid to workers of identical skill, exists in equilibrium?

Consider the following simple one-shot game. All workers are identical and the common value of their marginal product is $p$ in every firm. Assume that each worker receives a finite sample of job offers, say
of size $n$, chosen at random from the set of all offers. Since the worker has no future in this formulation, his or her best strategy is to accept the highest offer in the set provided that it exceeds the opportunity cost of employment, denoted above by $b$. Of course, positive gain from trade requires that $p > b$. Given this strategy, what will profit maximizing employers offer?

Suppose that $n = 2$, that is, every worker receives offers from exactly two different firms. Because each worker will accept only the higher of the two offers, any employer paying a wage strictly less than all the others will hire no workers. Hence, a strictly positive fraction of employers must offer the lowest wage in the market: denote it by $w$. It follows that the expected profit earned is $\Pi = (1 - \alpha) \frac{1}{2} (p - w)$ where $\alpha$ is the fraction of workers that receive a strictly larger offer. In other words, the other wage drawn by the worker must also be the smallest in the market, an event that occurs with probability $1 - \alpha$.

If so, the worker chooses one of the two offers at random, with probability $1/2$. But it will always pay an individual employer to break ties by offering slightly more. That is, because the profit obtained by doing so is $\Pi = (1 - \alpha) (p - w - \varepsilon) > \Pi = (1 - \alpha) \frac{1}{2} (p - w)$ for all sufficiently small $\varepsilon > 0$ if $p > w$, it follows that the smallest offer is $w = p$ in any equilibrium. Hence, all offers equal the competitive equilibrium wage, $w = p$. Obviously, this argument holds for any value of $n \geq 2$.

The fact that Bertrand competition obtains when every worker receives at least two offers would seem to rule out wage dispersion. However, this conclusion is false because the price-gathering process embodies an information externality as Rothschild (1973) points out. Suppose for the sake of argument that the first wage quote is costless but there is a small cost of finding a second. In this case, all workers sampling twice is not a non-cooperative equilibrium strategy in the game of wage search. Namely, if all workers see two prices, there would be no dispersion as we have just shown. But, if there is no dispersion, no worker has an incentive to pay the cost of obtaining a second price quote. It follows immediately that a single common wage equal to the opportunity cost of employment, $w = b$, is an equilibrium, a result due to Diamond (1971). However, Burdett and Judd (1983) demonstrate that another equilibrium generally exists in which a fraction of the workers seeks two offers while the complementary fraction obtains only one. The equilibrium in this case can be characterized by a unique continuous distribution of wage offers.

The details of the Burdett–Judd argument are beyond the scope of this article. However, the reason why an equilibrium of a wage posting game of the kind outlined above can be characterized by a distribution of offers is easily understood in the context of the sequential search model outlined above extended to allow for search on-the-job as in Burdett and Mortensen (1998).

If search costs are not too large, it is obvious that the employed as well as unemployed workers have an incentive to search when wage offers are dispersed. Hence, in the model there will be two kinds of workers: the unemployed, who only see one wage offer at a time, and employed workers, who will be able to choose between continuing employment at the same wage or moving to alternative employment when the opportunity arises. In short, at any point in time a strict subset of the workers have two offers while another fraction has one.

Given search on-the-job, employers who pay more attract a larger fraction of applicants and suffer less turnover. This trade-off between wage and turnover costs provides the reason for dispersion. Formally, let $V(w)$ represent the value of meeting a prospective employee to an employer who pays wage $w$. It is the product of two terms, the probability that an applicant will accept the wage offered and the present
value of the future stream of profit that the employer can expect to earn if he or she accepts. Under the assumption that all the employed workers accept any wage above a common reservation value, \( R \), but an employed worker accepts if and only if the wage offer exceeds that currently earned, the acceptance probability is equal to

\[
\mathcal{A}(w) = u + (1 - u) G(w)
\]

where \( u \) is the unemployment rate and \( G(w) \) is the fraction of workers who currently earn less than the wage offered, \( w \). Given that job separations occur at rate \( \delta \) for exogenous reasons and a worker will quit when ever a higher-paying job is located, the expected present value of future profit is

\[
V(w) = \mathcal{A}(w) J(w) = \frac{[u + (1 - u) G(w)](p - w)}{r + \delta + \lambda [1 - F(w)]}
\]

where the production of \( \lambda \), the rate at which the worker generates outside offers, and \( 1 - F(w) \), the probability that an alternative offer exceeds the worker's current wage, is the rate at which an employed worker can be expected to quit. Hence, the expected value of meeting a worker contingent on the wage offered is

Because a higher wage increases the acceptance rate and reduces the quit rate, a trade-off between wage and turnover costs is evident in this relationship. It is natural to assume that each individual employer will choose the wage to maximize the expected present value of future profit, the function \( V(w) \), given the wage offers of all the other workers. However, because all the employers are identical by assumption and the offer distribution \( F(w) \) is endogenously determined by all their wage-setting decisions, it follows that profits must be both maximal and equal to the support of any equilibrium distribution. Furthermore, because unemployed workers accept all offers and an employed worker accepts an offer only if it exceeds that currently earned, the acceptance probability is the unemployment rate and the quit rate is the offer arrival rate \( \lambda \) at the lowest equilibrium offer, which is the common reservation wage \( R \). Hence, the equilibrium distribution is the unique solution for \( F(w) \) to the following equal profit condition:
As no worker will accept employment at a wage below \( R \) and any wage offer above \( \bar{w} \) yields less profit, this condition is also sufficient for profit maximizing. Variations and extensions of this model have been used to study the link between wages, labour turnover, the return to education, discrimination, and the duration of employment spells. The approach has also proven to be a valuable tool for the analysis of firm data on employment and workers flows. Eckstein and van den Berg (2007) provide a review of the literature that uses the model as the basis for parameter estimation. See Mortensen (2003) for a more complete development of the theory and a review of the empirical applications of the approach.

**Equilibrium unemployment**

Search and matching model of unemployment, those based on the original two-sided search models of Diamond (1982), Mortensen (1982) and Pissarides (1985) have focused on the time required to find employment. In this family of models, match rent exists after worker and employer meet because finding an alternative is costly. When worker and employer meet, they are assumed to bargain over their joint output. According to Nash (1950), the outcome of the bargaining problem yields a wage equal to the flow value of unemployment, represented by the reservation wage \( R \), plus some share of the rent attributable to the current job–worker match, when search for an alternative partner is assumed to be the outside option. Formally,

\[
V(w) = \frac{[u + (1 - u)G(w)](p - w)}{r + \delta + \lambda[1 - F(w)]} = \frac{u(p - R)}{r + \delta + \lambda} = V(R) \forall w \in [R, \bar{w}] \text{ where } F(\bar{w}) = 1.
\]

where \( p \) represents match output and the value share parameter \( \beta \) reflects the worker’s relative ‘bargaining power’. When all matches are identical, the wage is the same for all job–worker matches. Furthermore, one can show all matches are acceptable if and only if match product \( p \) exceeds the opportunity cost of employment \( b \).

As wages are the same in all jobs in this model, there are no quits, which implies that the expected present value of the future profit attributable to employing a worker is \( J(w) = \frac{p - w}{r + \delta} \). Hence, an employer has an incentive to create a job whenever \( J(w) \) exceeds the cost of doing so. For example, if the cost of advertising a job opening is \( c \) and the advertisement will attract applicants at frequency \( \eta \) per period, then it pays to post a vacancy whenever the expected cost of filling it, \( c/\eta \), is less than the expected return to doing so as represented by \( J(w) \).

At this point, it may have occurred to the reader that the rate at which workers are matched with jobs,
denoted above as $\lambda$, and the rate at which vacant jobs are matched with worker, $\eta$, above must be related. In the literature these are determined by a *matching function*, a market relationship between the flow of matches that form, and the number of workers and jobs seeking, a match. In this view, the matching function, denoted as $M(u, v)$, is a kind of ‘production function’ that relates the match inputs to match output. Given this function, it follows that $\lambda u \equiv M(u, v) \equiv \eta v$ since $\lambda u$ and $\eta v$ are both equal to the total match flow in the aggregate.

It is natural to suppose that the matching function, like an aggregate production function, is increasing, concave and homogenous of degree one. There is now a relatively extensive empirical literature, reviewed by Petrongolo and Pissarides (2001), which for the most part confirms these assumptions. When they hold, the vacancy-filling rate $\eta = \frac{M(u, v)}{v} = \frac{M(u)}{v, 1}$ is decreasing function of the ratio of vacancies to unemployment. Hence, if the expected return to filling a vacancy exceeds the cost of posting it, more vacancies will be created, driving down the expected return. Under the assumption of free entry, then, the market equilibrium number of vacancies posted at any point in time satisfies the free entry condition

$$\frac{c}{\eta} = \frac{c\theta}{M(1, \theta)} = j(w) = \frac{p - w}{r + \delta}$$

(3)

where the vacancy–unemployment ratio, $\theta = v/u$, is referred to as *market tightness*.

In summary, an equilibrium solution to the model is a wage, reservation wage, and market tightness triple $(w, R, \theta)$ that joint satisfies the eqs (1), (2), and (3). Finally, because existing jobs are destroyed at rate $\delta$ and the flow of unemployed workers who find jobs is $\lambda u = M(1, \theta) u$, the steady state value of unemployment rate, that which equate the flows in and out of the unemployment state, is

$$u = \frac{\delta}{\delta + M(1, \theta)}.$$  

(4)

In other words, unemployment tends over time to a steady state value that increases with the rate of job destruction, $\delta$, and decreases with market tightness, $\theta$. Furthermore, market tightness depends on the incentive to create new jobs, the profit an employer can expect to earn in the future after the match forms. From eq. (3), it follows that labour productivity, represented by the parameter $p$, is a major contributor to that incentive. Indeed, a positive shock to $p$ first increases vacancies and, consequently, market tightness. Over time unemployment falls in response until its new steady state value is realized as characterized in eq. (4). As a consequence, shocks to productivity trace out a downward sloping relationship between vacancies and unemployment, known in the empirical literature as the Beveridge

http://www.dictionaryofeconomics.com.proxy.library.csun.edu/article?id=pde2008_L000220&goto=B&result_number=935
The effect of productivity shocks on unemployment is amplified by the fact that the rate of job destruction, $\delta$ in the model, falls with $p$. This channel of influence is incorporated into an extended version of the formal model by Mortensen and Pissarides (1994).

The theory has clear implications for labour market policy. For example, unemployment insurance is common in all developed economies and is either enacted or under consideration in many developing countries. As unemployment benefit is income contingent on being unemployed, it can be represented in the model by the parameter $b$. From eqs (1) and (2) it follows that any increase in the benefit will raise wages, though its effect on the worker's bargaining threat point. In turn, the increase in wages will decrease future expected profit which will lead to a reduction in vacancies and market tightness according to the free entry condition (3). These facts together with eq. (4) imply that a higher unemployment insurance benefit will raise the steady state level of unemployment. By clarifying this mechanism, the theory has played an important role in the debate over labour market policy reform in Europe.

For an extensive discussion of the matching model of unemployment and its implications see Mortensen and Pissarides (1999a; 1999b), Pissarides (2000), and the recent review article by Rogerson, Shimer and Wright (2005).

Summary

The development of the search-theoretic approach to the analysis of labour markets has focused on two different issues, wage dispersion and unemployment, and the models used in each case are not fully consistent with one another. For example, in one branch wages are set by the employer while in the other wages are the outcome of a bilateral bargain between worker and employer. This and other specification differences are subjects of current theoretical and empirical research designed to collect the features of each approach that best explain all the phenomena of interest. The ongoing research, designed among other purposes to integrate the two approaches, is reviewed by Rogerson, Shimer and Wright (2005).

The analysis of labour supply is placed in a general framework within which empirical models and their resulting elasticity estimates can be interpreted. An explicitly intertemporal life-cycle structure is developed for the choice of hours and participation. The relationship between economic substitution effects found in the labour supply literature and wage impacts on different concepts of employment is considered. We provide a separate discussion of the main issues surrounding the analysis of family labour supply and the analysis of the impact of taxation. We conclude with a discussion on the interpretation of labour supply elasticities for policy analysis.

Article

The formal analysis of labour supply in economic research extends back to the 1960s, in the work of Becker (1965), Cain (1966), Hanoch (1965) and Mincer (1960), among others. It was developed further in the 1970s, most importantly in the work of Ashenfelter and Heckman (1974), Burtless and Hausman (1978), Gronau (1974) and Heckman (1974a). It would seem reasonable to ask why interest continues in the study of labour supply and what unanswered questions and puzzles remain.

Policy interest in labour supply continually motivates research on all aspects of the subject. One area of active inquiry evaluates the consequences of the new ideas in tax and welfare reform, especially those related to the growing focus on work requirements in the design of welfare reform and on the supply of effort by top-rate tax payers. Another important topic concerns the impacts of reforms of pension and
labour supply: The New Palgrave Dictionary of Economics

health-care systems on labour supply decisions in later life. Yet another involves gender inequality and the role of female labour supply in removing gender earnings differences and in supporting family incomes. If in addition to these policy motivations, understanding hours-of-work behaviour lies at the heart of explaining the reasons underlying a variety of key trends in the economy. One is the unprecedented growth in female labour supply across many developed economies since the 1970s; a second is the decline in labour supply among older men over the same period, again a phenomenon common to many developed economies; and a third is the labour supply impact of the growth in the disparity between the labour market returns of the educated and those with little formal training. Add to these questions the importance of labour supply in understanding employment over the business cycle and over the life cycle, and it becomes clear why labour supply has maintained a prominent position in economic research.

Having established its importance, what does the study of labour supply involve? Although the parameter(s) of interest in a labour supply model may seem obvious, on closer inspection it is not so clear-cut. We are typically interested in examining the reaction of labour supply to a change in the wage. But what measure of labour supply and what measure of the wage? Is it employment – the extensive margin – or hours of work for workers – the intensive margin – that is of key interest? Is it the impact that of an anticipated change in the wage or an unanticipated change in the wage? Are we simply concerned with individual labour supply or does family labour supply matter too?

What labour supply elasticity should be used? The wealth of empirical studies on labour supply has produced a plethora of estimated elasticities and response parameters. Differences between estimates can often be attributed to data measurement issues but, as documented in Blundell and MaCurdy (1999), more often than not, a large component of the differences can be explained by the economic framework within which each the estimates is derived. Apart from hourly wages and other income, are controls for lifetime wages included? What about expected changes in other income sources? The precise conditioning variables included in a labour supply model critically change the interpretation and therefore the comparability of estimated elasticities and response coefficients. It is also clear that labour supply responses differ according to the extensive or intensive margin, especially for women. To understand differences across these margins, the specification of effective budget constraints and the nature of fixed costs matter. For men it may well be that the retirement margin could be a margin of growing importance.

An important role of a review of this type is to provide a coherent framework within which different labour supply models can be compared. It is clearly useful to have an explicitly intertemporal framework, although, as we shall see, perfectly interpretable estimates of some important parameters of interest can be recovered from models that look essentially static. Much of the difference across empirical models reflects differences in data availability, and this provides another argument for this approach. The precise form of income, hours or wage variables available will vary wildly across data sources, but this does not necessarily imply incomparable results. Some data provides longitudinal information on individual wages and hours; other data is repeated cross-section but may have more detailed information on asset or consumption levels.

To set the scene we start with a brief discussion of the standard ‘static’ labour supply model. We then go on to ask what is meant by employment and how one translates estimates of economic substitution effects found in the labour supply literature into wage impacts relevant for the employment concept. Next we look at the extension to a life-cycle setting. The objective is always to present a framework
within which empirical models and their resulting elasticity estimates can be interpreted. We provide a separate discussion of the main issues surrounding the analysis of family labour supply and for analysing the impact of taxation and welfare reform. If the literature in respect to all of these topics is too rich to include all of the key references in the text, but a list of some of the leading references is provided at the end of this review. The review ends with a discussion on the interpretation of labour supply elasticities for policy analysis.

1 Setting the scene

In the standard labour supply model as applied to individual decisions at a point in time, choices are made over consumption and leisure hours. In each period of time $t$ each individual $i$, defined by characteristics $\nu_{it}$, has preferences over consumption and leisure hours described by a (within) period utility

$$U(c_{it}, l_{it}; \nu_{it})$$

(1)

in which $c_{it}$ and $l_{it}$ are within-period consumption and leisure hours respectively. (The important extension to family labour supply is considered below.) The elements of the vector $\nu_{it}$ alter preferences, both through observed characteristics of the individual and through this person's unobserved factors influencing 'tastes'. This utility is assumed to be maximized subject to the budget constraint

$$c_{it} + w_{it}l_{it} = y_{it} + w_{it}T$$

(2)

in which $w_{it}$ is the hourly wage rate, $y_{it}$ is non-labour income and $T$ is the total time available for work and leisure.

Non-labour income is made up of two components: asset income and other unearned income. Assuming beginning of period assets, denoted $A_{it}$, earn a return $r_{it}$ during period $t$, the former is $r_{it}A_{it-1} + \Delta A_{it}$, in which $\Delta A_{it}$ denotes capital gains. Other unearned income is primarily benefit or transfer income and denoted $g_{it}$. The r.h.s. of (2) is often defined as ‘full income’ and we denote this income concept as $m_{it}$ throughout, so that

$$m_{it} = y_{it} + w_{it}T.$$ 

(3)
First-order conditions take the familiar form:

\[ U(c_{it}, l_{it}; v_{it}) = \lambda_{it} \]  

(4)

and

\[ U(l(c_{it}, l_{it}; v_{it}) \geq \lambda_{it}w_{it} \]  

(5)

where \( \lambda_{it} \) is the marginal utility of income. The inequality in (5) determines the reservation wage rule for labour market participation.

Solving for \( \lambda_{it} \) using the budget constraint (2) yields the (Marshallian) decision rule and

\[ l_{it} = l(w_{it}, m_{it}; v_{it}) \leq T_{it} \]  

(6)

where \( m_{it} \) is full-income defined in (3) above. Equivalently we have the hours of work rule

\[
\begin{align*}
    h_{it} = h^S(w_{it}, v_{it}; v_{it}) & \forall \{w_{it}, v_{it}; v_{it}\} \in U_L(c_{it}, l_{it}; v_{it}) \geq w_{it}U(c_{it}, l_{it}; v_{it}) \\
    = 0 & \text{otherwise}
\end{align*}
\]

(7)

where \( y_{it} \) is defined as in (2).

Preferences over hours of work can, of course, be written analogously to direct utility (1) as

\[ U(y_{it}, T - h_{it}; v_{it}) \]
or by the expenditure (that is, cost) function

\[ \xi_{it} = \xi(w_{it}, v_{it}, \nu_{it}); \tag{9} \]

or by the indirect utility function

\[ V_{it} = V(w_{it}, v_{it}, \nu_{it}). \tag{10} \]

The expenditure function solves the problem

\[ \xi_{it} = \xi(w_{it}, v_{it}, \nu_{it}) = \min c_{it} + w_{it}(T - h_{it}) \text{ subject to } V = U(v_{it}, T - h_{it}; \nu_{it}, \theta); \tag{11} \]

and the indirect utility inverts the expenditure function to obtain a solution for \( V_{it} \). Whether analysis is conducted with the direct utility, expenditure function, indirect utility or the labour supply equation will depend largely on the approach to estimation.

The inequality (7) represents a corner solution for hours of work and can be stated as a reservation wage condition for participation \( w_{it} \geq w_{it}^* \), where \( w_{it}^* \) is derived by inverting \( h^S(w_{it}, v_{it}, \nu_{it}) = 0 \). The key econometric problem that follows from this corner solution is that \( w \) will not be observed when \( h=0 \). Consequently a specification for wages is also required and together they create the selection problem addressed by Gronau (1974) and Heckman (1974a, 1979).

### 1.1 Substitution and income effects

In a static framework the literature typically cites two types of substitution effects when describing how labour supply responds to changes in the wage rate. First, the uncompensated (or Marshallian) effect refers to the following derivative of labour supply function (7):
which holds non-labour income $y_{it}$ constant when measuring how much hours of work respond to a shift in wages. If second, one can derive an expression for the compensated labour supply function by computing the derivative of the expenditure function $\xi_{it}$ with respect to $w_{it}$, and then constructing a function defined as $T$ minus this derivative. This compensated function holds utility constant, and its derivative with respect to $w_{it}$ measures the compensated (or Slutsky or Hicksian) effect. A familiar relationship linking compensated and uncompensated substitution effects is the Slutsky decomposition given by:

$$\frac{\partial h^s}{\partial w} \bigg|_u = \frac{\partial h^s}{\partial w} + h \frac{\partial h^s}{\partial y},$$

(13)

where the derivative $\frac{\partial h^s}{\partial y}$ shows the impact of changing income on hours of work holding wages constant. Regular integrability conditions from optimization theory imply that the compensated substitution effect is non-negative

$$\frac{\partial h^s}{\partial w} \bigg|_u \geq 0.$$

(14)

In sharp contrast, the compensated effect $\frac{\partial h^s}{\partial w}$ can be negative or positive depending on the strength of the income effect on labour supply. When $\frac{\partial h^s}{\partial w}$ is negative labour supply is said to be ‘backward bending’.

1.2 Empirical evidence

The empirical analysis of the standard labour supply model described here tends to distinguish
individuals by gender and by whether there are children at home, finding rather different elasticities across these groups (see Johnson and Pencavel, 1984). Allowing for a separate impact of the way the market wage affects the employment and the hours decision has proven to be essential. This partly reflects fixed costs of work and the workings of the welfare system, to be discussed below, but it also highlights the strong evidence that labour supply responses at the extensive margin dominate those at the intensive margin; see Blundell and MaCurdy (1999) for a review of this evidence.

### 1.3 Some popular labour supply specifications

In discussing particular specifications it is useful to be able to move between all three representations of preferences over labour supply (8)–(10). For example, if the focus is on taxation and welfare participation it is typical to express decisions as a multinomial choice problem over discrete hours choices and work with the direct utility specification. This will be discussed below.

To complete this brief review of the standard labour supply model we consider four popular specifications. The **linear expenditure system** assumes the direct utility function

\[
U(c_{it}, T-h_{it}, v_{it}) = \beta_h(v_{it}) \ln [T - h_{it} - \gamma_h(v_{it})] + \beta_c(v_{it}) \ln [c_{it} - \gamma_c(v_{it})],
\]

where the notation \( \beta_h(v_{it}), \beta_c(v_{it}), \gamma_h(v_{it}) \) and \( \gamma_c(v_{it}) \) indicates that the preference parameters \( \beta_h, \beta_c, \gamma_h \) and \( \gamma_c \) are functions of individual attributes \( v_{it} \) and therefore can vary across members of the population. (Imposing the restriction \( \beta_h(v_{it}) + \beta_c(v_{it}) = 1 \) identifies these coefficients.) Abstracting from the dependence on heterogeneous tastes \( v_{it} \), the expenditure function (9) implied for the **linear expenditure system** takes the form:

\[
\xi(w, v) = \gamma_h w + \gamma_c + w^{\beta_h} v;
\]

and the uncompensated labour supply function is:

\[
h^S(w, y) = T - \gamma_h - \frac{\beta_h}{w} (m - \gamma_h w - \gamma_c).
\]

A second popular preference specification is the **linear labour supply**
\[ h = \alpha + \beta w + \gamma y \]  
(17)

(for example, see Hausman, 1981; 1985a), which comes from the indirect utility function:

\[ V(w, y) = e^{\gamma w} \left( y + \frac{\beta}{\gamma} w - \frac{\beta}{\gamma^2} + \frac{\alpha}{\gamma} \right) \text{ with } \gamma \leq 0 \text{ and } \beta \geq 0. \]  
(18)

Note that since \( \frac{\partial h}{\partial y} = \gamma > 0 \), the Slutsky condition (13) all but requires \( \beta > 0 \), ruling out backward bending labour supply. It is arguable that this linear specification allows too little curvature with wages. Alternative *semilog specifications* and their generalizations are also popular in empirical work. For example, the semilog specification

\[ h = \alpha + \beta \ln w + \gamma y \]  
(19)

with indirect utility

\[ V(w, y) = \frac{e^{\gamma w}}{\gamma} (\alpha + \beta \ln w + \gamma y) + \frac{\beta}{\gamma} \int_{-\gamma w}^{e^{-t}} \frac{e^{-t}}{t} dt \text{ with } \gamma \leq 0 \text{ and } \beta \geq 0. \]  
(20)

Moreover, the linearity of (19) in \( \alpha \) and \( \ln w \) makes it particularly amenable to an empirical analysis with unobserved heterogeneity, endogenous wages and non-participation as discussed below (see Blundell, Duncan and Meghir, 1998).

Neither (17) nor (19) allows backward bending labour supply behaviour, although it is easy to generalize (19) by including a quadratic term in \( \ln w \). Note that imposing integrability conditions at zero hours for either (17) or (19) implies positive wage and negative income parameters. A simple specification that does allow backward bending behaviour, while retaining a three parameter linear in variables form, is
that used in Blundell, Duncan and Meghir (1992):

\[ h = \alpha + \beta \ln w + \frac{\gamma}{w} \]  
(21)

with indirect utility

\[ V(w, y) = \frac{w^{1+\gamma}}{1+\gamma} \left( \alpha - \frac{\beta}{1+\gamma} + \beta \ln w + (1+\gamma) \frac{\gamma}{w} \right) \text{with } \gamma \leq 0 \text{ and } \beta \geq 0; \]  
(22)

see Stern (1986). This form has similar properties to the specification of Heckman (1974). Further empirical specifications are described in Blundell, MaCurdy and Meghir (2007), where the econometric issues of dealing with the extensive margin and missing wages are discussed in detail.

2 The impact of wages and income on hours of work and employment

Addressing many of the questions asked by policymakers about labour supply involves evaluating the extent to which employment in a population can be expected to change in response to a shift in the returns to work. Relying on existing empirical work to answer such questions requires resolution of two issues: (1) what is meant by employment?; and (2) how does one translate estimates of economic substitution effects found in the labour supply literature into wage impacts relevant for the relevant employment concept?

2.1 Three concepts of employment and labour supply

There are three distinct concepts of labour supply or expected hours of work, which are often confused in the literature. Consider a population of consumers all of whom receive a common wage \( w \) and non-labour income \( y \), but who have different tastes \( \nu_{ii}'s \). Let the density function \( f(\nu) \) denote the distribution of ‘preferences for work’ over the population.

One measure of labour supply is the fraction of the population who works:

\[ P(w, y) = \Pr(h^S(w, y, \nu_{it}) > 0) = \int_{\Theta} f(\nu) \, d\nu \text{where } \Theta = \left\{ \nu_{it}: h^S(w, y, \nu_{it}) > 0 \right\}. \]  
(23)
A second concept is the average hours worked among those employed:

$E(h^s(w_{it}, v_{it}; v_{it})|h^s_{it} > 0) = \frac{\int_{0}^{\infty} h^s(w, v, v_{it}) f(v) dv}{P(w, v)}$  

(24)

Yet a third measure of labour supply is the average hours worked in the entire population:

$E(h^s(w_{it}, v_{it}; v_{it})) = \int_{0}^{\infty} h^s(w, v, v_{it}) f(v) dv.$  

(25)

While these three measures of labour supply depend on many of the same parameters, they are clearly distinct concepts. If a researcher is interested in the effect of wages on employment, then the derivative of (23) with respect to $w$ measures the appropriate quantity. If, instead, one wants to know how much an increase in the wage rate affects total aggregate hours of work, then the derivative of (25) with respect to $w$ gives the relevant measure.

There is also some confusion in the literature concerning the appropriate interpretation of the partial derivatives of these different measures of labour supply. The partial derivatives of the hours of work function given by (7), $h^s_w$ and $h^s_y$, produce the textbook uncompensated wage and income effects. Casual inspection of (23) reveals that the derivatives of $P(w, y)$ with respect to $w$ and $y$ do not correspond to $h^s_w$ and $h^s_y$ (Lewis, 1967; Ben-Porath, 1973). Whereas $P_w$ must be positive, $h^s_w$ need not be. Moreover, the partial derivatives of (24) or (25) with respect to $w$ and $y$ do not correspond to the uncompensated substitution and income effects, $h^s_w$ and $h^s_y$, unless the inequality condition (7) is satisfied for everyone in the population and the labour supply function $h^s$ takes a special form. These simple points have been ignored in much of the literature. For example, Hall (1973) and Boskin (1973) interpret the partial derivative of estimates of eq. (25) with respect to $w$ and $y$ as estimates of $h^s_w$ and $h^s_y$ respectively. Others interpret partial derivatives of (24) (estimated from labour supply functions fit on samples of working individuals) as estimates of the Marshallian–Hicks–Slutsky parameters. If non-participation is a significant phenomenon in the population being sampled, estimates of (23), (24) nor (25) do not generate meaningful structural labour supply parameters.
2.2 Aggregate labour supply

Conditions have been established for utility functions that enable one to aggregate micro labour supply functions to obtain economically meaningful market functions. Satisfaction of these conditions implies equivalency of micro and macro substitution effects. In the case when consumers face a common set of prices and have different incomes, Gorman's (1961; 1976) seminal contributions specify those sets of preference consistent with linear Engel curves, which he shows are required properties of preference to carry out exact aggregation of micro demand functions to macro formulations. The macro specification is a ‘representative consumer’ version of the original individual preference relationship. Gorman's conditions are insufficient for aggregation of labour supply functions since wages, in contrast to prices, vary considerably across individuals in any interesting empirical application. Muellbauer (1981) refines Gorman's aggregation conditions to apply to the labour supply case allowing for wages along with income to different across individuals.

For a market labour supply function to have a form consistent with the underlying micro specifications aggregated to derive its construction, the expenditure function (9) must necessarily take the general form:

\[\xi(w_{it}, V_{it}, v_{it}) = \alpha_t(v_{it}) + w_{it}\beta_t + w_{it}\beta_t V_{it}.\]  
(26)

(Inspection of the specification – the equation above eq. (16) – for \(\xi(w_{it}, V_{it}, v_{it})\) for the linear expenditure system reveals that it has the form required by (26) when \(\beta_h(v_{it}) = \beta_h, \beta_c(v_{it}) = \beta_c\), and \(\gamma_h(v_{it}) = \gamma_h \forall v_{it}.\) The uncompensated labour supply function implied by (26) is given by:

\[h^*(w_{it}, V_{it}, v_{it}) = \pi_t - \frac{\delta}{w_{it}}(V_{it} - \alpha_t(v_{it}))\]  
(27)

where

\[\pi_t = (1 - \delta)(T - \beta_t).\]  
(28)

In this specification, only the preference components \(\alpha(v_{it})\) can vary across individuals in the static
labour supply: The New Palgrave Dictionary of Economics

setting. Rather than expressing this relationship as hours of work, one typically finds (9) it written as the earning function:

\[ w_{it} h_{it}^S = n_{it} w_{it} - \delta y_{it} + \delta_{it} (v_{it}). \]  

Given its linear structure, one clearly sees that estimation of the micro and aggregate substitution and income effects corresponds to the same preference parameters. Viewed in a pooled cross-section time-series context, the preference components \( \alpha_t \), \( \beta_t \), and \( b_t \) typically will be functions of prices in period \( t \) which are common across individuals in the cross section corresponding to the period, but these prices do change over time. To create a valid form for preferences, the \( \alpha_t \) and \( \beta_t \) must be homogeneous of degree 1 in prices, and \( b_t \) must be homogeneous of degree zero.

What concept of labour supply does this aggregate relationship represent? In a world where everyone works, the average of (27) corresponds to both the expected values of hours worked among the employed (24) and overall populations (25); after all, these are exactly the same samples. Moreover, the economic concept of the uncompensated substitution effect directly measures the response one would estimate using an empirical specification based on either eq. (24) or eq. (25).

These nice relationships, however, entirely break down when one recognizes that the employment decision is typically influenced by a change in wages, be it across people or a shift in the distribution that occurs over time. With the no-work/work decision being affected for some people, impacts now critically depend on the properties of distribution of preferences determined by the density function \( f(\nu) \), which could itself shift over time. The effects of wages on the three concepts of labour supply given by (23), (24) and (25) again become distinct, and none directly measures the economic notions of substitution effects outlined above. When labour market participation is a choice in the population, no conditions exist for consistently aggregating micro labour supply function to obtain a macro function that can be given a coherent ‘representative agent’ interpretation. Substitution effects estimated in an aggregate setting cannot be interpreted coming from a single agent-optimizing framework, and the wage effects estimated from micro data considered alone will typically provide insufficient information to project aggregated impacts.

3 Labour supply over the life cycle

Although its study is often placed in an effectively static framework as in (1) and (2), labour supply is clearly part of a lifetime decision-making process. Individuals attend school early in life, accumulate wealth while in the labour force, and make retirement decisions late in life; each of these activities can only be understood in a life-cycle framework. We know that savings from labour earnings are often required to sustain individuals, or their dependants, during periods when they are out of the labour market. In addition, variations in health status, family composition and real wages provide incentives for individuals to vary the timing of their labour market earnings for income-smoothing and insurance
labour supply: The New Palgrave Dictionary of Economics

purposes.
To keep things simple we assume life-cycle utility at time \( t \) has the form

\[
\mathcal{U}_{it} = E_t \left\{ \sum_{t'=s}^t \frac{1}{1 + \delta_t} \mathcal{U}(c_{it}, l_{it}, v_{it}) \right\}
\]

(30)

in which \( E_t \) is the expectations operator conditional on information up to and including period \( t \) and where \( \delta_t \) is the subjective discount rate. Maximization of (30) takes place subject to an intertemporal budget constraint. For this we need to write down the path of assets:

\[
A_{it} + 1 = A_{it} + r_t A_{it} + b_{it} + w_{it} h_{it} - c_{it}
\]

(31)

where \( A_{it} \) is the assets held at the beginning of period \( t \) and \( r_t \) is the return on assets earned in period \( t \).

The form of life-cycle preferences and of the budget constraint in (30) and (31) is not innocuous. The time-separability of (30) rules out habits and slow adjustment. The \( rA \) term in (31) assumes that individuals can borrow and lend via the simple credit market at rate \( r \) and consequently rules out borrowing constraints. Nevertheless, under these assumptions the first-order conditions (4) and (5) continue to hold and to determine within-period allocations of time and consumption. Intertemporal allocations are determined through the choice of the marginal utility of consumption \( \lambda_{it} \) in (4).

Consequently allocations over the life cycle will be summarized through the evolution of \( \lambda_{it} \).

To understand these conditions in an inter-temporal context we can use the knowledge that \( \lambda_{it} \), the marginal utility of wealth, evolves over time according to

\[
\lambda_{it} = \frac{1}{1 + \delta_t} E_t \left\{ \lambda_{it} + 1 (1 + r_{it}) \right\}
\]

(32)

where the real interest rate \( r_{it} \) is allowed to be stochastic. Relationship (32) is often referred to as the stochastic Euler equation (see Hansen and Singleton, 1983).
### 3.1 Frisch (λ-constant) labour supply equations

Frisch, or marginal-utility-of-wealth ‘λ’ constant, labour supply functions provide an extremely useful method for analysing life-cycle maximization problems (see Browning, Deaton and Irish, 1985). In this framework, the marginal utility of wealth, λ, serves as the sufficient statistic which captures all information from other periods that is needed to solve the current-period maximization problem. The time-separable form of the utility maximizing model implies that the marginal within-period decisions depend on the past and future through the single ‘sufficient statistic’ \( \lambda_{it} \). Even though the marginal utility of wealth \( \lambda_{it} \) is not observable to the empirical economist, the rule for its evolution (32) enables a method of moments estimation of the labour supply parameters.

To briefly see how estimation takes place in this framework, consider the simple parametric form for preferences chosen in MaCurdy (1981). The utility specification MaCurdy used does not allow for corner solutions and takes the form

\[
U_t = \theta_t c_t^{\gamma} - \varphi_t h_t^\alpha \quad 0 < \gamma < 1, \; \alpha > 1
\]

where \( h_t \) corresponds to hours of work and \( c_t \) to consumption. The range of parameters ensures positive marginal utility of consumption, negative marginal utility of hours of work and concavity in both arguments. The Frisch labour supply is

\[
\log h_t = \theta_t^* + \log \lambda + \frac{1}{\alpha - 1} \ln w_t + \frac{\rho - r}{\alpha - 1} t
\]

where the use of log hours of work presumes that all individuals work and hence \( h > 0 \). In (34) \( \lambda \) is the shadow value of the lifetime budget constraint and \( t \) is the age of the individual. Finally \( \theta_t^* \) reflects preferences and is defined by

\[
\theta_t^* = -\frac{1}{\alpha - 1} \log \theta_t
\]

This equation has a simple message: Hours of work are higher at the points of the life cycle when wages are high \( \left( \frac{1}{\alpha - 1} > 0 \right) \). Moreover if the personal discount rate is lower than the interest rate, hours of work decline over the life cycle. Finally, hours of work will vary over the life cycle with \( \theta_t^* \), which could be a function of demographic composition or other taste shifter variables.

The MaCurdy (1981) paper set out the first analysis of issues to do with estimating intertemporal labour supply relationships. However the approach did not deal with corner solutions and the extensive margin,
which is particularly relevant for women. The first attempt to do so, in the context of a life-cycle model of labour supply and consumption is the paper by Heckman and MaCurdy (1980). In this model women are endowed with an explicitly additive utility function for leisure $l$ and consumption $c$ in period $t$, of the form:

$$U_t = \theta_t \frac{l_t^\alpha - 1}{\alpha} + \varphi_t \frac{c_t^{\gamma} - 1}{\gamma}, \alpha, \gamma < 1.\quad (35)$$

Optimization is assumed to take place under perfect foresight. Solving for the first-order conditions we obtain the following equation for leisure

$$\ln l_t = \theta_t^* + \frac{1}{\alpha - 1} \ln w_t + \frac{\rho - r}{\alpha - 1} t + \lambda^* \text{ when the woman works}$$

$$= \ln l \text{ otherwise} \quad (36)$$

where

$$\lambda^* = \frac{1}{\alpha - 1} \ln \lambda \text{ and } \theta_t^* = - \frac{1}{\alpha - 1} \ln \theta_t. \quad (37)$$

### 3.2 Two-stage budgeting and Marshallian labour supply equations

In this time-separable optimizing problem there are alternative ‘sufficient statistics’ to the marginal utility of wealth that completely summarize the past and future as it impacts on the period $t$ labour supply decision. From Gorman (1959; 1968), intertemporal separability implies that the decision rule can be thought of in two stages. First allocate to period $t$ according to

$$m_{it} = M(w_{it}, v_{it}, A_{it - 1}, r_t, v_{it}, Z_{it}) \quad (38)$$
where $z_{it}$ represents the information used to form expectations of future real wages and other household attributes that are uncertain at time $t$. At the second stage, given $m_{it}$, the within-period first-order conditions (4) and (6) remain valid. Moreover, the estimation of ‘$m$-conditional’ labour supply functions are robust to liquidity constraints and other capital market imperfections.

### 3.3 Marginal rate of substitution equations

Eliminating $\lambda_{it}$ from the first-order conditions (4) and (6) yields the marginal rate of substitution function

\[
MRS_i(c_{it}, l_{it}; v_{it}) = \frac{w_{it}}{u_i}.
\]  

(39)

where

\[
MRS_i(c_{it}, l_{it}; v_{it}) = \frac{U_I}{U_c}.
\]

(40)

Again, (39) is robust to liquidity constraints and other capital market imperfections. As we know from our general discussion of elasticities, the constant marginal utility of wealth (Frisch) elasticity is greater than the Slutsky-compensated (within-period) elasticity which is again greater than the standard uncompensated Marshallian elasticity, see Blundell (1998).

### 3.4 Relationships among the life-cycle elasticities

The Frisch specification treats the individual marginal utility of wealth as a ‘fixed effect’ and allows the researcher to estimate only the intertemporal substitution elasticity. Given that appropriate methods are employed to account for the fixed effect (generally first differencing in panel data), the relevant independent variables, apart from the wage, are simply within-period characteristics and age. The Frisch elasticity, by ignoring this (unexpected) shift in wealth from a once-and-for-all change in real wages, is larger than the policy-relevant elasticity and overestimates the impact of a reform.

Direct estimation of the simple parameterization of the full life-cycle model, required to recover policy-relevant elasticity, relies on specifications for both within-period utility and the individual marginal-utility-of-wealth effect. As a result, controls are needed for all of the following: ‘start of life’
characteristics, current-period characteristics which affect the within-period utility function, age, expected wages and initial wealth. Expected wages are typically unobservable and initial wealth is generally not included in data-sets, so these should be replaced with the parameters governing the time path of wages and property income, which must be jointly estimated with the labour supply equation. Estimation of this full framework allows computation of both the intertemporal substitution elasticity and the elasticity of labour supply in reaction to a full, parametric wage profile shift. However, it is also the most demanding in terms of data.

It is worth noting that the elasticity derived from the static specification which uses unearned income to compute virtual income can be placed in an intertemporal setting but is economically meaningful only under a strong assumption of either complete myopia or perfectly constrained capital markets. Otherwise, this elasticity confuses movements along wage profiles with shifts of these profiles and, thus, yields response parameters which are a mixture of these. Such hybrid estimates lack an economic interpretation and are not generally useful in policy evaluation.

To illustrate the challenges encountered with inferring the different substitution effects from one another, consider a life-cycle extension of the linear expenditure system (LES) in a deterministic setting. A multi-period expansion of the static LES utility function given by (15) takes the form

$$
U_t = \sum_{t=1}^{T} \varphi_t \cdot U(c_t, l_t, v_t) = \sum_{t=1}^{T} \varphi_t [\beta_h \ln (T - h_t - \gamma_h) + \beta_c \ln (c_t - \gamma_c)],
$$

(41)

where the normalization $\sum_{t=1}^{T} \varphi_t = 1$ (in addition to $\beta_h + \beta_c = 1$) identifies preference parameters. The specification implied for the life-cycle uncompensated labour supply function for hours of work in period $t$ is:

$$
h^s_t (\omega, R, M; v) = T - \gamma_h - \varphi_t \frac{\beta_h}{\omega_t} \left( M - \sum_{k=1}^{T} \gamma_h \omega_k - \sum_{k=1}^{T} \gamma_c R_k \right)
$$

(42)

where the quantities $\omega_t$ denote the discounted value of the period-$t$ wage rate; $R_t$ represents the discounted price of consumption in period $t$; and $M$ designates the ‘full income’ equivalent of the individual’s wealth. The period-$t$ marginal-utility-of-wealth ‘$\lambda$ ’ constant labour supply function takes the form: 
Accordingly, the uncompensated substitution effect associated with a change in wage rate $\omega_t$ on hours of work $h_t$ is given by:

$$h_{it} = h_t^\lambda(w_{it}, R_{it}, \lambda_{it}) = T - Y_t h_t + \frac{\varphi_t \beta_t h_t}{\lambda_{it} \omega_{it}}.$$

(43)

and the intertemporal substitution effect corresponding to change in $\omega_t$ on $h_t$ is:

$$\frac{\partial h_t^\delta}{\partial \omega_t} = \frac{\varphi_t \beta_t h_t}{\omega_t^2} \left( Y - \sum_{k=1}^{T} Y_k \omega_k - \sum_{k=1}^{T} Y_k R_k + Y_t \omega_t \right) = \frac{(T - Y_t)(1 - \varphi_t \beta_t)}{\omega_{it}} - \frac{h_t}{\omega_t}.$$

(44)

The following relationship links these two hour-of-work responses:

$$\frac{\partial h_t^\lambda}{\partial \omega_t} = \frac{\partial h_t^\delta}{\partial \omega_t} + \frac{(T - Y_t) \varphi_t \beta_t h_t}{\omega_{it}}.$$

(45)

Finally, if one were to estimate an uncompensated substitution effect relying on a two-stage-budgeting variant of a labour supply function based on LES utility function (41), then one would compute values for:

$$\frac{\partial h_t^\delta}{\partial \omega_t} = \frac{\beta_t h_t}{\omega_t^2} (Y - Y_t) = \frac{(T - Y_t)(1 - \beta_t)}{\omega_t} - \frac{h_t}{\omega_t}.$$

(46)
While inspection of these expressions not surprisingly reveals that the different substitution effects depend on common preference parameters, it also clearly indicates that one must exercise serious caution when attempting to infer values of one type of elasticity from any of the others. Relationship (46) shows that how one can vary endowments and preferences to change intertemporal substitution effects while not changing the uncompensated response. Of course, the above discussion has already described the additional complications encountered in any attempt to relate these economic notions of substitution effects to concepts of labour supply relevant for market measures of wage impacts on employment and hours of work which are the core concepts required for policy analyses.

3.5 Retirement and pension incentives

The study of retirement incentives and labour supply has typically focused on the dynamic effects of benefit entitlement that occur in many pension and social security schemes (Hurd and Boskin, 1984). This has resulted in the more formal use of dynamic programming tools; see Blau (1994) and Rust and Phelan (1997), for example. An important area for current research is the incorporation of these incentives into a life-cycle labour supply model.

4 Family labour supply

For the purposes of this discussion we are concerned with a family or household as comprising two working-age individuals, referred to as husband and wife below. These are the decision-making individuals in the family. Families with a single parent are subsumed in the discussion of the regular labour supply model. The central issue then becomes one of the mechanism whereby labour supply decisions are made within the household. Are they taken in a fully coordinated way as if by a single decision maker – the unitary model – or are they the result of some collective bargain – the collective model?

4.1 The unitary model of family labour supply

Suppose we can take a family or household as being made up of two working-age individuals, referred to as husband and wife below. Children and any other dependants will be included in the vector of observable household characteristics \( \nu \). For such a household, within period utility may be written

\[
U_{it} = U(c_{it}, l^h_{it}, l^w_{it}, \nu_{it})
\]
and budget constraint

\[ c_{it} + w_{it}^{h}h + w_{it}^{w}w = m_{it} \]  
(49)

where \( w_{it}^{h} \) and \( w_{it}^{w} \) refer to the hourly wage of the husband and wife respectively. The marginal conditions for the \( \lambda \)-constant (Frisch), Marshallian and marginal rate of substitution labour supply equations described in the previous section follow naturally from the first-order conditions

\[ U(c_{it}, l_{it}^{h}, l_{it}^{w}, v_{it}) = \lambda_{it}, \]  
(50)

\[ U_{h}(c_{it}, l_{it}^{h}, l_{it}^{w}, v_{it}) \geq \lambda_{it}w_{it}^{h} \]  
(51)

and

\[ U_{w}(w_{it}, l_{it}^{h}, l_{it}^{w}, v_{it}) \geq \lambda_{it}w_{it}^{w} \]  
(52)

where the subscripts \( h \) and \( w \) refer to derivatives with respect to the non-market hours of husband and wife respectively. See Ashenfelter and Heckman (1974), Wales and Woodland (1976) and Blundell and Walker (1982), for example.

Notice that there is still only a single marginal utility of wealth \( \lambda_{it} \) and therefore the extension to the life-cycle framework of the previous section is straightforward. There remains only one life-cycle condition (32). Consequently allocations to each individual in this time-separable model satisfy equality of marginal utility of wealth; see Blundell and Walker (1986), for example.
The advantages of the unitary model are well known: it allows the direct utilization of consumer theory, recovering preferences from observed behaviour in an unambiguous way, and provides a coherent intertemporal framework for interpretation of empirical results. An argument against this approach is that it treats individuals in the family as a single decision-maker rather than as if they were a collection of individuals. Although true, this can be weakened through a simple decentralization argument.

Suppose we let $c^h$ and $l^h$ refer to the private consumption of the husband and his own leisure time respectively. Defining the private consumption of the wife in the same way, we may write the within-period household utility as

$$U(c_{it}, l_{it}^h, l_{it}^w, v_{it}) = \tilde{U}(F_h(c_{it}^h, l_{it}^h, v_{it}), F_w(c_{it}^w, l_{it}^w, v_{it}))$$

(53)

where $F_h(c_{it}^h, l_{it}^h, v_{it})$ is the sub-utility for the husband and $F_w(c_{it}^w, l_{it}^w, v_{it})$ is the sub-utility of the wife. Family utility has a ‘weakly separable’ form and decentralization follows: allocations of total household (full) income are made between each household member and then individuals act as if they are making their labour supply and consumption decisions conditional on this initial-stage outlay. Of course, even if consumption goods are privately consumed, they are typically only measured at the household level – so that the individual consumptions are ‘latent’ to the economist.

So what is it that collective models offer? They effectively relax the income allocation rule between individuals so that this allocation can depend on relative wages and other variables in a way that reflects the bargaining position of individuals within the family rather than reflecting the symmetry assumption underlying the joint optimizing framework of the traditional approach. Individuals within the family can be altruistic and allocations Pareto efficient, but still the allocation rule can deviate from the optimal rule in the traditional model.

The most lucid statement of this argument can be found in the papers on household labour supply by Chiappori (1988; 1992). He states the family labour supply problem as one of

$$\max \theta U^h + (1 - \theta) U^w \text{ s.t. } c_{it} + w_{it}^h l_{it}^h + w_{it}^w l_{it}^w (= m_{it}) = (w_{it}^h + w_{it}^w) T + y$$

with some non-negative function $\theta = f(w_{it}^h, w_{it}^w, x_{it}, m_{it})$ representing the weight given to utility $U^h$. What Chiappori shows is that this is equivalent to a sharing rule solution in which $U^h$ gets income $\phi(w_{it}^h, w_{it}^w, x_{it}, m_{it})$ out of $y$, and then allocates according to the rule:
labour supply: The New Palgrave Dictionary of Economics

\[
\max h \delta \cdot c_t^h + w_t^h l_t^h = w_t^h T + \phi(w_t^h, w_t^W, x_t, m_t)
\]

where \(x_t\) may be a distribution factor.

Conditions for the identification of preferences and the sharing rule (up to a linear translation) simply require an observable private good – here assumed to be the individual's leisure. The intuition behind identification is simple: under the exclusive good assumption the spouse's wage can only have an effect through the sharing rule. Variation of income and wage will then provide an estimate of the marginal rate of substitution in the sharing rule. The same can be done for both spouses, and since the sharing rule must sum to 1, the partial derivatives of the sharing rule can be recovered.

The empirical implementation of the collective model has been slow but is growing in recent years; see Donni (2003) and Fortin and Lacroix (1997), for example. Generalizing the collective model to allow for non-participation and corner solutions requires additional care (see Blundell et al., 2006). The generalization to an intertemporal framework is still in its infancy.

The collective approach is not the only way to conceive of bargaining in family labour supply; see Kooreman and Kapteyn (1990), Lundberg (1988) and McElroy (1981) for important alternatives.

5 Labour supply with taxation and welfare participation

The tax and welfare system leads to well documented nonlinearities and non-convexities in the budget constraint facing any individual. This considerably complicates the labour supply problem and, even in the static setting, discrete choice programming methods are required. The basic nonlinear budget constraint problem has been described in detail in Hausman (1985a), Moffitt (1986), MaCurdy, Green and Paarsch (1990) among others.

To further address the issues encountered with nonlinear budget sets, there has been a steady expansion in the use of sophisticated statistical models characterizing distributions of discrete-continuous variables that jointly describe both interior choices and corner solutions in demand systems. These models offer a natural framework for capturing irregularities in budget constraints, including those induced by the institutional features of tax and welfare programmes. Typically the overall stochastic specification is represented by a mixed-multinomial specification across discrete choices over ranges of hours, for example in the work of Hoynes (1996) and Keane and Moffitt (1998). In this research, individuals are assumed to maximize their (stochastic) utility subject to a budget constraint, determined by a fixed hourly wage and the tax and benefit system. The utility function (8) is often approximated with a second-degree polynomial in hours of work and net income. A common feature of these models is the introduction of unobserved preference heterogeneity in the marginal rate of substitution between work and consumption. Further unobserved heterogeneity in the ‘costs’ of programme participation and in fixed costs of work is also now commonplace; see Blundell and MaCurdy (1999).

5.1 Discrete hours choices
In view of the large number of non-convexities, it is common to discretize hours into hours bands, and consider the choice across these intervals. For example, in Keane and Moffitt (1998) the utility function is modelled as

\[ U_{Hj}^* = U(y_{Hj}, T - H_j^j; x) + \varepsilon_{Hj} \]  
\[(54)\]

where \( \varepsilon_{Hj} \) represents an unobserved preference component relating to the particular hours choice \( h = H_j^j \), assumed to be distributed as an extreme value random variable. Household disposable income, when supplying \( H_j^j \) hours, is defined by

\[ y_{Hj} = wH_j^j + b - R(H_j^j, w, g, x) \]  
\[(55)\]

where \( w \) is the pre-tax hourly wage rate, \( g \) is other income (not including benefits and transfers) and \( R(H_j^j, w, g, x) \) is the tax payable (positive or negative) when working \( H_j^j \) hours and having demographic composition \( x \). Thus \( R \) will reflect both tax payments and credits or welfare payments received. This expression reflects the fact that the tax and benefit system may be nonlinear and may give rise to non-convexities; in these cases it is no longer possible to express the impact of the tax system simply by a marginal tax rate.

5.2 Fixed costs of work

Fixed costs are the costs that an individual has to pay to get to work; see Cogan (1980; 1981) and Hausman (1980). For parents, they are made up in part by childcare costs. In particular, childcare induces both fixed and variable costs that effectively act as a marginal tax rate. However, there are additional costs, for example, transport, which will vary by household type and by region. These are typically modelled as a once-off weekly cost and are subtracted directly from net income for any choices that involve work. They enter the utility comparisons in each individual's work–non-work choice.

5.3 Missing wages

For non-workers gross wages are not observed. As in the discussion of corner solutions and non-
participation in Section 1, for each individual we could write the logarithm of hourly wages as

$$\ln w = z'\gamma + \omega$$

(56)

where $\omega$ has density $g(\omega)$ and where $z$ will include education, cohort and time dummies and their interactions. In principle the wage equation and the labour supply model can be estimated jointly. However, for computational reasons it is common to pre-estimate the marginal density of wages and then treat it as known at the estimation stage. This method can account for the endogeneity of gross wages and also allows for the complex relationship between gross wages and marginal wages in the tax and benefit system.

5.4 Programme participation, stigma and benefit take-up

Since the important work of Moffitt (1983) and Ashenfelter (1983), the formal analysis of welfare stigma and programme participation has been a key component of the labour supply impacts of tax and welfare programmes. Suppose $P=1$ indicates that an eligible individual participates in a welfare programme. Eligibility at any hours point $H^j$ will typically depend on earnings, other income sources, family characteristics, and the rules of the tax and benefit system. Suppose that the hassle cost and stigma is given by $\eta$, an unobservable random variable. Then we may express utility for combination $\{H^j, P\}$ as

$$U^* = U^*(y_{H^j}, P - F, T - H^j, x) - \eta P$$

(57)

where $F$ is fixed costs of work. The stigma cost variable $\eta$ may be modelled as a single unknown parameter representing a common cost across all individuals. More usefully it can be modelled as a random process with unknown mean $\mu \eta$ and distribution $f_\eta (\eta)$. The parameters of its distribution are then recovered during estimation. Notice that net income $y_{H^j}$ also depends directly on $P$ through the working of the benefit and credit system. For any distribution of stigma costs an increase in the generosity of the benefit will increase the probability of take-up. Consequently, other things equal, take-up will be higher among those eligible for a larger benefit.

As documented in Blundell and MaCurdy (1999), for each hours $H^j$ where the family is eligible to participate in the programme, utility function (57) defines a reservation stigma cost $\eta_{H^j}^*$ above which the
family would prefer not to participate at that hours level (note that the same family may choose to participate for some other hours level where it is also eligible for the programme). Given the family characteristics and the tax/benefit rules, the eligibility of each family at each level of hours can be determined, and the likelihood used in estimating the unknown parameters of labour supply, wages, fixed costs and programme participation can be fully specified.

5.5 Family labour supply and taxation

The modelling structure for couples requires but few modifications provided a ‘unitary’ model of family labour supply is adopted. The important difference in practice, as far as taxation and welfare is concerned, is that now we have to take into account the interaction of the welfare benefits that individuals may receive; see Hausman and Ruud (1984), Hoynes (1996) and van Soest (1995). Thus, the options facing each spouse are typically very different depending on whether the other family members work. Tax credit systems tend to lead to complex interactions between the effective tax rates for spouses (see Blundell et al., 2000; Eissa and Hoynes, 2004).

5.6 Optimal taxation and labour supply

One of the key developments in the use of labour supply elasticities has been in the design of ‘optimal’ tax and transfer systems following the innovative work of Saez (2001; 2002) and Laroque (2004). This has established a close link between the empirical analysis of labour supply responses and the early literature on optimal taxation (Mirrlees, 1971); see for example the implementation of these ideas in Immervol et al. (2007).

5.7 Randomized control trials and quasi-experimental approaches

Focusing purely on the reduced form impact of tax reform on labour supply, there have been several influential studies that have sidestepped the labour supply choice model and attempted to recover the impact of reforms on labour supply using randomized control experiments and quasi-experiments. The leading pure experiments are the Seattle–Denver Income Maintenance Experiment documented in Ashenfelter and Plant (1990) and the more recent Canadian Self Sufficiency Program for single mothers on welfare analysed in Card and Robins (1998). These provide a direct impact of a specific reform and also provide a useful basis from which to judge estimates from structural models. Quasi-experimental methods, which compare an eligible and a comparison group before and after a reform, have also been influential – for example the Eissa and Liebman (1996) study of the 1986 expansion of the Earned Income Tax Credit in the United States and the impact of tax rate changes on the taxable earnings of higher-income earners; see, in particular, the study by Feldstein (1995) and the further analysis by Gruber and Saez (2002). However, these quasi-experimental approaches require strong assumptions to be interpretable as measuring behavioural responses; see Blundell and MaCurdy (1999).
6 Conclusions: which labour supply elasticities for policy evaluation?

An argument has been made for an explicitly intertemporal framework, although, as we have seen, perfectly interpretable estimates of some important parameters of interest can be recovered from models that look essentially static. Much of the difference across empirical models reflects differences in data availability, and this provides another motivation for our approach. Precisely what form of income, hours or wage variables is available will vary widely across data sources, but this doesn't necessarily imply incomparable results. Some data provides longitudinal information on individual wages and hours; other data is repeated cross section but may have more detailed information on asset or consumption levels.

In whatever context the analysis of labour supply takes place, estimation will benefit from exogenous wage and income variation. One thing is clear: the type of trends that have occurred in many economies since the 1970s and the wide range of policy reforms designed to change labour supply incentives do strengthen the case for exploiting time-series information and avoiding complete reliance on purely cross-section data.

Four basic elasticities have been described which cover the main wage elasticities estimated in empirical labour supply analysis. Two are within-period elasticities: the first relating to the purely static formulation and the second relating to the two-stage budgeting specification. Two are life-cycle elasticities: the first being the intertemporal elasticity of substitution relating to the Frisch specification and measuring responses to evolutionary movements along the life-cycle wage profile, and the second relating to a full life-cycle specification and measuring responses to parametric shifts in the life-cycle profile itself. As most tax and benefit reforms are probably best described as once-and-for-all unanticipated shifts in net-of-tax real wages today and in the future, the most appropriate elasticity for describing responses to this kind of shift is the last of these. For the standard business cycle model it is the anticipated change that is of importance. As we have noted, these two elasticities can be substantially different due to income and wealth effects.

If a researcher regresses log hours of work on age; all age-invariant characteristics determining lifetime wages, preferences, and initial permanent income; and log wage, then the coefficient on the current wage rate is the Frisch elasticity. Intuitively, this approach controls for differences in the initial value of the marginal utility of wealth across consumers and leaves higher-order age variables as instruments to identify wage variation. Hence, only evolutionary wage variation along the age–wage path is included. If, alternatively, a researcher regresses log hours worked on property income, age, age squared, and log wage, the coefficient on wage is the response of labour supply to a parametric wage shift – including both the intertemporal substitution effect and the reallocation of wealth across periods captured by a change in the marginal utility. Intuitively, this approach controls for age effects and leaves individual characteristics as instruments for wage. Changes in these characteristics capture full profile shifts rather than movements along the age–wage path.

The standard static labour supply representations fit neither of these patterns, as they include property income together with personal characteristics rather than age and age squared. Hence, given the existence of life-cycle effects they confuse the effect of movements along the wage profile with shifts in the profile and, thus, yield parameters without an economic interpretation.

labour surplus economies

Gustav Ranis
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract
In some sectors with a large endowment of unskilled labour and without sufficient cooperating land or capital, given technology and a wage level bounded from below, labour markets cannot clear. A full employment solution would drive remuneration below socially acceptable, possibly subsistence, levels of consumption. Consequently, a labour surplus exists in that much of the labour force contributes less to output than it requires: its marginal product falls below its remuneration, set by bargaining. A reallocation of such workers to other, competitive, sectors would eliminate the inefficiency and enhance total output. Open economy dimensions, extensions and critiques are dealt with.

Article
Labour surplus economies are closely associated with the concept of economic dualism, that is, the existence of organizational heterogeneity as between major sectors of an economy. The basic premise is that there exist some sectors or sub-sectors in which, in the presence of a large endowment of unskilled labour and the absence of sufficient cooperating land or capital, and with a given technology and a wage level bounded from below, labour markets cannot clear. A full employment, neoclassical ‘wage equals marginal product’ solution would drive remuneration below socially acceptable, possibly subsistence, levels of consumption. Consequently, a labour surplus exists in the sense that a substantial portion of the labour force contributes less to output than it requires, that is, its marginal product falls below its remuneration, set by bargaining. The ‘labour surplus’ designation then arises from the fact that a reallocation of such workers to other, competitive, or neoclassically functioning sectors would eliminate the aforementioned inefficiency and thus materially enhance the total output of the system.

The prime location for such surplus labour has traditionally been developing countries’ agricultural sectors, concentrated especially in subsistence agriculture, characterized by family farms, that is, excluding commercialized plantation agriculture which consists of profit maximizing entities able to hire and fire workers following well-known neoclassical principles. Surplus labour makes its appearance in the context of owner-operated extended family networks, communes, villages or similar tenurial arrangements, all configurations in which income or output shares are determined via bargaining in relation to (though not necessarily equal to) the average rather than the marginal product of labour. Wage determination is thus based on a sharing principle, a function of the fact that, when high man–land ratios are among the initial conditions, low marginal-productivity workers cannot be dismissed or otherwise eliminated.

Here, we first present the static version of the labour surplus economy. Next we describe the conditions for balanced growth. Then open economy dimensions are introduced. Finally, some extensions are cited and rejoinders offered to some critiques.

The static labour surplus economy

http://www.dictionaryofeconomics.com.proxy.library.cisuniversity.edu/article?id=pde2008_L000170&goto=B&result_number=6881
Labour surplus economies: The New Palgrave Dictionary of Economics

Figure 1 illustrates the situation of relatively scarce land, intensively cultivated, yielding extremely low increments of output at the margin. Labour is measured on the horizontal and land on the vertical axis, with production contour lines indexed as M, M', and M'' in Figure 1. Given technology, fixed land at ON, and labour endowment at OS = OS' = OS'' in Figures 1, 2 and 3, the total product curve is ODQA in Figure 2 and the marginal product of labour, depicted by curve ABC in Figure 3, approaches very low levels, substantially below the bargaining or institutional wage or income share OWa which is related to (again, not necessarily equal to) the average product (slope of OQA in Figure 2). Under these conditions, we can locate the proportion of the total agricultural labour force which is ‘in surplus’ in the sense that it is ‘disguisedly unemployed’ or ‘underemployed’ as S’T in Figure 3. This includes all those whose marginal product lies below their consumption or income share. They represent the ‘labour surplus’ phenomenon or what Rosenstein-Rodan (1943) and Nurkse (1953) long ago designated as ‘hidden rural savings’ which could be mobilized via reallocation to higher-productivity activities elsewhere in the economy.

Figure 1

Figure 2
It should be emphasized that ‘labour surplus’ therefore does not mean, as has often been asserted, that a substantial portion of the agricultural labour force can be withdrawn without loss of output. Such a zero marginal product condition constitutes a statistically highly unlikely razor’s edge event but, partly because it has been assumed for purely diagrammatic and/or mathematical convenience by Lewis (1972), by Fei and Ranis (1964), and by others, it has drawn extensive and often intemperate critical comment in the literature. Schultz (1964, p. 70), for example, cited the fact that output in India fell with a decline in the agricultural working population due to an influenza epidemic as proof that surplus labour was a ‘false doctrine’. As Sen (1967) pointed out in rebutting Schultz on this point, when some workers with low (or even zero) marginal productivity are withdrawn, some of those left behind are likely to adjust by working harder. Or, put more broadly, any withdrawal of labour from agriculture is very likely to be accompanied by a reorganization of production arrangements on the part of those left behind, that is, by technology change. This would be equivalent to an upward shift of the $ODQ_A$ curve in Figure 2 and of the $ABC$ curve in Figure 3.

**Balanced growth in the labour surplus economy**

Dynamically, the labour surplus condition can thus be seen as permitting an increasing number of agricultural workers and an increasing volume of agricultural surplus, defined as the
difference between total agricultural output and what is needed to satisfy the remaining agricultural population's consumption requirements, to move out and support the expansion of commercialized activities, industry and services, rural and urban. This labour surplus condition of the economy then ultimately comes to an end when increases in agricultural productivity, which free up workers and generate agricultural surpluses and, accompanied by increases in productivity in the expanding commercialized sector, enhance the demand for workers, have proceeded in a more or less ‘balanced’ fashion long enough, and at a rate preceding population growth, to mop up the disguisedly unemployed, that is, all those whose marginal product lies below their wage or consumption standard.

This critical concept of the need for ‘balance’ between the non-commercialized and commercialized components of the labour surplus economy has really three ingredients. One, the most obvious, is that the release of labour from non-commercialized agriculture is roughly in balance with its absorption by commercialized non-agriculture. Another, focused on the product rather than the organizational dimension of dualism, suggests that relative advances in productivity in the two sectors proceed in such a fashion that the inter-sectoral terms of trade are not substantially affected, that is, that the system does not encounter food shortages or, less likely, food surpluses in the course of the development process. Third, the financial intermediation network, primitive at first, more sophisticated later, represents a crucial link as it must be capable of transforming non-commercialized sector surpluses, joined by commercialized sector profits, into efficient investment, mainly in the commercialized sector.

To turn first to more specifics on the inter-sectoral labour market, it should be noted that the unskilled real wage in the commercialized sector will tend to be tied to, though certainly not equal to, the non-commercialized agricultural real wage. A substantial unskilled labour wage gap is indeed likely to be required, partly to induce the typical agricultural worker to overcome her attachment to soil and family, partly to meet transport costs, and partly as a consequence of such institutional factors as commercialized sector minimum wage legislation, unionization, the public sector wage setting, and so forth, all of which usually do not extend into non-commercialized activities. Once these two wage levels are given within a general equilibrium context, the release of labour by the non-commercialized sector and its absorption by the commercialized sector represents an essential ingredient of balanced growth in the labour surplus economy.

It should also be noted that both wages may be expected to rise over time, in part because, as agricultural sector labour productivity increases, there is also likely to be some upward adjustment of the bargaining wage which is tied to the rising average product. Moreover, the inter-sectoral wage gap may rise as a consequence of a change in the extent of commercialized sector interventions via minimum wage increases, enhanced union bargaining power, and so on. The two unskilled real wage patterns over time may thus be conceived of as a step function, horizontal at any point in time, reflecting the labour surplus condition, but at a slightly higher level, on horizontal, in the next period. All of this will, of course, yield a gently rising labour supply curve over time, giving way to a sharply rising pattern once the labour surplus has been exhausted and remuneration is determined neoclassically, that is to say, by the marginal product. Meanwhile, the existence of a relatively constant or gently upward-sloping real wage over time in both sectors, with a possibly growing gap between them, can be expected to induce labour-intensive technology choices and, more importantly, labour-using technological change in both the non-commercialized and commercialized sectors of the labour surplus economy.

Second, an understanding of the workings of the inter-sectoral commodity market is required for an assessment of the contribution of the non-commercialized sector to the rest of the economy. This can be seen in terms of the net real resources transferred, that is, the difference between the shipments of food and raw materials delivered to the commercialized sector and the shipments of goods and services sent in the opposite direction. The agricultural sector's export surplus may thus be viewed as the contribution of that sector to both the reallocation and overall growth process over time.

The main participants in the dualistic commodity market are thus, on the one hand, the owners of the agricultural surplus and, on the other, the newly allocated workers who may be thought of as receiving wage income in the form of non-agricultural goods and anxious to trade some of these for the food 'left behind'. Once this transaction is completed, the reallocated worker finds herself in possession of the agricultural goods needed to at least maintain her consumption standard – most likely to increase it because of the aforementioned inter-sectoral wage gap. In this fashion the dualistic commodity market is indispensable for transforming the consumption bundle of the agricultural labour force into a wages fund for the newly allocated non-agricultural workers. At the same time the owners of the agricultural surplus, such as the landlords and/or the government via land taxes, obtain a claim against a portion of the newly formed non-agricultural capital stock; the other portion results from the reinvestment of profits by commercialized sector entrepreneurs. The above underlines the importance of the product, along with the organizational dimension of balanced growth in the closed labour surplus economy, rooted in the fact that food and non-agricultural products cannot readily be substituted for each other. Agriculture is thus a necessary condition for non-agriculture, while the converse does not strictly hold. In the open economy, food imports, of course, become possible, thus helping the system avoid premature food shortages, as illustrated by Japan's historical experience in the early decades of the 20th century (see Hayami and Ruttan, 1970).

Third, the financial counterpart of the real resources contribution of the non-commercialized to the commercialized sector over time is effected through the workings of the intersectoral financial market. As we have seen, the savings of the agricultural sector become a claim against non-agriculture, the magnitude of which is determined by the size of its export surplus. These savings must somehow be channeled into non-agricultural investment; that is, what is left of the agricultural surplus that is not siphoned off by consumption or intermediate input requirements must find its way into capital formation in the rest of the economy.

The dynamics reflecting all the main facets of such a balanced growth path can be illustrated by reference to Figure 4 within a simplified setting, that is, without intermediate input flows between the two sectors. Total population $L$ is shown on the horizontal axis in quadrant II, moving from right to left, with agricultural output and the institutional consumption standard $c = w^L_2$, measured in terms of agricultural goods, on the vertical axis. The curve $Q^T_O$ describes per capita food availability for the total population, or $Q/L$, at a given level
of technology, for various possible proportions, $\theta$, of the total population already allocated to other activities, $B$, that is, $\langle \theta = B / L \geq 0 \rangle$. One equilibrium point along a balanced growth path may then be defined as follows: let initial consumption $c = w_0^0$, and the terms of trade between $w_a^0$, the ‘wage in terms of agricultural goods’ ($Q_A$), and $w_{na}^0$, the ‘wage in terms of non-agricultural goods’ ($Q_{NA}$) be given. For simplification only, we assume that there is no wage gap between unskilled agricultural and non-agricultural workers. The price–consumption curve ($PC$) in quadrant I of Figure 4 then indicates all possible points of tangency between changing terms of trade and a given typical worker's consumer preference between agricultural and non-agricultural goods. Point $e$ is the consumption equilibrium point for the typical worker, given the terms of trade shown, regardless of whether she is engaged in agricultural or non-agricultural activities. $B$ is the population outside of agriculture and the remaining agricultural population $V (L = B + V)$ produces enough food to meet everyone's consumption requirements at the institutional wage.

Figure 4
The auxiliary 45° line in quadrant III transposes workers \( B° \), already allocated to non-agricultural work, onto the vertical axis, that is, \( OB° \). The consistent equilibrium point for employment in the non-agricultural sector is then point \( d° \), located at the intersection between the ‘horizontal’ supply curve of non-agricultural labour, at wage level \( w_{NAG} \), and the demand curve for non-agricultural labour, or the marginal productivity curve corresponding to a particular level of the capital stock and technology in that sector. This describes an equilibrium position \( a°b°d° \) in both the intersectoral labour and commodity markets.

To turn to the definition of balanced growth over time, and on the assumption of no upward adjustment of the agricultural real wage and, thus, of the non-agricultural real wage which is ‘tied’ to it, balanced increases in agricultural and non-agricultural productivity resulting from capital accumulation and technology change can be shown by a shift of the per capita food availability curve to \( OA°^1 \) in quadrant II, with \( Lb^1 \) or \( OB^1 \) workers now allocated, as well as of the marginal productivity of non-agricultural labour curve to \( d^1 \) in quadrant IV. This would result in a new equilibrium position \( a^1b^1d^1 \) where, once again, the two intersectoral markets clear. Such a growth path would clearly meet the labour market equilibrium condition, and a little more work would permit us to demonstrate that equilibrium in the commodity market sense, as previously defined, also continues to be achieved, permitting agricultural and non-agricultural workers to exchange some of the goods they produce for the goods they need, at the given terms of trade, enabling everyone to remain at the same equilibrium point \( e \).

To turn to the inter-sectoral financial market, the landlords and/or the government, whoever owns the agricultural surplus, would end up with a claim against some part of the non-agricultural capital stock. This, plus the reinvested industrial profits represented by the shaded area in quadrant IV of Figure 4 would be invested in the non-agricultural sector, causing, along with technology change, the indicated shift of the marginal productivity curve. The investment fund for the next period is thus composed of this period’s savings out of the agricultural surplus plus the savings out of non-agricultural profits. For the sake of convenience, we have made the assumption of no leakage into consumption by either landlords or capitalists. The allocation of the society’s investment fund plus its innovative energies, as between the sectors, would then be guided by the relative shortages of agricultural and non-agricultural goods, as reflected, in the case of a market economy, by changes in the inter-sectoral terms of trade. In a non-market economy the role of changes in the terms of trade as a signalling device would be taken over by evidence of unplanned shortages or surpluses in the material balances sense. We have here again made a simplifying, but not critical, assumption that technology change is responsible for agricultural productivity change, while all the investment funds are allocated to non-agriculture.

As we have already noted, the entire transition process must not only be balanced but also proceed at a pace in excess of population growth if the initial reservoir of surplus labour is to ultimately be exhausted and neoclassical wage determination is to take over. Moreover, if balanced growth, as indexed by the rate of labour reallocation, only marginally exceeds the rate of population growth on average, the length of time it takes to arrive at the commercialization point, marking the end of labour surplus, must also be politically acceptable. The real world, of course, does not quite operate in such a smooth fashion. There are times when, under the impetus of an ‘industry first’ strategy, non-agricultural productivity increases for some time at a rate in excess of agricultural productivity growth, leading to food shortages, the shifting of the terms of trade in favour of agriculture, and an increase in the non-agricultural real wage. The reverse can also occur, although empirically there seems to be less danger of that. Most successful labour surplus societies (such as historical Japan and post-war South Korea, Taiwan and Thailand) have, in fact, experienced something approaching constancy in the terms of trade.

In any case, progress along a balanced growth path at a rate in excess of population growth – and sufficiently in excess to guarantee a politically acceptable time perspective – is essential to a society’s successful transition into a modern growth regime. Success is defined as the end of labour surplus, that is, the end of organizational dualism in the labour market. Once balanced growth has proceeded long enough and fast enough labour surplus gives way to labour shortage in both sectors, which means that the marginal productivity calculus of wage determination takes over. At this point organizational dualism disappears; and, given considerable increases in per capita incomes and the workings of Engel’s Law, product dualism also atrophies over time as agriculture gradually becomes an appendage to the economy, or just another symmetrical sector within the system’s input–output matrix. Increasingly the economy is then ready to perform according to the rules of modern economic growth as described by Simon Kuznets (1966).

**Open economy dimensions**

Thus far we have discussed the development of the labour surplus economy mainly in a closed economy context. The open economy or trade-related dimensions of development in the labour surplus economy are, of course, important enough to warrant substantial amendment of the analysis presented here. During the early colonial, or open agrarian, phase of development, the economy may well be tied to foreign markets by virtue of some of the labour force being weaned away from food production and into land-based export-oriented...
labour surplus economies: The New Palgrave Dictionary of Economics

activity: for example, minerals and other primary products of interest to foreign investors. This typically leads to a triangular relationship among the cash-crop export sector, the foreign sector, and the food producing domestic agricultural sector. But once the economy moves out of its colonial or ‘overseas territory’ phase and into a national development-oriented effort, our analysis must be amended to take ‘openness’ into account.

To do so, we must, first, recognize that the export-oriented cash crop agricultural sub-sector continues to generate foreign exchange earnings but that these are now used, in addition to possible food imports, to assist in the construction of a new, domestically oriented, non-agricultural sector producing previously imported non-durable consumer goods, that is, to fuel so-called primary or ‘easy’ industrial import substitution. These raw material-intensive exports thus provide a second source of agricultural surplus which, converted into industrial capital goods imports, and possibly supplemented by the inflow of foreign savings, helps finance non-agricultural growth in the same balanced growth context. In this way a new triangular relationship between two kinds of commercialized activities, one agricultural and the other non-agricultural, plus the food producing non-commercialized agricultural hinterland, replaces the colonial triangle.

What happens at the end of this primary import substitution phase is critical; that is, once domestic markets for the non-durable consumer goods are exhausted, it is apparent that relatively natural resources rich labour surplus countries have a tendency to continue with import substitution, now shifting from labour-intensive light industries to the more capital-intensive durable consumer goods, the processing of raw materials, and the production of capital goods. At the same time, in the minority of countries which have a relatively poor natural resources base we observe a shift from a domestic to an export-market orientation for the same labour-intensive non-durable consumer goods. In that case the export sector now constitutes a powerful new production function available to the economy through which traditional and, later, non-traditional exports can be converted into imported capital goods and raw materials. Moreover, the openness of the economy permits foreign capital to provide additional finance in support of the balanced growth process. Finally, an important potential advantage of the economy’s openness is, of course, the whole range of additional technological alternatives now made available, which, hopefully with modifications and adaptations, can help increase the efficiency and speed of the balanced growth process.

The open economy, in other words, not only permits the labour surplus economy to harvest the normal gains from trade, to benefit from the vent for surplus of previously underutilized resources – in this case not only raw materials but also unskilled labour – but also, dynamically, to affect the direction of technology change and thus introduce competitive forces and ideas from abroad which are able to diffuse throughout the economy and are undoubtedly of considerable importance in determining the success of the labour surplus economy’s transition efforts.

Extensions and critiques

Up to now we have focused exclusively on owner-operated agriculture as the typical representative of the non-commercialized sector of the labour surplus economy. It should, however, be recognized that there are very likely to exist substantial portions of non-agricultural activities, both rural and urban, and both industry and services-oriented, which are labour surplus in the way we have defined the condition. This time, the cooperating factor in short supply is capital. Most relevant is the so-called informal sector – both rural but most heavily urban – which occupies a large, often dominant, position in many developing countries. Family and cooperative ventures in this setting are characterized by the same sharing of total income, that is, a bargaining wage, coupled with low marginal productivity, that we encountered in subsistence agriculture. We are here including not only the substantial portions of both the rural and urban populations engaged in distributive trades and services – ranging from the vendors of tea, flowers and cigarettes to barbers, bootblacks and car watchers – but also to blacksmiths, metal workers, and repair shops that dominate the landscape in most labour surplus developing countries. Some portions of this informal sector, especially its urban branch, are likely to be static and of the labour-absorptive ‘sponge’ variety; others may be capable of technology change, of subcontracting arrangements with the urban formal or commercialized sector as well as of generating surpluses for investment in that sector. Thus, organizational dualism is quite pervasive in both rural and urban non-agriculture, even as product dualism now loses its distinctive characteristic.

As development since the 1950s has proceeded apace, some initially labour surplus countries, including Taiwan, South Korea and Thailand, have graduated from their initial labour surplus condition, evidenced by gently rising unskilled wages in both sectors, finally giving way to rapid and sustained increases as secular labour shortages make their appearance. Such a turning point was reached around 1968 in the case of Taiwan, around 1973 in the case of South Korea and around 1993 in the case of Thailand. It is also true that many developing countries, starting with up to 80 per cent of their population and 50 per cent of their output in food producing agriculture, have gradually shifted substantially into non-agricultural pursuits, with services retaining their dominant position, even as their composition has changed radically, in the commercialized direction. As a consequence, the number of contemporary developing countries with typical initial labour surplus characteristics has been declining. Nevertheless, a large preponderance of the developing world, certainly by weight of population, continues to find itself in a labour surplus condition. This holds, for example, for China and India, huge countries both currently engaged in a vigorous balanced growth effort, as well as for other parts of South Asia, much of Central America, the Caribbean and parts of South America. Even some countries of sub-Saharan Africa, once considered land surplus by some observers, may, as a consequence of population growth and the loss of land to the Sahara, be approaching labour surplus status—though, given the AIDS epidemic, this remains a more controversial issue.

It should, finally, be noted that the fundamental concept of the labour surplus economy has come under increasing attack by the dominant neoclassical school of economics. While still viewed as relevant in the South and wherever heavy population pressure on scarce cultivable land remains a feature of the landscape, most Northern economists in the Becker microeconometric tradition find it difficult to accept the notion of an exogenous or bargaining wage in the non-commercialized sectors instead of one determined endogenously by the
customary interaction between demand and supply. The crux of the critique is based on the rejection of the notion that initial conditions, that is, a highly unfavourable ratio of people to cooperating land or capital, can lead to the subsidization of some members of the society by others, in lieu of ejecting them.

The work of Rosenzweig and associates (for example, Rosenzweig, 1988), presenting evidence of rising labour supply curves in a cross-section of such heavily populated agricultural sectors as India’s, typifies current mainstream rejection of the ‘unlimited supply of labour’ condition underlying the labour surplus economy construct. Yet we would contend that such efforts capture an expressly static snapshot picture, addressing cross-sectional labour–leisure decisions across households already working at full capacity (that is, with little leisure to spare), while labour surplus models are concerned with the conditions governing inter-sectoral labour reallocation over time.

The exogenous agricultural wage assumption underpinning labour surplus economies, so troubling to neoclassical economists, gets support from anthropologists like Geertz (1963) and Scott (1976), as well as from economists like Lewis (1972), Ishikawa (1975), Fei and Ranis (1964), Osmani (1991), Ohkawa (1972) and others. Fafchamps (1992) provides an overview of the principles underlying the ‘solidarity network’ among peasants as depicted in anthropological evidence. Ishikawa (1975), long an astute observer of Asian economic development, endorses the concept of a ‘minimum subsistence level of existence’ (MSL), one version of the institutional real wage. His work indicates the prevalence of a ‘community principle of employment and income distribution’. This principle promises all member MSL families… an income not less than MSL’ (Ishikawa, 1975, p. 474). Hayami and Kikuchi (1982, p. 217), basically neoclassical in outlook, find that in Indonesia

… wage rates cannot adjust directly to changes in labor's marginal productivity. Adjustments in wage rates are allowed only through modification of institutional arrangements themselves … In other words, ‘institutional wages’ based on a system of community-wide work and income-sharing similar to the classical concept can adjust to the neoclassical equilibrium through institutional innovations.

Only over time is there a tendency to adjust, but even then it does not necessarily occur by altering wages to equal the marginal product, which could reduce the wage below subsistence. Instead, in Java harvest contracts are adjusted to include weeding duties without a complementary rise in the wage rate, thereby not threatening the MSL but moving institutionally towards equilibrium. Even Kenneth Arrow (1988), one of the high priests of neoclassical economics, states that it may take a considerable period of time before equilibrium is reached. Osmani (1991) presents a model of downward rigidity of the sharing rule insisted on by the workers themselves. Current work in what is called behavioural economics may also prove to be of help in developing a theoretical structure to rationalize cross-worker subsidization in the absence of assured reciprocity – especially as some members of the group are likely to be leaving agriculture over time.

Perhaps even more relevant, there is evidence, not only for Taiwan, Korea, and Thailand but also for post-enclosure England between 1780 and 1840 and for post-Restoration Japan between 1870 and 1920, indicating substantial increases in agricultural labour productivity while both agricultural and non-agricultural unskilled real wages were rising only gently, until commercialization was reached and wages began to rise steeply in line with rising marginal productivity. Thus, both historical and 20th-century development patterns are inconsistent with the neoclassical school's one-sector full-employment equilibrium assumptions.

In the final analysis, what is relevant is whether the labour surplus model provides a better fit for the observed empirical pattern of successful labour-abundant developing countries; whether the model is better suited to analysing relative agricultural neglect in failure cases; whether it is better able to explain changing patterns of technology choice and the direction of technology change; whether, in sum, it makes better sense than to assume away the initial existence of underemployment and disequilibrium before the one-sector, fully commercialized modern growth epoch can be reached.

How to cite this article

The only instance in which Adam Smith makes the value of commodities depend on the quantity of labour required to produce them is where ‘the whole produce of labour belongs to the labourer’ (Smith, 1776, vol. 1, p. 54; see ibid., p. 72). ‘In that early and rude state of society which precedes both the accumulation of stock and the appropriation of land’, he asserts ‘the proportion between the quantities of labour necessary for acquiring different objects seems to be the only circumstance which can afford any rule for exchanging them for one another’ (ibid., p. 53).

This contention is illustrated by the famous example of the beaver and the deer:

If among a nation of hunters, for example, it usually costs twice the labour to kill a beaver which it does to kill a deer, one beaver should naturally exchange for or be worth two deer. It is natural that what is usually the produce of two days or two hours labour, should be worth double of what is usually the produce of one day's or one hour's labour (ibid., p. 53).

According to Smith, when profit and rent make their appearance alongside the labourer's income, the above rule is no longer applicable. The price of a commodity is then obtained by adding up its ‘component parts’: wage, profit and rent. These revenues, which Smith calls ‘the three original sources … of all exchangeable value’ (ibid., p. 59), enter into the ‘natural price’ of each commodity at their respective ‘natural rates’, such that ‘the natural price itself varies with the natural rate of each of its component parts, of wages, profit and rent’ (vol. I, p. 71).

The ‘adding-up’ theory of prices must be distinguished from Smith's claim that the price of every commodity ‘resolves itself’ entirely into wage, profit and rent (see vol. I, p. 57). The latter was accepted by Ricardo and rejected by Marx. The former was rejected by both.

1. Against the ‘adding-up’ theory Ricardo sets the labour theory of value extended to the capitalist mode of production:

All the implements necessary to kill the beaver and deer might belong to one class of men,
and the labour employed in their destruction might be furnished by another class; still their comparative prices would be in proportion to the actual labour bestowed, both on the formation of the capital, and on the destruction of the animals. (Ricardo, 1821, p. 24)

The value of the product would go partly to the labourers and partly to the capitalists; yet this division could not affect the relative value of these commodities, since whether the profits of capital were greater or less, whether they were 50, 20 or 10 per cent. or whether the wages of labour were high or low, they would operate equally on both employments. (ibid.)

As gold, the standard of value, is a commodity like any other, the above argument makes the price of commodities – the exchange-ratio between each of them and gold – independent of the level of the wage, a change in which is exactly offset by a change in the opposite direction of the rate of profits: the relative weight of the two ‘component parts’, wages and profits, varies, but their sum remains the same. According to Ricardo the value of a commodity produced from natural resources in short supply is regulated by the quantity of labour expended to produce it ‘under the most unfavourable circumstances … under which the quantity of produce required, renders it necessary to carry on the production’ (ibid., p. 73). Thus the quantity of labour governing the value of the entire quantity produced of a commodity is not that actually expended on its production, but that which would need to be expended if the entire production took place under the most unfavourable circumstances. That portion of the value which is absorbed by rent corresponds to the difference between this fictitious quantity of labour and the one actually expended on the production of the commodity. The portion of value corresponding to the quantity of labour actually expended is split up into wages and profits.

Thus the labour theory of value enables Ricardo to conceive the different revenues as resulting from the breakdown of a known magnitude, rather than that magnitude (value) as resulting from the adding up of ‘component parts’ (the different revenues) determined independently of each other. The contrast between these two conceptions is fixed by Marx in a highly effective image:

If I determine the lengths of three different straight lines independently, and then form out of these three lines as ‘component parts’ a fourth straight line equal to their sum, it is by no means the same procedure as when I have some given straight line before me and for some purpose divide it, ‘resolve’ it, so to say, into three different parts. In the first case, the length of the line changes throughout with the lengths of the three lines whose sum it is; in the second case, the lengths of the three parts of the line are from the outset limited by the fact that they are parts of a line of given length (Marx, 1885, p. 387).

2. If gold is produced by an unchanging quantity of labour, a rise in the price of a commodity can only stem from a process of ‘extensive’ or ‘intensive’ diminishing returns (only the former, however, will be considered in what follows). In discussing the consequences of an increasing ‘difficulty of procuring the necessaries on which wages are expended’, Ricardo takes the quantities consumed by each labourer as given. It follows that, as the price of corn (a typical necessary) rises, the wage in terms of gold also rises,
and the profits of the manufacturers fall:

suppose corn to rise in price because more labour is necessary to produce it; that cause
will not raise the prices of manufactured goods in the production of which no additional
quantity of labour is required. If, then, wages continued the same, the profits of
manufacturers would remain the same; but if, as is absolutely certain, wages should rise
with the rise of corn, then their profits would necessarily fall (Ricardo, 1821, pp. 48, 110–
11).

Let us assume that the entire production of corn is initially obtained from land of uniform quality, and
that thereafter, in order to increase the quantity produced, land of an inferior quality be brought into
cultivation. The value of the quantity of corn produced on the second quality of land is governed by the
quantity of labour actually expended on its production and ‘is divided into two portions only: one
constitutes the profits of stock, the other the wages of labour’ (ibid., p. 110). The increase in the value of
the quantity of corn obtained from the first quality of land is wholly swallowed up by the rent, which
now begins to be paid for the use of this quality of land.
In the production of corn both expenses and proceeds per unit of produce increase. But the result is the
same as in manufacturing (where only expenses increase) since the farmer ‘will not only have to pay, in
common with the manufacturer, an increase of wages to each labourer he employs, but he will be
obliged either to pay rent, or to employ an additional number of labourers to obtain the same produce;
and the rise in the price of raw produce will be proportioned only to that rent, or that additional number,
and will not compensate him for the rise of wages’ (ibid., p. 111).
What causes the ratio of profits to wages to fall is not the rise of rent, but – in agriculture as well as in
manufacturing – the increase in wages consequent upon the increased expenditure of labour required to
produce necessaries in the most unfavourable circumstances. If the commodities which increase in value
are not among those purchased by labourers, the ratio of profits to wages remains unchanged (even
though a part of the capitalist's purchasing power is transferred to the landowners).

3. What is true of the ratio of profits to wages is also true, in Ricardo's opinion, of the rate of profits,
which forms his main concern. Indeed, what he does is simply to refer to the latter his conclusions
regarding the former, so that the two concepts appear to shade into one another. ‘In his observations on
profit and wages’, says Marx, taking up a remark of G. Ramsay's (1836, p. 174n.), ‘Ricardo … treats the
matter as though the entire capital were laid out directly in wages’ (Marx, 1905–10, vol. II, p. 373).
Marx traces this confusion back to ‘the absurd dogma pervading political economy since Adam Smith,
that in the final analysis the value of commodities resolves itself completely into … wages, profit and
rent’ (Marx, 1894, p. 841).
Smith's teaching is that, while the price of a commodity includes – along with the revenues derived from
its direct production – the value of its means of production, the latter value can be broken down in the
same way, and so on, going backwards, until an initial stage of production is reached, in which the
means of production of the stage following are produced without the aid of any other means of
production. Only the value of the output in the initial stage of production resolves itself immediately into
wage, profit and rent. But the output in each stage, whose value equals the sum of the revenues obtained
in that stage as well as in all the preceding ones, supplies the means of production for the next stage, so
that ‘the whole price still resolves itself either immediately or ultimately into the same three parts of rent, labour, and profit’ (Smith, 1776, vol. I, p. 57; here ‘labour’ obviously stands for ‘wages’).

Marx's criticism of Smith's thesis of complete ‘resolution’ of prices into revenues is made up of two parts, which should be kept strictly distinct. The first is of a factual nature. In moving back from a commodity to its means of production, and from these to their own means of production, and so on, one will never – in Marx's view – reach an initial stage of production, since sooner or later one is bound to encounter commodities that, either directly or indirectly, participate in the production of themselves. Since one can never get rid of these commodities, however far back one goes, ‘it is [of] no avail for Adam Smith to send us from pillar to post’ (Marx, 1905–10, vol. I, p. 99).

The conception according to which commodities are produced in a finite number of stages does not, of itself, lead to a confusion between the rate of profits and the ratio of profits to wages. Since, however, in this conception the value of the means of production employed in each stage resolves itself into the revenues obtained in all the previous stages, ‘one may … imagine along with Adam Smith’ – this being the second part of Marx's criticism – ‘that constant capital is but an apparent element of commodity-value, which disappears in the total pattern’ (Marx, 1894, p. 845; by ‘constant capital’ Marx means the value of the means of production).

That in dealing with the economy as a whole Smith and Ricardo fall into this error emerges clearly, for example, from Smith's statement, repeated almost verbatim by Ricardo, according to which ‘what is annually saved is as regularly consumed as what is annually spent, and nearly in the same time too; but it is consumed by a different set of people’ (Smith, 1776, vol. I, p. 359; see Ricardo, 1821, p. 151n.).

The funds devoted to accumulation are here treated as wholly employed in producing the necessaries for the labourers. This may help explaining how, when Ricardo approaches the problem from the point of view of the economy as a whole, he does not seem to make any distinction between the rate of profits and the ratio of profits to wages, referring to the former as depending only on the ‘proportion of the annual labour of the country [which] is devoted to the support of the labourers’ (Ricardo, 1821, p. 49; see Sraffa, 1951, p. xxxiii).

4. Although it is the labour theory of value that makes it possible for Ricardo to determine the rate of profits, his adherence to this theory appears anything but firm. Indeed, ‘the principle that the quantity of labour bestowed on the production of commodities regulates their relative value’ turns out to be, as Ricardo puts it, ‘considerably modified’ (ibid., p. 30) by the influence of other factors.

To show this Ricardo makes use of a numerical example which deserves to be quoted in full:

Suppose I employ twenty men at an expense of £1,000 for a year in the production of a commodity, and at the end of the year I employ twenty men again for another year, at a further expense of £1,000 in finishing or perfecting the same commodity, and that I bring it to market at the end of two years, if profits be 10 per cent., my commodity must sell for £2,310; for I have employed £1,000 capital for one year, and £2,100 capital for one year more. Another man employs precisely the same quantity of labour, but he employs it all in the first year; he employs forty men at an expense of £2,000, and at the end of the first year he sells it with 10 per cent. profit, or for £2,200. Here then are two commodities having precisely the same quantity of labour bestowed on them, one of which sells for £2,310 – the other for £2,200 (ibid., p. 37).
Let \( w \) be the wage (equal in the example to £50 per labourer) and \( r \) be the rate of profits (equal to 10 per cent). For the sake of simplicity, we shall further suppose that the quantity produced of each of the two commodities be one unit. The price of commodity \( a \), the first commodity in the example, is then

\[
20w(1 + r)^2 + 20w(1 + r) = P_a
\]

The price of the second commodity, \( b \), is instead

\[
40w(1 + r) = P_b
\]

Although Ricardo does not deal systematically with the subject, here, as well as in other numerical examples, he does offer a theory in embryo, which – for any given rate of profits – makes natural prices depend not only on the quantity of labour directly or indirectly expended on each commodity, but also on what we may call the distribution over time of that quantity of labour.

5. Since in the foregoing example the prices of the two commodities are determined on the basis of prior knowledge of the wage and the rate of profits, one may be inclined to think, with Marshall, that according to Ricardo value is regulated by the cost of production, which includes ‘Time or Waiting as well as Labour’; and that Marx wrongly interpreted his doctrine ‘to mean that interest does not enter into that cost of production which governs … value’ (Marshall, 1920, p. 672 and pp. 672–3, n. 1). That this is not the case will emerge clearly if we look at Ricardo's approach to the problem of relative price variation as set forth in a numerical example contained in his 1823 paper on *Absolute Value and Exchangeable Value* (Ricardo, 1823, pp. 383–4); an example which closely follows the one we have just examined (the only differences, which we shall ignore, being that the prices of commodities \( a \) and \( b \) corresponding to \( r=10 \) per cent are said to be £231 and £220 respectively, rather than £2,310 and £2,200, and that a third commodity is also considered).

Ricardo supposes ‘labour to rise in value and profits to fall – that from 10 pc\(^t\) they fall to 5 pc\(^t\). He further supposes that commodity \( b \) be the standard of value. Making the two examples into a single one, we shall suppose that gold is produced in a single stage. If, then, the price of commodity \( b \) is £2,200, that is not because the wage is £50 and the rate of profits 10 per cent, but rather because it has been produced, like gold, in a single stage, employing a quantity of labour equal to 2,200 times that required to produce the quantity of gold corresponding to £1. The fall in the rate of profits from 10 to 5 per cent will thus leave the price of commodity \( b \) unchanged; which amounts to saying that in its production (as in that of gold) the increase in wages and the fall in profits offset each other.

However, the same increase in \( w \) and fall in \( r \) cannot bring about a similar offsetting in the case of commodity \( a \), whose price must fall from £2,310 to £2,255 (from £231 to £225.5 in Ricardo's 1823 example). This result is obtained by applying the rate of profits of 5 per cent (instead of 10 per cent) to
the value of the means of production employed in the second stage of production of commodity a. The latter value, £1,100, does not vary, since the means of production are produced, like gold (and commodity b), in a single stage. The value of the term \(20w(1 + r)^2\) in the equation of commodity a falls, therefore, from £1,210 to £1,155. The value of the second term in the sum, \(20w(1+r)=£1,100\), can be assimilated to the unchanging value of a commodity produced in a single stage.

It is evident that, if gold were produced in two years, with the same proportional distribution of labour between the two corresponding stages of production as commodity a, the new ratio \(P_a/P_b\) would emerge from a rise in \(P_b\) with \(P_a\) constant. It is also evident that, if all commodities were produced with the same proportional distribution of labour over time, they would all be in the same situation as gold, in whose production an increase (fall) in wages is exactly offset by the corresponding fall (increase) in profits, and the labour theory of value would stand in no need of ‘modification’.

The ‘modifications’ have, therefore, nothing to do with the alleged necessity of adding to the labour what is depicted as a second element of the cost of production. The misunderstanding may be traced back to Malthus, who ascribes to Ricardo the very fault that Marshall seeks to acquit him of, shifting the blame onto Marx. ‘We have the power indeed’, Malthus remarks:

‘arbitrarily, to call the labour which has been employed upon a commodity its real value, but in so doing, we use words in a different sense from that in which they are customarily used; we confound at once the very important distinction between cost and value; and render it almost impossible to explain with clearness, the main stimulus to the production of wealth, which in fact depends upon that distinction’.

To which Ricardo counters:

Mr Malthus appears to think that it is part of my doctrine, that the cost and value of a thing should be the same; – it is, if he means by cost, ‘cost of production’ including profits. In the above passage, this is what he does not mean, and therefore he has not clearly understood me (Ricardo, 1821, p. 47n.).

What Ricardo makes clear in this passage (which, surprisingly enough, Marshall quotes as evidence in support of his reading of the matter: see Marshall, 1920, p. 672) is that the labour theory of value, in its ‘unmodified’ as well as its ‘modified’ form, takes full account of ‘the very important distinction between cost and value’; that is, of the existence of profits (‘the main stimulus to the production of wealth’).

What equals value according to this theory is not, Ricardo argues, ‘cost’ as commonly understood, but ‘cost of production including profits’, profits being what is left of the value of a commodity once wages have been deducted. (Reference to the most unfavourable circumstances under which production is carried on has been dropped since the preceding section, land being now supposed to be abundant and all of the same quality.)

6. The reader will perhaps have noted how Ricardo omits to specify by how much the wage must increase in order to cause a fall from ten to five per cent in the rate of profits (elsewhere, again when dealing with the problem of relative price variation, he postulates ‘such a rise of wages as should occasion a fall of one per cent. in profits’: Ricardo, 1821, p. 36). Even though Ricardo continues to
express himself as if, in the relation between \( w \) and \( r \), the independent variable were represented by the wage, in actual fact he reverses the roles, and makes \( w \) depend on \( r \). The value of \( w \) when \( r = 10 \) per cent is, as we know, \( w = £50 \). Its value when \( r = 5 \) per cent can be calculated from the equation of commodity \( b \) (whose price remains £2,200). This value is slightly less than \( w = £52.8s.0d \).

As a matter of fact, Ricardo's argument is made up of two distinct stages. In the first of these the rate of profits is determined on the basis of the 'unmodified' labour theory of value; in this stage the necessaries consumed by each labourer are taken as given (see section 2 above). The second stage takes the rate of profits as given, the problem being now to determine the prices which make the rate of profits uniform throughout the economy. These prices, as Ricardo realizes, are not regulated by the quantities of labour expended on the production of the commodities, as they were assumed to be for the purpose of determining the rate of profits. And the wage (the £52.8s.0d or so of the example) will in general turn out to be different from the value of the necessaries it was assumed to purchase in the first stage of the argument.

It does not escape Ricardo that the rate of profits should be determined on the basis of the 'modified' theory, and therefore of prices which, in turn, cannot be determined before the rate of profits is known. But he is unable to provide a theoretical construction capable of coping with this interdependence. Thus he does not see any other solution but that of continuing to base his analysis of income distribution on the 'unmodified' labour theory of value, which he defends as 'the nearest approximation to truth as a rule for measuring relative value, as any I have ever heard' (Letter to Malthus of 9 October 1820, in Ricardo, 1951–73, vol. VIII, p. 279).

7. A major difference between the Ricardian version of the labour theory of value and its Marxian version, to which we must now turn, lies precisely here: that the former can be described as an approximation, whereas the latter cannot. According to Marx the values of commodities exactly (not approximate) reflect the quantities of labour expended on their production, although this is not true, in general, of the 'prices of production' (Marx's name for 'natural prices'), which coexist with values. In discussing Marx's position we shall reckon the value of commodities directly in units of labour (say, man-years). The value of the means of production which assist one labourer in the annual cycle of production of any particular commodity, or constant capital per unit of labour \( (c) \), and the value of one labourer's necessaries, or variable capital per unit of labour \( (v) \), are thus made equal to the quantities of labour expended on the production of those means of production and of those necessaries respectively. If only circulating capital is used, the value of the output per unit of labour of any commodity is \( (c+1) \), or \( c \) plus the value added per unit of labour. Since \( v \) is uniform throughout the economy (each labourer being assumed to consume the same bundle of commodities), the surplus-value per unit of labour \( (1−v) \) will also be uniform. The same is obviously true of the ratio of surplus-value to variable capital (the rate of surplus-value), but not, in general, of the ratio of surplus-value to total (i.e. constant plus variable) capital. The latter ratio will be the higher, in any particular branch of production, the lower is the ratio \( c/v \) (the organic composition of capital).

Competition, however, redistributes the overall surplus-value of the economy among the various branches of production in such a way as to render it proportional not to the variable, but to the total capital. Thus a general rate of profits comes to be established, equal to the weighted average of the \( (1−v) \) to \( (c+1) \) ratios in the different branches of production – or, which amounts to the same thing, to the ratio of the overall surplus-value of the economy to the overall capital employed. The same mechanism establishes the prices of production, which make that rate of profits uniform throughout the economy.
Unlike Ricardo's Marx's argument is *explicitly* framed in two stages. Since the prices of production differ from the values only on account of the different distribution of the overall surplus-value of the economy, according to Marx the rate of profits is accurately determined, for the economy as a whole, on the basis of the labour theory of value. The prices of production are then obtained from the values by replacing the surplus-value produced in each branch of production with the part of the overall surplus-value of the economy belonging to that branch according to the general rate of profits.

8. ‘Surplus-value and the rate of surplus-value’, says Marx, ‘are, relatively, the invisible and unknown essence that wants investigating, while rate of profit and therefore the appearance of surplus-value in the form of profit are revealed on the surface of the phenomenon’ (Marx, 1894, p. 43). To reveal the invisible: herein lies the task of science. But Marx's theoretical programme also involves explaining just why the intimate essence of things is invisible, why it does not reveal itself ‘on the surface of the phenomenon’. Marx's explanation is that those ‘who are entrapped in bourgeois production relations’ (ibid., p. 817) witness the *result* of the redistribution of surplus-value—the profit proportional to capital – but not the *process* leading up to this result:

The actual difference of magnitude between profit and surplus-value … in the various spheres of production now completely conceals the true nature and origin of profit not only from the capitalist, who has a special interest in deceiving himself on this score, but also from the labourer (ibid., p. 168).

Thus it comes about that

the splitting of the value of commodities after subtracting the value of the means of production consumed in their creation; the splitting of this given quantity of value, determined by the quantity of labour incorporated in the produced commodities into three component parts … appears in a perverted form on the surface of capitalist production, wage, profit and rent taking on the aspect of ‘independent revenues in relation to one another, and as such related to three very dissimilar production factors, namely labour, capital and land’, from which ‘they seem to arise’ (ibid., pp. 867–8; we shall, however, continue to assume the absence of rent). ‘To have destroyed this false appearance and illusion’ represents ‘the great merit of [classical] political economy’ (ibid., p. 830). Against classical political economy – of which Ricardo is the ‘last great representative’ (Marx, 1873, p. 24) – Marx sets ‘vulgar’ economy: the first of these studied ‘the real relation of production in bourgeois society’, whereas the second ‘deals with appearances only’ (Marx, 1867, p. 85, n.1).

But even Ricardo cannot be completely acquitted, in Marx's opinion, of having taken as the *starting-point* of the argument the *result* of the redistribution of surplus-value. Indeed, it is the natural prices themselves that Ricardo claims are regulated (even if only approximately; but, as will be remembered, it is the nearest approximation to truth’ among those available; see section 6 above) by the quantities of labour expended on the production of commodities. Hence Marx's allegation that Ricardo confuses values and prices of production.

If Ricardo is compelled to presuppose what he should explain (the profit proportional to capital, as it
emerges from the redistribution of surplus-value), this is – according to Marx – because his unsatisfactory treatment of non-wage capital (see section 3 above) blinds him to the distinction between surplus-value and profit:

Ricardo wrongly identifies surplus-value with profit … these are only identical in so far as the total capital consists of variable capital or is laid out directly in wages … Ricardo evidently shares Smith's view that the total value of the annual product resolves itself into revenues. Hence also his confusion of value with cost-price (Marx, 1905–10, vol. II, p. 426; as so often in Theories of Surplus-Value, ‘cost-price’ here stands for ‘price of production').

Here, in Marx's opinion, lies the origin of the analytical difficulties with which Ricardo had to wrestle and which Marx himself claims to have overcome, thanks to his discovery of the redistribution mechanism.

9. On 24 August 1867, a few days after correcting the proofs of the first volume of Capital, Marx wrote to Engels:

The best points in my book are: (1) the double character of labour, according to whether it is expressed in use value or exchange value (all understanding of the facts depends upon this …) (2) the treatment of surplus-value independently of its particular forms as profit, interest, ground rent, etc (Marx and Engels, 1942, pp. 226–7).

The second of these two contributions has been dealt with in sections 7 and 8 above (and something more on the subject will be said in section 11 below), within the limits of the hypothesis that all surplus-value is received in the form of profit. We must now turn to the first contribution – the one on which ‘all understanding of the facts’ is based: the ‘double character of labour’. In the production of commodities the distribution of labour in a society among its various productive activities is not regulated a priori, through some form of agreement or coercion, but only a posteriori, through the exchange of products (Marx, 1867, p. 336). The labour of individuals is therefore not, immediately, the labour of society – as is the case in, say, a peasant family, within which ‘the labour-power of each individual, by its very nature, operates … merely as a definite portion of the whole labour-power of the family’ (Marx, 1867, p. 82; see Marx, 1859, p. 33). On the contrary, we are dealing here with ‘the labour of private individuals or groups of individuals who carry on their work independently of each other’; this labour ‘asserts itself as a part of the labour of society, only by means of the relation which the act of exchange establishes directly between the products, and indirectly, through them, between the producers’ (Marx, 1867, pp. 77–8). It is only when the social division of labour takes this particular form that the products of labour become commodities, or acquire the quality of possessing value.

In the first chapter of Capital (as well as in the first chapter of A Contribution to the Critique of Political Economy) Marx emphasizes how in the eyes of producers commodities count not for their ability to satisfy this or that human want, but rather for their ability to find a purchaser: not for their use-value but for their (exchange-) value. Of these two qualities of commodities, use-value is the one abstracted from
in the exchange, which cancels the difference between the products, in the sense that in the exchange different products are equated, or treated as equal, and reduced to their quality of possessing value. Labour participates in the two-fold character of commodities, as useful things and things possessing value. On the one hand, ‘it must, as a definite useful kind of labour, satisfy a definite social want, and thus hold its place as a part and parcel of the collective labour of all, as a branch of a social division of labour’ (Marx, 1867, p. 78). On the other hand, just as ‘in viewing the coat and linen as values, we abstract from their different use-values, so it is with the labour represented by those values: we disregard the difference between its useful forms, weaving and tailoring’ (ibid., p. 52); which is what producers themselves actually do, production of commodities being production for value – production, therefore, of abstract wealth, indifferent to its material content. What remains is a uniform, undifferentiated labour, which ‘counts only quantitatively’, having been ‘reduced to human labour, pure and simple’ (p. 52), to ‘abstract human labour’ (p. 81). Such is the labour which, embodied in commodities, figures as their value.

‘Whenever, by an exchange’, Marx writes, ‘we equate as values our different products, by that very act, we also equate, as human labour, the different kinds of labour expended upon them. We are not aware of this, nevertheless we do it’ (ibid., pp. 78–9). The reduction of a commodity to its mere quality of possessing value and the reduction of labour to abstract labour are thus in Marx’s conception the outcome of one and the same real process (see Colletti, 1968, sect. 8). And it is only by being reduced to abstract labour and assuming the form of a quality of commodities, their value, that the private labour of the weaver and the private labour of the tailor enter into relation with each other, becoming part of a social division of labour. This is, in Marx's words, ‘the specific manner in which the social character of labour is established’ (Marx, 1859, p. 32) in the production of commodities. ‘But what is the value of a commodity?’, Marx enquires. ‘The objective form of the social labour expended on its production’ (Marx, 1867, p. 501). Or, to put it another way, abstract labour (social only in so far as abstract) represents ‘the substance of value’ (ibid., p. 46).

10. The picture is now complete, and we can attempt to gather together the threads of Marx's position. As we have just seen, the thesis of the reduction of labour to abstract labour is put forward by Marx in close connection with his theory of value. Indeed, the two merge into one, abstract labour being indicated as the substance of value and value as the form that labour must assume in order to acquire a social character. It remains to be added that the conception of abstract labour as the substance of value presupposes the sort of redistribution mechanism described in section 7 above. What constitutes the substance of value cannot, in fact, but constitute the substance of revenues, as the latter stem from the breakdown of the value of a given set of commodities. It follows that the conception of abstract labour as the substance of value necessitates that the whole of this substance be found in the prices of production, having merely been partly diverted away from some commodities and channelled into others (see the enlightening comparison with the ‘conservation of energy’ in Lippi, 1976, pp. 50–52). If this is not the case, then the aforesaid substance is not the ‘substance’ of anything real, and ‘value’ is merely a name for the quantity of labour directly and indirectly expended on the production of a commodity.

11. In the Afterword to the second (German) edition of Capital we read that ‘the method of presentation must differ in form from that of inquiry’ (Marx, 1873, p. 28). We are, now in a position to understand this celebrated (as much as hermetic) warning. If we attend to the ‘method of inquiry’, the theory of the rate of profits and of the prices of production (contained in the manuscripts published posthumously as
labour theory of value: The New Palgrave Dictionary of Economics

the third volume of *Capital*) represents – as stated in the preceding section – a premise for the conception of abstract labour as the substance of value, and the cornerstone of the whole theoretical structure of *Capital*. (From a chronological point of view, it has been remarked that ‘once Marx had attained – at the beginning of 1858 – what he regarded as the correct solution of the problem of how to determine the rate of profit, various elements in his thinking seem to have found an organic unity in the concept of value – the concept of a “substance” to be redistributed’ (Ginzburg, 1985, pp. 105–6); the ‘various elements’ being basically Marx’s analysis of the social division of labour and his theory of income distribution and prices.)

But if, instead, we attend to the ‘method of presentation’, things take on a rather different aspect. Marx calls his own presentation of the argument ‘genetical’, meaning by this that it consists in ‘elaborating how the various forms come into being’ (Marx, 1905–10, vol. III, p. 500), proceeding from the form of value that labour assumes in the act of acquiring a social character, to arrive at surplus-value, the redistribution mechanism and the establishment of a general rate of profits.

The two ‘methods’, or procedures, reflect the two different aims mentioned in section 8 above: the aim (proper to scientific analysis) of tearing away the veil of appearances, and the aim (proper to genetical presentation) of showing how that veil is woven together. The latter aim is not regarded by Marx as less important than the former, to explain how appearances are produced being in his opinion the only sure way of evading their deceptions.

As we have already seen, Ricardo himself is believed by Marx to be partly the victim of such deceptions, even while he contributed so greatly towards dispelling them. In conceiving the labour theory of value as a theory of natural prices, Ricardo ‘omits some essential links and directly seeks to prove the congruity of economic categories with one another’ (Marx, 1905–10, vol. II, p. 165). He does so by taking ‘the rate of profits as something pre-existent which, therefore, even plays a part in the determination of value’ (ibid., p. 434), thus missing the inner connection of forms which is reflected in Marx’s genetical presentation, and according to which ‘the determination of value is the primary factor, antecedent to the rate of profits and to the establishment of production prices’ (ibid., vol. III, p. 377; see Gajano, 1979, ch. 3).

12. If, however, the presentation must proceed from value to the rate of profits and the prices of production, it must assume (at least provisionally) that the foundation of value be independent of what comes after, as a result of the redistribution of surplus-value. Marx thus finds himself in an *impasse*, no such independent foundation being provided by his analysis.

So it comes as no surprise that value is introduced in *Capital* in a rather sketchy way. Marx starts by declaring, as something self-evident, that in two commodities equated in exchange ‘there exists in equal quantities something common to both’ (Marx, 1867, p. 45). He then goes on to enquire wherein this common element consists. It is at this point that we meet the argument according to which exchange involves an abstraction from the use-value of the commodities exchanged (‘the exchange of commodities is evidently an act characterised by a total abstraction from use-value’: (ibid., p. 45; see section 9 above). But, Marx pursues, ‘if then we leave out of consideration the use-value of commodities, they have only one common property left, that of being products of labour’ (ibid., p. 45). Thus he does his best to lead the reader into thinking that the prices of commodities are regulated by the quantity of labour expended on their production (otherwise the common element would not be ‘in equal quantities’). Only later on does Marx put the reader on his guard with sporadic and obscure hints.

(‘Average prices do not directly coincide with the values of commodities, as Adam Smith, Ricardo, and
labour theory of value: The New Palgrave Dictionary of Economics

others believe': ibid., p. 163n.; see ibid., p. 212n., where the reader is referred to vol. III – unpublished – and ibid., p. 290, where Marx mentions the ‘many intermediate terms’ wanted to resolve the ‘apparent contradiction’ between the labour theory of value and the existence of a uniform rate of profits.) ‘Analysis’, writes Marx, ‘is the necessary prerequisite of genetical presentation’ (Marx, 1905–10, vol. III, p. 500). But it is a prerequisite which cannot be openly declared if presentation is to remain genetical. This limitation has given birth to two opposite and equally wrong interpretations. The one holds that Marx's theory of value has no foundation whatsoever, and treats that theory and the theory of prices of production as two mutually incompatible theories of prices (this is the thesis of the ‘contradiction’ between the first and the third volumes of *Capital*, put forward in Böhm-Bawerk, 1896). The other interpretation tries to defend the labour theory of value on the basis of Marx's analysis of the social division of labour, making no appeal to the redistribution mechanism and maintaining, in the last analysis, that labour forms the substance of value because it is through the exchange of commodities that the various labours, performed outside any conscious coordination, enter into relation with one another (this traditional Marxist reply to Böhm-Bawerk's criticism first appears in Hilferding, 1904, and finds its best expression in Colletti, 1968).

Obviously the labour theory of value cannot be defended on the grounds indicated by Hilferding and Colletti (as the latter has acknowledged: see Colletti, 1979). But, just as obviously, Böhm-Bawerk's grounds for dismissing it are not good ones. Actually, the reason why the labour theory of value must be rejected is not that it is devoid of foundation, but rather that what in Marx's view represents its foundation – his theory of the rate of profits and of prices of production – proves untenable in the light of the subsequent work of Tugan-Baranovsky (1905), Bortkiewicz (1907) and others, up to Sraffa (1960).

labour-managed firms

Louis Putterman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Labour-managed firms (LMFs) are enterprises over which suppliers of labour hold full control rights. Theoretical analysis suggests that such firms will behave in a distinctive and sometimes ‘perverse’ manner in response to short-run changes, but richer models can reverse the more problematic results, and the simple model indicates that LMFs behave no differently from capitalist firms in long-run competitive equilibrium. Empirical studies indicate that LMFs, while uncommon in most market economies, can achieve high productive efficiency. The search for an understanding of why LMFs are relatively rare has contributed to both positive and normative economic analysis.

Article

Although the traditional theory of the firm gave little attention to institutional detail, the common assumption about the units that engage in the production and sale of goods and services was that they are owned and controlled by individuals who provide risk-bearing capital and who hire the services of workers as one among several variable inputs. Worker-run cooperatives had existed in small numbers at least since the Industrial Revolution, but the study of such firms using formal analytical tools awaited the added stimuli provided by the challenge of understanding collective farm performance in the Soviet Union and China, and Yugoslavia's experiment with worker-managed market socialism. The models developed in the late 1950s and thereafter were subsequently applied not only to those cases but also to understanding worker-owned firms in industrial market economies, to investigating hypothetical economies consisting exclusively of worker-run firms, and to attempting to explain why worker control
is relatively rare. As studies on the topic multiplied, the term ‘labour-managed firm’ (LMF) came to be used by economists to describe an enterprise that operates under the ultimate control of those who work in it.

Such a definition of an LMF permits considerable variation in other dimensions. To qualify as an LMF, for example, an enterprise's workers must have control in the sense that managers are appointed and can be removed by them or by their representatives. But the degree of direct worker involvement in decision-making can vary, from the more direct democracy of small cooperatives to the representative structures of large Mondragon cooperatives or the now-defunct Yugoslav firms. A frequent assumption is that the exercise of worker control follows ‘one worker one vote’ lines, but the LMF concept has sometimes been extended to firms that include a class of workers lacking control rights. Most importantly, perhaps, the term LMF has been applied both to firms in socialist economies, in which the private ownership of capital is prohibited and the enterprise's capital is the property of ‘society’ or of a collective, and to worker-owned firms in capitalist economies, in which individual workers can hold property rights in their enterprise's assets, for example through ‘partnership deeds’, ‘individual capital accounts’ or shares. The principal example of an LMF with ‘social capital’ was the Yugoslav social enterprise, which arose from the application of new laws and principles to that country's Soviet-style state enterprises. Collective property was the prevailing legal notion applied to the land and equipment of collective farms in the Soviet Union, China, and other Communist states, and has also accounted for a portion of the assets of some Western worker-run firms. The canonical example of ‘partnership deeds’ is provided by worker-owned plywood companies in the United States. The capital account model was adopted by the group of worker-owned enterprises centered in the town of Mondragon in the Basque province of Spain. More hybrid cases with only elements of worker control, such as (a) the partial employee ownership of many American companies, (b) legal, medical, and other professional partnerships, (c) co-determination in Western Europe, and (d) the widespread employee ownership resulting from privatization programmes in many transition economies, also continue to stimulate interest in the economic analysis of firms run by workers.

Although the economic analysis of worker-run firms was stimulated by the cases mentioned, interest in the concept appears to be explained by other factors as well. Normative dissatisfaction with the capitalist employment relationship, in which workers assume a subordinate role in the production process and lack claims on enterprise profits, can be found among leading economists ranging from John Stuart Mill and Leon Walras to James Meade and Jacques Drèze. In his Principles of Political Economy, Mill, who dominated English political-economy in the mid-19th century, wrote

> To work at the bidding and for the profit of another, without any interest in the work – the price of their labour being adjusted by hostile competition, one side demanding as much and the other paying as little as possible – is not, even when wages are high, a satisfactory state to human beings of educated intelligence, who have ceased to think themselves naturally inferior to those whom they serve. (Mill, 1848, pp. 760–1, n. 1)

He predicted the extinction of the capitalist firm (‘There can be little doubt … that the relation of masters and workpeople will be gradually superseded by partnership’, pp. 763–4) and opined that the result ‘would be the nearest approach to social justice, and the most beneficial ordering of industrial affairs for the universal good, which it is possible at present to foresee’ (p. 792). Modern political
The New Palgrave Dictionary of Economics

Theorists such as Carole Pateman (1970) and Robert Dahl (1985) have argued that self-government of the workplace by workers is an implied requirement of the principle of control of government by the governed, and that it would help to deepen democracy in more traditional political spheres. Another source of interest in LMFs is the fact that the theoretical analysis of such firms promises insights into why the large majority of firms in market economies are established and controlled by investors rather than workers (Dow, 2003). Whether that fact is to be attributed to social custom, to the exercise of economic power by the wealthy, to aversion to risk by the poor, or to other factors, seems important for judging policies such as the expansion of codetermination or the use of worker ownership in future privatizations. It also has an important part to play in the ethical evaluation of the economic system as a whole.

The first wave of models of worker-management abstracted from issues of ownership and financing by assuming a fixed charge for capital or land, presumed to be rented by the firm but fixed in quantity in the short run. By contrast, the number of worker-members was taken to be variable, and the firm's main decision problem was to select a level of this input. In the seminal model of Ward (1958) and in subsequent treatments by Domar (1966), Vanek (1970), Meade (1972) and others, the objective was taken to be maximizing revenue per worker net of capital, land, or other charges. The first and most frequently noted finding of such models was that, with the maximand being the (endogenous or firm-specific) net earnings of a variable input, output might not respond normally to changes in the product price. In particular, Ward showed that, if labour is the only variable input, workers share net revenue on an equal basis, and the firm's objective is to maximize the earnings of each worker employed (without concern for workers who might have to be expelled to achieve earnings maximization for those remaining), then an increase in the product price would reduce optimal employment and thus the firm's output level. An industry consisting entirely of worker-run firms would accordingly exhibit a downward- rather than upward-sloping short-run supply curve, so that output would go down, rather than up, in response to increased demand (on the assumption that a short-run equilibrium is even possible). Labour would be misallocated among firms in the short-run equilibrium of a labour-managed economy, since those with high marginal product of labour would have no incentive to accept workers from those with low marginal product. As an added oddity, the firm would seek more workers if the cost of its fixed factor or a lump sum tax rose, and it would reduce its membership if the opposite occurred.

Long-run outcomes are less peculiar. Abnormal returns would attract new capital investments by existing firms and entry of other firms into the industry, giving the long-run supply curve a more conventional shape. In the very long run, with both the number of firms and their utilization of all factors being variables, equilibrium behaviour of labour-managed and conventional firms would be identical (Drèze, 1976). Even short-run perverse supply responses would be rendered unlikely by a variety of factors. For example, Domar (1966) showed that the tendency of hypothetical LMFs to take on additional workers, as output prices fell or as net revenue was reduced by higher charges for fixed factors, could be annulled by incorporating in the model the supply of labour facing a firm. Other factors tending to weaken or reverse the ‘perverse output supply response’ include (a) use of variable inputs additional to labour, (b) flexibility of working hours, (c) reallocation of labour between product lines in multi-product firms, (d) reluctance to vote for the expulsion of incumbent members, perhaps because the voters face similar probabilities of being selected for expulsion, and (e) tradable membership rights.

Empirical research failed to provide evidence for backward supply responses by LMFs. Chinese
collective farms were found to increase their output in response to higher government-set prices. Yugoslav firms were sometimes argued to be reluctant to take on new workers, in line with Ward model predictions, but no evidence has been adduced that they had insufficient flexibility over work hours or an inability to allocate workers among tasks and product lines so as to respond positively to better market conditions for a given product. In what is probably the most rigorous study of the supply response of worker-owned firms, that on US plywood cooperatives by Craig and Pencavel (1992), the authors concluded that the firms’ output was significantly less responsive to product price changes than that of conventionally owned competitors, but they rejected backward bending supply at high levels of significance.

Property rights and investment incentives were another major concern of the LMF literature beginning in the late 1960s. In Yugoslavia, workers were empowered to elect councils which selected and had governing authority over their companies’ managers, but the capital stock of the company was legally owned ‘by society’, with workers having rights to current revenue but obligations to maintain and ideally to add to that stock. Furubotn and Pejovich (1970) demonstrated theoretically that with this rights structure self-interested workers would privately value new investments in their company only in so far as they expected to remain employed there and have their pay enhanced by the resulting higher productivity. For capital goods having a useful life exceeding the expected employment horizon of a worker, the privately appropriable rate of return must be adjusted downward to take into account truncation of the future earnings stream from the standpoint of the worker. Furubotn and Pejovich argued that Yugoslavia avoided an otherwise predicted dearth of investment only because government and Communist authorities continued to have considerable leverage over managers, and because the government encouraged companies to finance their investments with low-cost loans from the state banks, although this had the effect of pumping money into the economy and thereby fuelling inflation (Pejovich, 1969).

Most economists studying the issue agreed that firms with social ownership of capital would suffer from a horizon problem of the sort that Furubotn and Pejovich identified. More generally, Vanek (1977) argued that failure to consider the scarcity price of capital can lead to inappropriate choice of technology, a factor that he viewed as being of sufficient importance to explain the historical failure of experiments with workers’ management. He noted, however, that this need not be a general feature of LMFs. The truncation of the revenue stream that is considered when evaluating investments is a result not of worker control but of assuming that workers are deprived of any and all rights to their investments’ returns after separation from their firm. The problem could thus be ameliorated or eliminated entirely by several methods, for instance the calculation of a severance payment based on the capitalized value of each worker's past contributions to their company's capital stock. Another possibility is for the worker to sell his position as a partner or member of the firm in a market. In a perfectly functioning membership market, the estimated remaining productivity or marketable value of physical and other assets created during the incumbent worker's career with the firm would be incorporated in the sale price of the membership right. Sertel (1982), Dow (1986), and Fehr (1993) demonstrated the theoretical ability of a membership market to eliminate the inefficiencies of worker control in other dimensions as well. Pencavel (2001) and Dow (2003), however, point out the rarity of such markets and evidence of their imperfect functioning, suggesting this as another place to search for possible explanations of why LMFs are not more common.
A much-discussed dimension of worker control and ownership is that of work incentives. Vanek argued that, as a means of motivating workers to give their full energies to their jobs, sharing profits is likely to be far superior to paying a fixed wage, since the worker on fixed pay receives the contractual wage regardless of how intensively she works and regardless of how the firm fares. At a theoretical level, such a claim can be disputed. On the one hand, the short-run insulation of the worker from the effects of her varying quantity or quality of effort need not imply the total absence of a connection, since the wage can be adjusted over time, including by performance-contingent promotions. Efficiency wage models also demonstrate the potential to elicit effort through the threat of firing for sub-par performance. A company's very survival may depend on the effort it obtains from its workforce. On the other hand, if workers share equally or according to predetermined proportions in the same pool of profit, then the incentive provided by profit-sharing suffers from the profit's dilution among many workers, and the prediction of a static or finitely repeated model of effort choice is that rational workers will choose to free ride.

Despite this inconclusiveness of theory, empirical studies have given Vanek's intuition about profit-sharing and motivation more support than refutation. Profit-sharing has often appeared to boost work incentives, in part because it changes the dynamics of worker–worker interactions – each worker now being far more inclined to show disapproval at a co-worker's slackness. The prevalence of mutual monitoring in worker-run firms is associated with concrete cost-saving from using fewer hired supervisors. Craig and Pencavel (1995) found total factor productivity to be between 6 and 14 per cent higher in worker-owned than in conventional plywood firms. Weitzman and Kruse (1990) found a positive effect of profit-sharing on productivity in a meta-analysis of studies of both worker-owned and conventional firms linking pay to profit. A similar finding is recorded by Doucouliagos (1995) in a meta-analysis of studies focusing on the effect of worker participation in decision-making.

If worker-run firms don't actually suffer from dysfunctional responses to changes in their economic environments, if they aren't dissuaded from investing by horizon problems, and if they motivate work effort at least as effectively as do conventional firms, why aren't they as common as Mill predicted they would one day be? Among the answers that have been proposed is that control by investors is superior to control by workers because investors’ representatives can reach decisions more easily, the idea being that investors share a uniform objective of maximizing the firm's market value, whereas workers have multiple interests (job security, pleasant working conditions, higher earnings) upon which each may place a different weight, thus defying easy consensus (Hansmann, 1990). Another answer, suggested by Kremer (1997), is that less productive workers tend to use the firm's internal decision process to obtain a flatter wage dispersion, which weakens incentives for the more productive workers to stay with the firm. Still another possibility, formalized by Ben-Ner (1984) and Miyazaki (1984) based on an earlier suggestion by Mikhail Tugan-Baranovsky (1921), is that successful LMFs have an incentive to replace retiring members with non-member hired workers, concentrating the profits in the hands of a smaller member group which, in the limit, collapses to contain only one member, a proprietor. Studies of the life cycle of cooperatives, from creation to dissolution, find few cases following precisely this scenario, but situations in which workers sell their firm to private owners and become their employees are reported, for example, in the U.S. plywood sector.

Possibly the most promising place to search for explanations is in the area of financing. Because inputs are committed before output value is certain, and because time passes between the utilization of input
labour-managed firms: The New Palgrave Dictionary of Economics

services and the realization of revenue from product sales, firms typically need the services of both risk-bearers and financiers. There is no technical reason why all input suppliers, including workers, could not share in providing these services by accepting payments in the future and by working for shares of an uncertain total revenue, rather than for fixed wages. What is observed, however, is consistent with the view that the supply of risk-bearing and financing services follows comparative advantage: specialists with greater willingness to bear risk and/or ability to pay for inputs up front become the suppliers of equity and debt finance, while workers are paid within short intervals in amounts promised in advance and not contingent on the firm's results. The fact that workers typically have less wealth and thus both less ability to supply funds or to finance their consumption from savings, as well as less willingness to bear risk, is likely to play an important part in explaining this (Putterman, 1993). The thinness of potential markets for worker partnership shares and thus the absence or imperfection of the partnership market may add to the burden that financing their own firm imposes on workers (Dow, 2003).

Although workers do accumulate substantial assets in pension funds in the United States, risk aversion (and pension fund regulations) may deter them from investing too much of it in their own company or in any other single project. In a world in which wealth was quite equally distributed and was held mainly by workers, workers as principal owners of their own firms might still remain rare because workers might prefer to hold diversified portfolios containing shares of many firms other than their own. If control (by managers) and ownership (by shareholders) are in any case separated in modern corporations, why not worker control with (outside) shareholder ownership? The fact that the de-linking of ownership and control remains incomplete even in those firms where ownership is most diffuse (in other words, the fact that shareholders retain ultimate control rights in publicly traded corporations) suggests an answer. Presumably ownership and control are almost universally linked in a market economy because the owner, the return on whose investment is subject to so many uncertainties, is unwilling to cede control over key decisions affecting that return. Until worker desires for control of their enterprises are strong enough that they are willing to bear considerable financial risk, or until market outcomes are altered by government interventions facilitating the de-linking of control rights from financial risk-bearing, LMFs appear likely to remain the exception to the rule in market economies.

labour's share of income

Douglas Gollin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economists have long studied labour's share of national income as a crude indicator of income distribution. More recently, labour's share has also been seen as offering insights into the shape of the aggregate production function. This has made labour's share a parameter of interest for macroeconomics, growth economics, and international economics, among other fields. Recent studies support the long-standing observation that labour's share of national income is relatively constant over time and across countries. Measurement of labour income, however, can be difficult in economies where many people are self-employed or work in family enterprises.

Keywords

aggregation; balanced growth; Cobb–Douglas functions; constant-returns production function; entrepreneurial income; factor shares; labour's share of income; national income accounting

Article

At least since the time of Adam Smith, economists have been interested in the shares of production accruing to the owners of different factors. In the era before formalized national income and product accounts, factor shares were observed primarily at the firm or industry level. But Smith himself recognized that national product could similarly be divided into the income received by owners of land, labour and capital (the last of which he termed ‘stock’). Early in Book I of The Wealth of Nations, Smith (1776, p. 155) notes that

the exchangeable value … of all the commodities which compose the whole annual produce of the labour of every country, taken complexly, must resolve itself into … three parts and be parcelled out among different inhabitants of the country, either as the wages of their labour, the profits of their stock, or the rent of their land … Wages, profit, and
labour's share of income: The New Palgrave Dictionary of Economics

rent, are the three original sources of all revenue as well as of all exchangeable value.

Smith and other early economists viewed the distribution of income among factors of production as intimately related to the level of wages and the degree of income inequality within a country. This was probably a reasonable assumption, given that, outside of agriculture and certain types of self-employment, most individuals probably subsisted entirely on wage income.

Factor shares were, in fact, one of the few available sources of data on the size distribution of income – a subject that was viewed as crucial for policymaking, but about which little was known. As late as 1912, a prominent US labour economist wrote (Streightoff, 1912, p. 155), ‘Knowledge of the distribution of incomes is vital to sane legislative direction of progress. In a form definite enough for practical use, this knowledge does not exist. No time should be wasted in obtaining this knowledge.’

Labour's share of national income was seen as a particularly sensitive issue – intimately related to the supposed struggle of labour against capital. Simon Kuznets (1933, p. 30) referred to ‘[t]he significant political and social conflicts that center about the relative share of these productive factors’. Because of the importance of the topic, and because factor shares could be estimated reasonably well from micro data, a considerable literature emerged to document cross-section and time series observations on factor shares. In fact, the literature on factor shares eventually served as one of the foundations for the emergence of national income and product accounts.

From the beginning, the measurement of factor shares has been complicated by the difficulty of disentangling individual incomes into their functional components. Certain categories of income are easily assigned to land, labour, or capital. For example, wages and salaries are generally classifiable as labour income – although for some high-skill workers (such as hedge fund managers, star athletes), they may also embody some rents. Dividends and interest must be forms of capital income. Land rents are easily classified. But Kuznets (1933) pointed out that entrepreneurial income – which was about one fourth of national income in the 1920s – represented a mix of wages, salaries, interest, rent, and profits. As national income accounting evolved over the succeeding decades, there were few improvements to the categorization of income according to factors of production. Irving Kravis (1962, p. 122) noted that ‘the theory of distribution remains in a parlous state’, largely because ‘the components of income for which we have data has not been determined by the requirements of the economists but by the legal and institutional arrangements of our society’.

Nevertheless, by the 1950s a striking empirical regularity had begun to emerge. Labour's share of national income in the United States appeared to have remained roughly constant over a long period of time. Modest increases in the share of wages and salaries in national income appeared to have come at the expense of declines in entrepreneurial income – consistent with a structural shift away from self-employment and towards wage work. The regularity was sufficiently pronounced that Charles Cobb and Paul Douglas, writing in 1928, suggested that a simple constant-returns production function in the now familiar form $Y = AK^{1/4}L^{3/4}$ would provide an accurate representation of the US time series for aggregate output as a function of aggregate capital stock and labour. They considered a value for labour's share as low as two-thirds to be plausible.

As national income accounting became more systematic, evidence on factor shares accumulated over succeeding decades. John Maynard Keynes, writing in 1939 (p. 48), referred to the ‘stability of the proportion of the national dividend accruing to labour, irrespective apparently of the level of output as a
labour’s share of income: The New Palgrave Dictionary of Economics

whole and of the phase of the trade cycle’. He went on to refer to this (p. 48) as ‘one of the most surprising, yet best-established facts in the whole range of economic statistics, both for Great Britain and for the United States’.

D. Gale Johnson (1954) constructed and analysed data for the US economy going back over a century, to 1850, and concluded (p. 175) that there had been no ‘significant secular change’ in labour’s share of income over that period. Robert Solow’s paper (1957) on the sources of growth in the US economy noted that the data for the US economy seemed consistent with a Cobb–Douglas representation for the aggregate production function, with a capital share of 0.35 (and thus, implicitly, a labour share of 0.65). (However, Solow, 1958, professed scepticism over the proposition that factor shares were actually constant, suggesting instead that variation within sectors was balanced out at the aggregate level.) Nicholas Kaldor (1961) characterized the phenomenon as one of the stylized facts of modern economic growth.

This apparent consensus soon began to unravel, however. A major challenge to the hypothesis of constant factor shares appeared in comparisons of factor shares across countries. Kuznets, in an influential 1959 paper, further argued that the cross-country evidence did not support the view that factor shares were constant across countries or over time. Kuznets argued that data for other countries – and in particular for poor countries – revealed very different levels for labour's share in other countries. In particular, Kuznets suggested that labour's share of income was systematically lower in poor countries than in rich countries, while the share of unincorporated enterprises in national income was higher in poor countries than in rich countries. Kuznets concluded that the concept of a labour share lacked useful meaning – particularly as a proxy for discussions of the size distribution of income. His scepticism over constant factor shares was echoed by Solow (1958) and by Kravis (1962), among others.

To a large degree, scholarly interest in the labour share waned in succeeding years, although quantitative studies in both international trade and growth continued to rely on Cobb–Douglas aggregate production functions. In the trade literature, it was commonplace to assume that rich countries had a relatively high labour share, while poor countries had lower shares. Macro and growth studies of advanced economies typically assumed a Cobb–Douglas production function with a labour share of about two-thirds, often based on the employee compensation share of GNP for the United States, but this parametrization was seen as problematic for models that were intended to characterize both poor countries and rich ones. This apparent discrepancy between cross-country and time series observations on labour's share was largely unaddressed in the literature until Gollin (2002) revisited the question. Drawing on the earlier work of Kuznets and others, he noted the potential significance of self-employment in skewing ‘naive’ calculations of factor shares. Gollin argued that poor countries typically have far higher levels of self-employment than do rich countries; as a result, cross-country comparisons of the employee compensation share (or wage share) will tend to yield large differences between rich and poor countries. Gollin showed that, after adjusting labour's share to account for differences in self-employment rates, no systematic patterns remained in the cross-country data between a country's income and its imputed labour share. Gollin reported labour shares in most countries, adjusted for self-employment, between 0.6 and 0.8. Similar results were obtained by Ben Bernanke and Refet Gürkaynak (2002), who used a different approach to adjust for the fraction of output produced by unincorporated enterprises. Recent and preliminary work by Rodrigo García-Verdú (2005) for Mexico found that labour's share falls into this range when estimated from household survey data, rather than from national income accounts.
might suggest. However, Daniel Ortega and Francisco Rodríguez (2006) present evidence from industrial census data that labour shares are lower in poor countries than in rich countries. And Samuel Bentolila and Gilles Saint-Paul (2003) show that labour's share within OECD countries is not constant, but rather moves in parallel with changes in the capital–output ratio.

Econometric studies of aggregate production functions, such as those by John Duffy and Chris Papageorgiou (2000) and Pol Antrás (2004), often reject the Cobb–Douglas specification of the aggregate production function. This suggests that, if factor shares are indeed (approximately) constant, there must be a different underlying mechanism. At the simplest level, any constant returns production function with labour-augmenting technical progress can give rise to constant factor shares if the rate of return on capital is constant over time – as, for example, on a balanced growth path. To see this, consider a simple Solow model with the constant returns aggregate production function \( \gamma = F(K, \theta L) \). The productivity parameter \( \theta \) grows at a constant rate \( g \), and there is an exogenous savings rate, \( s \). This economy will converge to a balanced growth path; assuming no population growth, the condition for balanced growth is given by

\[
k^* = \frac{sf'(k^*)}{\delta + g},
\]

where \( \delta \) is the depreciation rate and

\[
k \equiv \frac{K}{\theta L}.
\]

But the balanced growth path implies that the capital share is

\[
\frac{rk^*}{f(k^*)} = \frac{sr}{\delta + g},
\]

which will necessarily be constant because the rate of return is constant along the balanced growth path. An alternative way to generate constant factor shares is through aggregation. Charles I. Jones (2005) reproduces and generalizes a result of Houthakker (1955) in which an aggregate Cobb–Douglas technology can be derived from firm-level or industry-level Leontief techniques. Jones shows that the same intuition can be applied more generally to a world in which the underlying production technologies have almost any form, and the ‘aggregation’ can simply occur across ideas or techniques within a firm.
Jones's result is consistent with factor shares that are constant, but it also allows for movement in the factor shares and for differences across countries. In general, it appears to offer a useful theoretical framework for reconciling the different features of the data.

How to cite this article

A Laffer curve is a hump-shaped curve showing tax revenue as a function of the tax rate. Revenue initially increases with the tax rate but then can decrease if taxpayers reduce market labour supply and investments, switch compensation into non-taxable forms, and engage in tax evasion. The revenue-maximizing tax rate can be calculated from an estimate of the elasticity of taxable income with respect to the after-tax share. Some studies find this elasticity to be near zero, and others find it to exceed 1. The mid-range for this elasticity is around 0.4, with a revenue peak around 70 per cent.

Article

On a napkin in a Washington restaurant in 1974, Arthur Laffer famously drew his hump-shaped curve showing tax revenue as a function of the tax rate (see Figure 1). Revenue is zero both when the tax rate is zero and when the tax rate is 100 per cent or more. In between must be some $r^*$ that maximizes revenue. The point is that taxes discourage supply of labour, especially by secondary workers in the family who have elastic behaviour, and they discourage supply of capital over time. Thus, proponents became known as ‘supply siders’. So far, these points were well accepted, as economists are quite familiar with the idea of supply as well as demand. Even as far back as 1776, Adam Smith understood that ‘High taxes, sometimes by diminishing the consumption of the taxed commodities, and sometimes by encouraging smuggling, frequently afford a smaller revenue to government than what might be drawn from more moderate taxes’ (Smith, 1776, V, II).
The more controversial claim was that the US tax rate was greater than $t^*$, on the ‘prohibitive range’ where no rational government would knowingly operate, meaning that a reduction in tax would actually increase government revenue.

Initial research focused on static models of labour supply. Stuart (1981) builds a simple analytical model with a taxed sector and an untaxed sector, and he chooses parameters to represent Sweden. The untaxed sector includes illicit tax evasion as well as leisure and home production such as painting your own home, growing your own vegetables, cooking your own meals, and cleaning your own house. He finds a peak at 70 per cent, which is fairly high, but then he also finds that Sweden has an overall effective marginal tax rate of 80 per cent! Then Fullerston (1982) describes two models. First, in a simple partial equilibrium model where $\eta$ is the labour demand elasticity and $\epsilon$ is the labour supply elasticity, it is easy to show that $t^* = (\eta - \epsilon) / [\eta(1 + \epsilon)]$. If the labour demand curve is flat ($\eta = -\infty$), to focus on supply, then $t^* = 1 / (1 + \epsilon)$. Thus, higher $\epsilon$ implies lower $t^*$. The second model is a multi-sector computable general equilibrium model of the United States, but one that still requires an overall labour supply elasticity ($\epsilon$). Based on estimates that are zero or negative for men and positive for women, the choice of $\epsilon = 0.15$ in this model yields $t^* = 79$ per cent.

This research faces a number of problems. First, we do not really know the labour supply elasticity, and heterogeneity means we have no such thing as ‘the’ elasticity anyway. Second, we do not know the current tax rate either, since actual tax systems are complicated combinations of income, payroll, and sales taxes. For example, the payroll tax does not apply for workers whose tax payments are offset at the margin by additional expected social security benefits, and it also does not apply for those above the cap. Third, the income tax is progressive, which means different rates for different individuals. All this heterogeneity means no such thing as ‘the’ tax rate.

Fourth, even if we ignore heterogeneity, a progressive system means that the marginal tax rate (which affects incentives) exceeds the average tax rate (which affects revenue). Then the question of how a change in marginal tax rate affects revenue is not well defined, because one must also specify how the reform affects average rates. Even if an increase in all marginal rates raised revenue, for example, an increase in only the top marginal rate may not. Also, if a change in progressivity transfers money between groups, then the outcome depends on different income elasticities of labour supply. A reduction of the top marginal tax rate may seem to have the best potential for a Laffer effect if both (a) the rate is high and (b) those workers are elastic. But if part of the increased revenue comes from redistribution between taxpayers with different elasticities, then it is not a true Laffer effect.

Fifth, the Laffer curve itself is not well defined, with revenue on the vertical axis, because it matters how that revenue is spent. Interestingly, Malcomson (1986) shows that the Laffer curve may continue to slope upwards, all the way to a tax rate of 100 per cent, which would mean no prohibitive range at all! Yet Gahvari (1989) shows how this result depends on the assumption that revenue is used to provide a public good that is separable in utility. Then the tax hike has an income effect that increases work effort, and revenue may continue to rise. If the increased revenue is used for lump-sum transfers, however, then this cash tends to offset the income effect, leaving only the substitution effect that is so emphasized by the supply siders in the first place.

So far, these models are static models of labour supply. Agell and Persson (2001) build a one-sector endogenous growth model with capital as the only input, and no labour at all, yet they obtain a strikingly similar result. They allow for separable government spending with capital, and government can reduce a tax rate and still increase at least one future year's revenue. They then show that a world with no transfers can never have a dynamic Laffer effect. The second model they obtain a strikingly similar result. They allow for separable government spending with capital, and government can reduce a tax rate and still increase at least one future year's revenue. They then show that a world with no transfers can never have a dynamic Laffer effect. The second model they obtain a similar result. They allow for separable government spending with capital, and government can reduce a tax rate and still increase at least one future year's revenue. They then show that a world with no transfers can never have a dynamic Laffer effect.

The initial emphasis of the supply siders themselves was on supply of labour and capital, since these responses to a tax cut can increase income, growth, the tax base, and government revenue. Indeed, estimates of the labour supply elasticity mentioned above are estimates of the hours' elasticity, the effect of the tax cut on hours worked. Yet what matters for tax revenue is the effect of the tax cut on ‘taxable income’. Feldstein (1995) points out that a ‘change in individuals’ marginal income tax rates can induce them to alter their taxable base and may yield a dynamic Laffer effect.

The research takes a natural experiment approach that looks at years before and after a change in the income tax rate schedule, while comparing the top-bracket income group to the next-bracket income group. On the assumption that all other time trends affect the two groups similarly, then their $\epsilon$ can be calculated by taking the difference between the two groups’ change in reported taxable incomes compared with the difference between their changes in after-tax shares. Lindsey (1987) begins this literature by using cross-section data from the early 1980s for various income groups. The Economic Recovery Tax Act of 1981 reduced the top rate most, and the top bracket’s reported taxable income increased the most. The implied elasticity is around 1.5, so the implied revenue-maximizing overall tax rate is around $t^* = 1 / (1 + \epsilon) = 40$ per cent. This result stands in stark contrast to estimates mentioned above where $t^*$ was 70–80 per cent.

This type of research also faces a number of problems. First, income inequality was trending upwards during these years, which might mean rising incomes at the top, relative to other groups, irrespective of the tax change. Second, random shocks to income mean that the top bracket may not contain the same individuals across years. Feldstein (1995) deals with this
problem by use of panel data, tracking the same individuals before and after the top bracket rate cut of the Tax Reform Act of 1986. He also finds taxable income elasticities in excess of 1.0 (and sometimes 2.0 or 3.0).

Third, any given tax reform usually involves changes in the definition of taxable income, and not just changes in rates. Thus, these studies try to adjust their measure of income to use the same definition across years. Fourth, any change in the top personal income tax rate relative to the corporate tax rate might induce shifting: a change in personal taxable income that is offset by an opposite change in corporate taxable income. Fifth, the increase in taxable income in a single year after the tax change may be temporary rather than permanent.

Sixth, the first few papers in this literature looked only at tax rate cuts in the 1980s, where other periods may have tax rate increases. Finally, each tax rate reform may involve a different set of income tax rules that determine the ease of tax avoidance. In other words, there is no such thing as ‘the’ taxable income elasticity.

To deal with several of these problems, Goolsbee (1999) applies the natural experiment approach to six different tax reforms from 1920 to 1975, including both tax rate cuts and increases, and including periods with different trends in income inequality. He finds that the 1980s are atypical: ‘the largest regression estimates of the taxable income elasticity from all of the previous historical periods are lower than the smallest estimates in the literature based on the 1980s’ (1999, p. 43). Other studies find ε around zero, as reviewed by Gruber and Saez (2002). They use a 1979–90 panel of tax returns to analyse all state and federal tax reforms during the 1980s, and they ‘find that the overall elasticity of taxable income is 0.4, well below the original estimates of Feldstein but roughly at the mid-point of the subsequent literature’ (2002, p. 3).

Finally, Kopczuk (2005) adds a measure of the tax base, relative to total income for each individual, and finds that it affects the estimate of the taxable income elasticity. In other words, that elasticity is not just a taxpayer's behavioural parameter, but depends on the tax code. The rich have a narrower tax base, and thus a higher elasticity. This also means that reforms to broaden the base can raise τ* itself (and reduce excess burden).

In summary, if you choose to oversimplify the world by using a single elasticity and a single tax rate, and if you ignore other problems above with the whole concept of the Laffer curve, then the recent mid-point estimate of ε = 0.4 implies that tax revenue is maximized at \( t^* = 1 / (1 + ε) = 0.71 \) per cent.

Article
Jean-Jacques Laffont was born in 1947 and died in 2004 in Toulouse. He was one of the great economists of the last quarter of the 20th century. He made breakthroughs in many fields within both theory and econometrics, which made him perhaps the last encyclopedic mind in the economics profession at a time when the rapid growth of knowledge pushes most researchers into intense specialization. His creative and prolific contributions brought him widespread respect and recognition, from presidencies of learned societies (Econometric Society, European Economic Association) to numerous prizes (including the Yrö-Jahnsson prize), honorary memberships in foreign learned societies, honorary degrees from several universities and invitations to give numerous prestigious lectures. Besides his academic contributions – the topic of this contribution – Jean-Jacques Laffont will also be long
remembered for his selfless contributions to institution building in Europe and in particular Toulouse, where his warmth, devotion and energy allowed him, starting nearly from scratch, to create an enthusiastic and congenial research environment. In Africa, Asia and Latin America also, he encouraged young economists to work with him on frontier economics and helped build research centres.

Public goods

After completing his Ph.D. at Harvard University in 1974, Jean-Jacques Laffont embarked on a celebrated research agenda on public goods, in collaboration with Jerry Green (culminating in their 1979 book) and later with Eric Maskin. A collective decision-making problem with $n$ economic agents ($i = 1, \ldots, n$) who have quasi-linear preferences of the form:

$$u_i = v_i(a, \theta_i) + t_i$$

consists in selecting a policy $a$ and transfers $t_i$ for each configuration of taste parameters $\theta = (\theta_1, \ldots, \theta_n)$. An efficient policy $a^* (\theta)$ solves

$$\max_{\{a\}} \sum_{i=1}^{n} v_i(a, \theta_i).$$

A central issue is how to implement this efficient action through appropriate transfers when agents privately know their own taste parameters. Clarke (1971), Groves (1973) and Vickrey (1961) (CGV) had defined ‘mechanisms’, in which agents announce ‘types’ $\hat{\theta}_i$, the collective decision is $a^* (\hat{\theta})$ and agent $i$ receives a transfer of the form

$$t_i(\hat{\theta}) = \sum_{j \neq i} v_j(a^* (\hat{\theta}), \hat{\theta}_j).$$

They had shown that such schemes would induce each agent to truthfully reveal her preferences $\hat{\theta}_i = \theta_i$, as she internalizes the consequences of her choices on the welfare of others. Green and Laffont (1977) showed that these mechanisms were, up to the addition of a function $t_i(\hat{\theta}_{-i})$ which is independent of the announcement of the others, the only schemes in which truthful revelation is a dominant strategy.
Laffont and Maskin (1980), pioneering the ‘differentiable approach’ to mechanism design, then showed
that the transfers \( t_i \) were but constants of integration when the \( v_i \) are differentiable in \( a \) and \( \theta_i \).
A consequence of Green and Laffont's characterization was that dominant strategy public good schemes
are inconsistent with budget balance (\( \sum_i t_i = 0 \)). This negative result shifted the profession’s attention to
the weaker requirement of Bayesian implementation, in which truth telling is an agent's best response to
the other agents’ truth telling. Laffont and Maskin's (1979) pioneering work showed that inefficiency
necessarily resulted from the stricter requirement that the budget be balanced for each configuration of
preferences; their paper led the way to the equally pioneering paper of Myerson and Satterthwaite (1983)
stating the generic inefficiency of bargaining processes under asymmetric information. These two papers
thereby identified one important limitation of the Coase theorem.

Contract theory

More generally, during the decade following his Ph.D. Laffont was involved in many of the
developments of contract theory, from adverse selection to moral hazard, from single-agent partial-
equilibrium to general equilibrium settings. Examples of this work include the definitive treatment of
adverse selection with Guesnerie (1984), the first model of occupational choice in which Kihlstrom and
Laffont (1979) built a theory of entrepreneurs based on heterogeneity in risk aversion, and the prescient
piece with Green (1986) on limited scopes for misreporting (the report \( \hat{\theta}_i \) is restricted to belong to a
subset of types that depends on the true \( \theta_i \)), in which they showed how to amend the revelation
principle and derived some implications for the magnitude of distortions brought about by private
information.

Regulation

A common application of incentive theory is to the regulation of natural monopolies. The first
experiments with price caps in the mid-1980s and later with deregulation raised questions about what
could be expected from such reforms and about their potential pitfalls. Starting with the 1986 paper on
the power of incentive schemes and up to their 1993 book, Laffont and Tirole focused on these issues,
modelling the objective of the regulated firm as (variants of)

\[
 u = t - C(\theta, e, q) - \psi(e),
\]

where \( t \) is the firm's budget, \( C \) its monetary cost, \( \psi(e) \) an increasing and convex non-monetary function
of the effort \( e \), \( \theta \) a technology parameter unknown to the regulator and \( q \) the vector of outputs. While
costs and outputs are observable, the firm can transform naturally low costs into shirking (or private
benefits). For any abstract regulatory mechanism \( \{q(\hat{\theta}), t(\hat{\theta})\} \), expressing, as a function of productivity,
the effort needed to reach a given cost level for given outputs and applying the envelope theorem, the
regulated firm’s rent’s sensitivity to the productivity parameter is given by

\[ \frac{\delta u}{\delta \theta} = \psi'(e) \left| \frac{\partial e}{\partial \theta} \right| . \]

where \( \delta e/\delta \theta \) measures the firm’s ability to transform productivity gains into private benefits (for example, for a single output \( q \) and \( C(\theta, e, q) = (C_0 - \theta - e)q, |\delta e/\delta \theta| = 1 \)). This condition provides the intuition for the incentive-rent extraction trade-off: high-powered incentives schemes – that is, schemes for which the firm bears a high share of its cost (inducing a high effort and therefore a high \( \psi'(e) \)) – necessarily leave large rents (large \( u(\theta) \) s) on the table (this is the reason why price caps are often subject to political pressure for renegotiation). The 1986 paper provided sufficient conditions for a menu of linear contracts to be optimal.

Subsequent work focused on how the power of the incentive scheme is affected by concerns for quality, auctioning of incentive contracts, dynamics (the ratchet effect), and regulatory capture. Laffont and Tirole argued that a key enabler of political capture of the regulatory process is the asymmetry of information with the political principal (perhaps Congress, and certainly the citizens), and that the regulatory response to the threat of capture was low-powered incentives, as these reduce rents and therefore make the concerted manipulation of information by the firm and its regulator less attractive to them.

Later, Laffont and Tirole derived theoretical principles for the design of access prices, a key ingredient of the liberalization policy, in the case of one-way access to a bottleneck such as a local loop, an electricity grid or a railroad network (1994) and, in collaboration with Rey (1998a; 1998b), two-way access, that is, access to mutual termination bottlenecks present in telecommunications or the internet. Jean-Jacques Laffont was adamant about the ability of economic theory to help guide economic development, provided that the theory is properly adapted to reflect the specificities of the developing world. In his posthumous (2005) book, he did just that in the context of regulation. Characterizing less developed countries as countries with easy side transfers within families, ethnic groups and social networks, a lack of a constitutional control of government, a weak rule of law, a high cost of public funds, politically dependent regulators, and weak accounting structures, he systematically drew the implications for the design of regulation, from the power of incentive schemes to universal service obligations and a positive theory of privatization.

More contract theory

Convinced that collusion was a key determinant of economic outcomes and institutions, Jean-Jacques Laffont engaged in a thoughtful and seminal line of research on the methodology and implications of models of collusion, in particular in collaboration with David Martimort. Their 1997 paper developed a general approach for the analysis of collusion among \( n \) agents against a principal; an upper bound on the potential damage of collusive activities is obtained by introducing a fictitious coordinator (or cartel ringmaster in an auction) who (a) privately elicits the \( n \) agents’ types \( (\theta_1, \ldots, \theta_n) \), (b) dictates the
agents’ behaviours in the game designed by the principal, and (c) breaks even. This ‘side mechanism’ must be incentive compatible as well as individually rational (the agents must be willing to collude). In their 2000 paper, Laffont and Martimort point at the dual impact of the ‘commonness’ of information among agents. A fundamental insight due to Maskin (1999) is that information held by multiple agents can often be elicited at very low cost by having economic agents compete, challenge each other’s reports, exercise options, and so on. Maskin’s insight has wide-ranging consequences for the use of the informational content of financial and labour markets, auctions, options and other commonly used elicitation mechanisms for the design of contracts and organizations. Laffont and Martimort argue that Maskin’s insight is most potent when the schemes have integrity, that is, they are not vulnerable to collusion among agents; for it is precisely when agents have the same information that it is easy for them to collude. Put differently, informational asymmetries among agents hinder collusion. Faure-Grimaud, Laffont and Martimort (2003) show that delegation is an optimal response to collusion.

On the more applied aspects of side-contracting, Laffont and Martimort (1999) showed that the separation of regulators may make capture more difficult. Laffont and Meleu (1997) provided one of the first endogenizations of side transfers, and showed that reciprocal supervision provides an undesirable conduit for collusion.

Econometrics

Quite remarkably, Laffont also made key contributions to theoretical and applied econometrics. As a Harvard student, he collaborated with Jorgenson to produce one of the first methods for estimating nonlinear simultaneous equations, in particular extending and studying the efficiency of minimum distance and instrumental variable estimators, paving the way for Hansen and Hansen and Singleton’s 1982 pioneering contributions. Gouriéroux, Laffont and Monfort (1980) is another important illustration of Laffont’s contributions to nonlinear econometrics, this time motivated by the identification of simultaneous equation models with latent variables, and in particular disequilibrium macroeconomic models.

Later, Laffont was one of the pioneers of the new empirical industrial economics. He firmly believed in the importance of theory for imposing structural constraints in econometric estimation, and in the continuous back-and-forth interaction between industrial organization theory and empirics. His first research along these lines (with Gasmi and Vuong, 1992) is on the study of tacit collusion in price and advertising in the Coca–Pepsi duopoly. He then found in auctions and their clear extensive form a most favorable ground for structural econometrics in IO. Positing Bayesian equilibrium strategies and adding parametric restrictions allows the researcher to identify the underlying distribution of types and thus the structure of the model. For example, Laffont, Ossard and Vuong (1995) develop a simulated nonlinear least-squares method to estimate auctions with independent private values for a range of first- and second-bid mechanisms and apply it to eggplant auctions in the south-west of France.

Last, Jean-Jacques Laffont’s was also interested in the engineering cost models (with Gasmi et al., 2002) as he viewed these as enabling a better regulation of, say, universal service obligations or access prices.

Lagrange multipliers

S.N. Afriat
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Lagrange's 'method of undetermined multipliers' applies to a function of several variables subject to constraints, for which a maximum is required. Lagrange's procedure avoids the arbitrary distinction between independent and dependent variables. The method involves further variables, the 'multipliers' associated with the constraints, which have importance in application to economic problems. Beside the value obtainable from a given resource, one might also wish to know the 'marginal value' obtainable when a unit of it is added. The Lagrangian method is therefore a natural tool of the 'marginalist revolution', and the multiplier concept underlies 'shadow price', 'implicit value' and similar expressions.

Keywords

chain rule; convex programming; implicit function theorem; Kuhn–Tucker conditions; Lagrange multipliers; Lagrangian function; marginal revolution; separating hyperplane theorem

Article

Lagrange's 'method of undetermined multipliers' applies to a function \( f \) of several variables \( x \) subject to constraints, for which a maximum is required. The constraints can be stated as \( g(x) = q \) where the vector \( q \) is constant. Ordinarily one might distinguish independent and dependent variables under the constraints, and then by substitution for the dependent variables in \( f \) one has a function of independent variables whose derivatives must vanish. Instead Lagrange offered a procedure elegantly without the arbitrary distinction between variables and more suitable for some applications. The idea of it has other ramifications, such as for analytical mechanics, calculus of variations and control theory, beside the economic optimization dealt with here. The method involves introduction of further variables \( u \), the 'multipliers' associated with the constraints. With \( n \) function variables and \( m \) constraints we then have \( m + n \) variables \( (x, u) \). Lagrange's method depends on \( m + n \) relations he obtained to determine these, and so the \( n \) function variables \( x \) which are among them and should give the required maximum. The
remaining \( m \) variables \( u \), the ‘undetermined multipliers’, really are just as well determined. But originally they were just part of this device for determining a maximum and their values had no interest even if they could be determined.

The multipliers in fact have a further significance, as derivatives that tell how the maximum value varies as the constraints have variation from a variation of \( q \). They therefore have importance in application to economic problems. For, beside the value obtainable from given resources, one might also wish to know the ‘marginal value’ of any resource, the extra value obtainable when a unit of it is added. The Lagrangian method is therefore a natural tool of the ‘marginalist revolution’ and the multiplier has become a part of economic language; it is also the concept that underlies ‘shadow price’, ‘implicit value’ and similar expressions.

The most typical economic maximum problem is formulated differently from that dealt with by Lagrange. Rather, the constraints have the form of inequalities, expressing that some resource availability must not be exceeded; also, functions involved have convexity properties required by diminishing marginal returns. The theory of such problems is different and does not depend on what we have for Lagrange's classical problem. Yet despite the essential difference there is an impressive similarity, from the role of ‘multipliers’, so one can think that here again is Lagrange's method in another shape. But about these multipliers in the new context quite new things can be said. In either case, classical or new, the required maximum is associated with multipliers enabling certain conditions to be satisfied. Here is similarity, but premises and conclusions related to such conditions in each case are different.

Though form brings the two lines together it is altogether a mistake to see coincidence, and rather it is proper to make the treatments entirely separate, instead of trying to deduce one from the other. The difference is well appreciated from the complete difference in proofs of main points. One requires the implicit function theorem, at least in a certain approach, or more simply just the chain rule, as here. The other, convex programming, requires instead the theorem of the separating hyperplane. Again, one is entirely concerned with differentiable functions while the other in its main part is not, though the differentiable case treated by H.W. Kuhn and A.W. Tucker is very familiar. Reassuring for the connection, there are special problems where both lines are applicable, and then the multipliers involved are identical. But even then more can be said about the multipliers than would come simply from the classical case. Our review of the classical and new multiplier theories will make clear the cleavages and connections. We will also see peculiar, and remarkable, features of the matter in the special context of linear programming. Following the ordinary method of distinguishing independent variables and eliminating dependent variables we can, without any other thought about it, arrive at Lagrange's method from consideration of the derivatives the multipliers happen to represent. In that way, beside other possible merit, the multipliers become at the same time identified with those derivatives. Though this is not a usual procedure, it is a counterpart for classical multipliers of an argument that is essential for the new multipliers of optimal programming theory.

It is convenient now to denote the \( n \) function variables by \( z \), reserving \( x \) for independent variables among these. Lagrange's problem is to determine a maximum of \( f(z) \) subject to \( m \) constraints, stated

\[
g(z) = q.
\]
Variables are column vectors, and all functions are understood to be differentiable, so for instance \( g \) has an \( m \times n \)-derivative matrix denoted \( g_z \) with elements \( g_{ij} = \frac{\partial g}{\partial z_j} \). As necessary for \( z \) to be a maximum (or minimum, in any case a stationary point) Lagrange concluded that

\[
f_z = u g_z \quad \text{for some} \ u,
\]

(ii)

in other words the \( n \) conditions

\[
f_i = \sum_j u_j g_{ij} (j = 1, \ldots, n).
\]

Together with the \( m \) conditions

\[
g_i = q_i (i = 1, \ldots, m)
\]

provided by the constraints (i) we have \( m + n \) Lagrange conditions on the \( m + n \) variables

\[
u_i (i = 1, \ldots, m), \ z_j (j = 1, \ldots, n).
\]

Lagrange's method depends on the idea that these \( m + n \) conditions can be solved to determine the \( m + n \) variables, and so the \( n \) variables \( z_j \) which are among these. Put in another way, the multipliers \( u_i \) can be eliminated (and so left 'undetermined') and the conditions obtained then solved for the \( z_j \).

With independent and dependent variables \( x \) and \( y \) under the constraints, the variables have a partition \( z = (x, y) \), and we have a function \( f(x, y) \) under constraints \( g(x, y) = q \) that determine \( y \) as a function \( y = \gamma(x, q) \). Then \( g[x, \gamma(x, q)] = q \) is an identity and so, by differentiation with respect to \( x \),
and with respect to $q$, $g_y Y_q = 1$, and since from here $g_y$ and $Y_q$ are inverse matrices we also have

$$Y_q g_y = 1.$$  

(iv)

For any $q$ the constrained values of $f$ are described by $f [x, Y(x, q)]$ as $x$ varies without restriction. The $x$-derivatives must vanish for a stationary point, that is

$$f_x + f_y Y_x = 0.$$  

(v)

On the assumption that this condition determines a unique point $x$ for any $q$, the stationary points for various $q$ are described by a function $x = X(q)$. Then the corresponding stationary values of $f$ are given by the function

$$F(q) = f [X(q), Y(X(q), q)],$$

with derivatives

$$F_q = f_x X_q + f_y (Y_x X_q + Y_q) = (f_x + f_y Y_x) X_q + f_y Y_q = f_y Y_q b_y (q).$$

Hence

$$F_q g_x = (f_y Y_q) g_x = (f_y Y_q) (-g_y Y_x) b_y (iii) = -f_y (Y_q g_y) Y_x = -f_y Y_x b_y (iv) = f_x b_y (v).$$
and also

\[ F_q g_y = (f_y g_q) g_y = f_y (g_q g_y) = f_y b_y (iv). \]

It has now been seen that

\[ F_q g_x = f_x, \quad F_q g_y = f_y, \]

that is, \( f_z = F_q g_z \), which is (i) with \( u = F_q \). Thus we have Lagrange's conditions, together with the identification \( u = F_q \) for the multipliers.

For any \( x \), the existence of \( u \) so that \((x, u)\) satisfy Lagrange's conditions (i) and (ii) is the condition for \( x \) to be a stationary point. It is therefore necessary for \( x \) to be a maximum, or a minimum, and on its own not sufficient for \( x \) to be either. Solutions of Lagrange's conditions, if there are any, therefore provide all stationary points, possibly many, without information that any should be a maximum. However, should a maximum be known to exist and the conditions be found to have a unique solution \((x, u)\) then \( x \) is known to be that maximum. This is a common circumstance with many applications and where the method has strength.

Given any stationary point \( x \), such as could be found from a solution of Lagrange's conditions, and so obtained by a condition on first derivatives at \( x \), one can possibly find out if it is a local maximum, or a maximum in some neighbourhood of \( x \) under the constraints, by an examination of further conditions bringing in higher derivatives of \( x \). However, no conditions on derivatives simply at the point \( x \) will tell anything about \( x \) except in the local sense. There is no way of telling \( x \) is a global maximum simply from a satisfaction of some condition on derivatives at \( x \), of any order. Of course in economics a maximum is significant only in the global sense. Fortunately, typical functions of economics have convexity properties that enable one to go further on the basis of local conditions. Connected with this, any stationary point of a convex, or concave, function is necessarily a global minimum, or maximum, so in such cases first order conditions are enough. This matter has a part in further theory of Lagrange multipliers in the more typically economic context of convex programming.

Lagrange's method can be described with reference to the ‘Lagrangian function’

\[ L(x, u) = f(x) - u[g(x) - g], \]

as requiring the \( x \) and \( u \) derivatives to be set to 0. This way of putting it is without significance except as
a cook-book statement. One first learns about setting derivatives to zero when there are no constraints, and now even though there are constraints one can with confident familiarity do it again, even with the impression that the Lagrangian function should be at a maximum as if the recipe had that sense. There is better occasion for something like this in convex programming, where $u$ is fixed so as to make $x$ a maximum. A problem with inequality constraints is stated

$$(M) \text{Max } f(x): g(x) \leq q,$$

functions being defined in a set $A$. It can be imagined that $A$ is an activity set, and the performance of any $x \in A$ gives a return $f(x)$ and has a cost in terms of various resources given by the vector $g(x)$, so for feasibility this must not exceed the available stock $q$, so $g(x) \leq q$ is required. The problem is to find an optimal solution, an activity $x$ that gives the greatest return attainable with the available resources, as asserted by the condition

$$M(x) = g(x) \leq q, \quad g(y) \leq q \Rightarrow f(y) \leq f(x).$$

The limit function associated with the problem is

$$F(z) = \text{Sup } \{ f(x): g(x) \leq z \},$$

and a support solution $u$ is defined by the condition

$$D(u) = F(z) - F(q) \leq u(z - q) \text{ for all } z,$$

equivalent to $u$ being a support gradient of $F$ at the point $z = q$. Support solutions correspond to Lagrange multipliers in that they are variables associated with the constraints that give a means for characterizing optimal solutions. Thus, for a pair $(x, u)$, complementary slackness is defined by

$$C(x, u) = g(x) \leq q, \quad u \geq 0, \quad ug(x) = uq,$$
An important proposition, not requiring any assumptions whatsoever about the set $A$ or the functions $f$ and $g$ defined in it, is that any given pair $(x, u)$ is a shadow solution with complementary slackness if and only if $x$ is an optimal solution and $u$ a support solution, that is,

$$M(x) \& D(u) \iff C(x, u) \& S(x, u).$$

For characterizing optimal solutions by means of the condition on the right, the outstanding issue therefore is the existence of a support solution. We will find this guaranteed under conditions natural for economics at least.

A convex problem is one where $f$ is a concave function and the elements of $g$ are convex. The only importance is to make the limit function $F$ concave. Then it has a linear support, and so a support gradient providing a support solution, at any interior point of the region where it is finite. Now with $F(q)$ finite, Slater's condition which requires $g(x) < q$ for some $x$ assures that $q$ is exactly such a point. Thus for a convex problem with Slater's condition, and with $F(q)$ finite, as it must be if an optimal solution exists, we do have the existence of a support solution, and so a characterization of all optimal solutions by means of shadow solutions with complementary slackness.

It is a short step from here to the characterization by means of Kuhn–Tucker conditions. These apply to a problem where the activity set $A$ is a space of non-negative vectors, and the functions are differentiable. All that has to be known further is that for a differentiable concave function $\phi(x)$ subject to $x \geq 0$ to be a maximum it is necessary and sufficient that

$$\phi_x \leq 0, \ x \geq 0, \ \phi_x x = 0.$$

Applied to the Lagrangian $f(x) - u[g(x) - q]$, with $u$ fixed and non-negative, and $x$ restricted non-negative, the conditions $S(x, u)$ for a shadow solution become

$$f_x - u g_x \leq 0, \ x \geq 0, \ (f_x - u g_x) x = 0,$$
and so now, with complementary slackness \( C(x, u) \), we have the Kuhn–Tucker conditions. In case \( x > 0 \) the conditions just obtained reduce to \( f_x = u \), in other words, ordinary Lagrange conditions, the support solution \( u \) providing the multipliers.

With \( F \) concave, it is differentiable at a point \( q \) if and only if it has a unique support gradient \( u \) there, and then the support gradient coincides with the differential gradient, \( u = F_q \). Thus uniqueness of support solutions is associated with differentiability of the limit function \( F \) at the point \( q \). The identification \( u = F_q \) that can be made in this case is comparable with the identity of classical Lagrange multipliers with derivatives of the stationary value function. But this new multiplier theory, even for the Kuhn–Tucker case, in no way depends on differentiability of the limit function. Also, for the linear approximation near \( q \) that is available in the differentiable case, we know more about it in that the error is always positive, or that it overestimates the limit function, not just locally but everywhere. Consider now a standard linear programming problem.

\[
(M) \text{ Max } px: ax \leq q, x \geq 0.
\]

Another characterization for support solutions of LP problems can be noted, coming from the homogeneity. Thus, with \( F \) as the limit function of \( (M) \), the condition for \( u \) to be a support solution becomes

\[
F(q) = uq, \quad F(z) \leq uz \text{ for all } z.
\]

Since \( (M) \) is a convex problem the foregoing will apply to it. Also it has the required form for application of the Kuhn–Tucker conditions, which, following the way we put them before with some rearrangement in the second line, become

\[
ax \leq q, \quad u \geq 0, \quad uax = uq,
\]

\[
u\alpha \geq q, \quad x \geq 0, \quad u\alpha x = px.
\]

We know from the foregoing that \( (x, u) \) is a solution of these conditions if and only if \( x \) is an optimal solution and \( u \) a support solution of the problem \( (M) \).

There is a symmetry in the situation that enables these conditions to be read differently. With an exchange of role between \( x \) and \( u \) they become Kuhn–Tucker conditions for the problem.
and so they hold if and only if $u$ is an optimal solution and $x$ a support solution of $(W)$. It follows that support solutions of either problem are identical with optimal solutions of the other. Of course, $(M)$ and $(W)$ are a standard dual pair of LP problems, and so by the LP duality theorem one has an optimal solution if and only if the other does. Hence an LP problem has a support solution if and only if it has an optimal solution. Most remarkable is the way for finding support solutions for an LP problem, as it were differentiating the limit function or finding the ‘Lagrange multipliers’, by finding optimal solutions for another LP problem – and we know how to do that.

laissez-faire, economists and

Roger E. Backhouse and Steven G. Medema
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article traces economists's attitudes towards government intervention since the term ‘laissez-faire’ was first used in late 17th- or early 18th-century France. Understanding of the term has changed significantly since then. Adam Smith, popularly associated with laissez-faire, had a much more nuanced and pragmatic view of the role of the state, as did many of the classical economists and their neoclassical successors. Dissatisfaction with certain aspects of industrial capitalism led to a more interventionist stance during the 20th century, though the second half of the century saw something of a reversion towards the classical approach.

Article

Origins
The maxim ‘laissez-faire’ is commonly attributed to Vincent de Gournay (1712–1759), on the basis of a claim made the Physiocrat Du Pont de Nemours. However, his likely source, Turgot's ‘Eloge de Gournay’, did not attribute the phrase to Gournay, but implied that Gournay agreed with a well-known remark, made to Louis XIV's minister, Colbert, ‘laissez-nous faire’. This remark was apparently made around 1680 by François Legendre, a merchant and author of a text on commercial mathematics, and may well have been an unpremeditated answer to a question (Castelot, 1987). However, Legendre's contemporary, Pierre de Boisguilbert (1646–1714), repeatedly used the phrase ‘laisse faire la nature’ (‘leave nature alone’), arguing that interference in business spoiled everything, even if it was well-intentioned (Faccarello, 2000). The same ideas appear in English writings of the same period, though the phrase itself does not occur in the writings of commentators such as Nicholas Barbon and Dudley North, writing in the early 1690s, and Henry Martyn and Bernard Mandeville in the early 1700s. North (1691, p. 37), for example, wrote, ‘no people ever yet grew rich by policies; but it is peace, industry, and freedom that brings trade and wealth, and nothing else.’ By the mid-18th century, the idea of laissez-faire was well known, perhaps most clearly stated by the Marquis d'Argenson, in 1858: ‘Laissez faire ought to be the motto of every public authority’ (Castelot, 1987; see also Oncken, 1886). It was Adam Smith who became associated, more than any other economist, with laissez-faire during the 19th and 20th centuries, even though he neither invented the idea, nor used the phrase. The elements from which his Wealth of Nations was constructed may not have been original, but the vision of society that he presented, with its emphasis on natural liberty, resonated widely. Smith used the idea of liberty as a radical idea that, though cautiously expressed, placed him alongside radicals such as Tom Paine and Condorcet. Liberty had a political as well as an economic dimension, involving freedom from being oppressed by guilds and monopolies as much as freedom from government interference in one's affairs. However, to those for whom such talk of liberty smacked of Jacobinism and the threat to property posed by the French Revolution, Smith could be reinterpreted as advocating a narrower economic freedom, more conservative in its political implications. Such a reinterpretation happened within a decade of his death (Rothschild, 2001).

The case for laissez-faire

Smith's case for the market did not rest on any claim that it would produce an optimal allocation of resources. Instead, he argued that the system of natural liberty would produce a better outcome than would intervention by the state. There were hints concerning efficient allocation of resources, as on the only occasion when he used the phrase ‘invisible hand’ in the Wealth of Nations: in seeking his own advantage, ‘every individual necessarily labours to render the annual revenue of the society as great as he can’ (Smith, 1776, p. 456). Smith opposed mercantilist policies so strongly, not because they prevented an efficient or optimal allocation of resources, or because state action was inherently less efficient than private, but because mercantilist policies were typically the result of using state power to serve the interests of a privileged minority. Merchants conspired to restrain trade, using the state where they could. Smith supported laissez-faire because removal of mercantilist restrictions on trade would help to undermine monopoly, enabling individuals to bring their capital into competition with those who were earning high profits and allowing labour to flow freely between industries and regions. But Smith's support for laissez-faire was not for laissez-faire in vacuo: his system presumed a framework of justice
and morality, the basis for which he had analysed in his *Theory of Moral Sentiments* (1759), a book to which he continued to attach great importance, revising it long after the *Wealth of Nations* was published, and in his lectures on jurisprudence delivered in the 1760s (1978).

The classical economists’ case for laissez-faire was substantially Smithian, though more narrowly focused on economic freedom. Their consumption-oriented view led them to the belief that freedom of choice was desirable for consumers, and that freedom for producers was the most effective means of satisfying these consumer desires. It was thought that the impersonal forces of the market, working through the system of natural liberty, would then serve to harmonize these interests – or at least would do so to a greater and more beneficial extent than would other systems. The case was comprised of some arguments, such as David Ricardo's theory of international trade, that could be interpreted in terms of optimal resource allocation, but it centred on raising the growth rate. However, some economists saw the case for laissez-faire as primarily a moral one, linked to arguments from evangelical Christian theology. Where Ricardo and many other economists focused on the link between laissez-faire and economic growth, economists such as Thomas Chalmers endorsed laissez-faire because it allowed individualistic capitalism to have its full educative, retributive and purgative effects. There has even been debate over whether this moral case for laissez-faire was in practice more influential than the economic one (cf. Hilton, 1988; Gash, 1989). Certainly in America during this period, the belief in laissez-faire could not be separated from the Protestant spirit of the times, and a belief in its virtues was considered a necessary identifying mark of an economist. When it came to free trade, there was the additional dimension, emphasized by John Bright and Richard Cobden, arguably the most influential advocates of laissez-faire in Victorian Britain, that free international commerce held out the prospect of harmony between nations. The most outspoken supporter of laissez-faire, however, was probably the French writer Frederic Bastiat, a brilliant economic journalist whose vivid examples (for example, candle-makers petitioning for protection against unfair competition from the sun) were influential in making the case for free trade. Standing in a French laissez-faire tradition going back to the 18th century, he linked laissez-faire with harmony between classes, in contrast with the class conflict seen by many English economists. In the United States, laissez-faire was also more than simply an economic doctrine, as is shown by the implications of the slogan of ‘free labour’ in a society divided over slavery. Along with the sanctity of private property it was part of a moral order that was believed to produce a harmonious society: free enterprise was strongly associated with the virtues of hard work and republican democracy (see United States, economics in (1776–1885 and 1885–1945)).

It was only towards the end of the century, with the developments commonly known as the marginal revolution, that economists began to argue that free competition might produce an optimal allocation of resources, thereby opening up a new defence of laissez-faire. Léon Walras (1954, p. 255) showed that if two conditions – that each product had only one price in the market and that prices equal corresponding costs of production – were satisfied, free competition would produce ‘the greatest possible satisfaction of wants’. Marshall offered a doctrine of ‘maximum satisfaction’ that wedded his demand–supply apparatus with the concept of consumer surplus. However, they did not use these arguments to make a case for laissez faire, for their arguments showed much more clearly than did those of their predecessors why laissez-faire might in practice fail to produce such an optimal allocation. For example, immediately after stating his theorem, Walras pointed out that economists typically exaggerated the implications of the principle of laissez-faire: the conditions of a uniform price and equality of price and cost of production would often not be satisfied and, in any case, it the theorem did not apply to the question of...
The limits to laissez-faire

Viner (1960, p. 45), in one of the classic studies of the history of laissez-faire, started by saying that he understood laissez-faire to mean:

the limitation of government activity to the enforcement of peace and of ‘justice’ in the restricted sense of ‘com mutative justice,’ [justice in exchange] to defense against foreign enemies, and to public works regarded as essential and as impossible or highly improbably of establishment by private enterprise or, for special reasons, unsuitable to be left to private operation.

However, whilst Viner is correct to argue that laissez-faire did not mean anarchy and a complete absence of government intervention, his definition begs the question of how much intervention should be allowed: of what are the limits to laissez-faire.

Smith's view of the role of government is close to Viner's view of laissez-faire. The duties of the sovereign included maintaining justice, police, defence and such beneficial public works as would not otherwise be provided. This included support for transport and education – both of which Smith thought essential contributors to the wealth of a nation. It is important to note, though, that Smith's conception often went beyond modern views. For example, his support for education and for the arts was grounded in part in his concerns about the stultifying effects of the division of labour. His analysis of national defence led him to advocate a standing army rather than a militia because of a concern about the problems of attracting the right sort of people to military service in an increasingly wealthy commercial society. Smith's view of the appropriate sphere for state action also went significantly beyond the traditional public goods categories. He supported regulations dealing with public hygiene, legal ceilings on interest rates (to prevent excessive flows of financial capital into high-risk ventures), light duties on imports of manufactured goods, the mandating of quality certifications on linen and plate, certain banking and currency regulations to promote a stable monetary system, and the discouragement of the spread of drinking establishments through taxes on liquor (this being one of various regulations Smith advocated to compensate for the imperfect knowledge – or diminished telescopic faculty – of individuals). He also argued for measures that came within what Viner described as commutative justice. For example, he supported regulations that restricted wages in the interests of the labourer (that is, minimum wages) on the grounds that these redressed the imbalance between worker and employer.

The 19th-century classical economists, while holding to a strong belief in the market as an allocation mechanism, also believed that the market could only operate satisfactorily – harmonizing actions of self-interested agents with the interests of society as a whole – within a framework of legal, political, and moral measures that facilitated certain forms of action while restricting others. They were, in essence, pragmatic reformers, inclined towards laissez-faire but in practice willing to consider each case on its merits. We see this reflected in John Ramsay McCulloch's assertion in 1848 that ‘The principle of laissez-faire may be safely trusted to do in some things but in many more it is wholly inapplicable; and to appeal to it on all occasions savours more of the policy of a parrot than of a statesman or a
philosopher’ (McCulloch, quoted in Robbins, 1952, p. 43). Over two decades later, John Elliot Cairnes (1870, p. 244) was even more forthright, asserting that the maxim of laissez-faire had ‘no scientific basis whatever’ but was a ‘mere handy rule of practice’. In terms of specific policies, they were willing to support an increasing range of interventions from factory legislation to the state provision of education, the poor laws and measures to promote public health (Robbins, 1952; O'Brien, 2004).

However, whilst the classical economists, like Smith, saw many cases where government action could improve on what would result from laissez-faire, they remained suspicious of government and were vociferously opposed to policies – like those of mercantilism, but also many others – that they believed served the interests of particular groups at the expense of the larger population. They were optimistic that the insights of political economy could be used to point the discipline in a direction that would be beneficial to society and help mitigate the negative effects of partisan advocacy within that process (for example, Mill, 1859; 1861; 1862).

More radical objections to laissez-faire were found outside Britain. The name ‘Manchesterism’ was widely used, particularly in Germany, to denote British laissez-faire doctrines, and was allegedly the ideology of Manchester's manufacturing classes. The most penetrating critique came from Friedrich List in *The National System of Political Economy* (1856). As Britain had industrialized first, free trade was in her interests, because other countries could not compete; until they were in a position to do so, tariffs were needed. List's ideas were particularly influential in the United States, where economists such as Henry Carey were able to combine commitment to individualism and free enterprise with support for protective tariffs.

One of the additional elements introduced after Smith was the utilitarianism of Bentham and his followers. Though utilitarianism has, on account of the prominence of Philosophic Radicals within political economy, been equated with laissez-faire individualism, this is not correct. On the one hand, there was an authoritarian streak in utilitarianism, from Bentham to reformers such as Edwin Chadwick. On the other hand, there were many supporters of laissez-faire, of whom Gladstone is perhaps the outstanding example, alongside many evangelical political economists, who would have no truck with Benthamite anti-religious rationalism.

The trend away from laissez-faire has its roots in the utilitarian tradition, for utilitarianism provided a basis on which exceptions could be justified. John Stuart Mill (1848, Book V, ch. XI), in what became the dominant textbook on political economy, laid out an extensive list of cases where the system of natural liberty failed to generate outcomes in the best interests of society. He argued that government interference was justified when individuals’ actions had spillover effects on others, when individuals did not have the capacity properly to judge the consequences of their own actions or when what would now be called principal-agent problems were present. Prominent here, too, was the distribution question: the classical period witnessed increasing concern about poverty but saw attempts at reducing it as at best futile (owing to natural laws governing distribution) and possibly even counterproductive (because redistributive measures could exacerbate the population problem). Mill challenged the received view here by positing that the laws of distribution were, in fact, mutable, and that state action had the potential to significantly improve the lot of the poor. However, his starting point remained the maxim that ‘Laisser-faire, in short, should be the general practice: every departure from it, unless required by some great good, is a certain evil’ (Mill, 1965, p. 945). It was not just Mill who used utilitarianism as a means of justifying departures from laissez-faire. Robert Lowe, a controversial Liberal politician, at one time...
Chancellor of the Exchequer, had very much a Smithian view of the merits of laissez-faire but used utilitarian arguments to justify an increasing number of exceptions to this rule (Maloney, 2005). William Stanley Jevons sought to move economic theory sharply away from the framework laid down by Ricardo and Mill, but used utilitarian arguments to justify extensive state intervention. These utilitarian defences of state intervention were part of a much broader move away from laissez-faire from around the 1870s and 1880s when there developed widespread consciousness of what was, in Britain, called ‘the social problem’ at a time when the electorate in many European countries was widening to include the members of the working class (see Hutchison, 1953; 1978). One reason for the timing was the long recession that followed the collapse of the worldwide boom of 1873 and the severe, and in some countries prolonged, unemployment that resulted. Questioning of laissez-faire was particularly strong in Germany, where the Verein für Sozialpolitik was founded, essentially as an interventionist think tank (see Historical School, German). Its members, of whom Gustav Schmoller was pre-eminent, were known as the ‘Socialists of the lectern’. These attitudes carried over to the United States: many of the founders of the American Economic Association were exposed to them whilst taking their doctorates in Germany, only to find, on their return, a conflict with traditional laissez-faire attitudes. Their challenge to laissez-faire affected not just economic analysis, but economic policy: in the United States, the rise of big business was associated with the development of numerous and very obvious anti-competitive practices, which resulted in the government developing policies of industrial regulation not found in other countries, at least in relation to inter-state trade, culminating in the anti-trust acts of 1890 and 1913. Economists supported such measures with analysis of phenomena such as ‘cut-throat’ competition that went beyond anything found in, say, Jevons, Walras or Marshall (see United States, economics in (1885–1945)).

The British approach was dominated by the Cambridge School, at the headwaters of which was Henry Sidgwick, the author of one of the classic defences of utilitarianism ethics (1907). Sidgwick (1904) took Mill's analysis further: all outcomes that constituted departures from social utility maxima were potential candidates for government intervention. Sidgwick's optimism about the prospects for state action marked a significant turn. He was convinced that recent reforms in governance structures – such as the establishment of boards and commissions staffed by experts – portended great things for the ability of state action to improve on market performance.

Sidgwick's perspective signalled what was to become a distinctive Cambridge approach to issues of laissez-faire, continued by Marshall (1890) and A.C. Pigou (1912; 1920). Marshall wedded his demand-supply analysis with the concept of consumer's surplus to provide a tool with which the welfare implications of laissez-faire and government intervention could be analysed. In analysis since seen as flawed through its neglect of producer's surplus, Marshall argued that subsidies to industries characterized by increasing returns and taxes on industries operating under decreasing returns could enhance efficiency. Pigou took all this a step further with his analysis of private and social net products, which proved to be a very effective tool for illustrating both the nature of market failures and the means by which government corrective actions could prod markets toward efficiency. He argued that divergences between private and social net products constituted a ‘prima facie case’ for government intervention, but he also allowed that the state will not necessarily be capable of improving on market performance. Like his predecessors, Pigou was optimistic that governmental reforms held great promise, but he was also concerned about many of the governance problems that we now associate with public
choice analysis. The policy conclusions of the Cambridge economists, including the case for free trade, rested as much on beliefs about the competence of government to implement beneficial policies as on the results of formal economic theory.

The First World War and its aftermath

Laissez-faire was far from universally accepted before the First World War, but the move towards the welfare state and towards regulation of industry was generally gradual (free trade had never become universal, some countries never having abandoned protective tariffs). Economists made frequent concessions to socialism (this was easy because the term had such an elastic meaning) but could maintain the idea that laissez-faire should remain the general rule. After 1918, that confidence was harder to maintain. The Bolshevik revolution and the establishment of the Union of Soviet Socialist Republics (USSR) presented the challenge of an alternative economic system. Economic dislocation was widespread in Europe in the 1920s and worldwide after the onset of the Great Depression. To an extent unparalleled before 1914, laissez-faire and even capitalism were called into question, in the writings of economists as much as among politicians and policymakers.

Of particular significance was the extension of discussions of laissez-faire to what would now be considered macroeconomic issues – money and the business cycle. ‘Free banking’ might exist in some American states, but the need for some sort of monetary policy had been generally accepted since the bullion debates during the Napoleonic Wars. Though there were exceptions, it became accepted that paper money should have a fixed value in terms of precious metal. There were several reasons why this was seen as consistent with laissez-faire. To allow the value of paper to fall below par was to defraud those who had entered into contracts denominated in terms of money. A metallic standard, which increasingly meant the gold standard, facilitated trade. Most important, though there were underconsumptionists (more than are often recognized), they were in a clear minority among economists.

The parallel with 20th-century debates over laissez-faire in macroeconomics is found in the debate between the Currency and Banking Schools in the 1840s (see Banking School, Currency School, Free Banking School). The Currency School sought to prevent the emergence of financial crises by making paper currency behave like a metallic one, removing discretion from central bankers. In contrast, the Banking School argued that, in times of depression, a central bank should pursue an accommodating monetary policy, lending according to sound banking principles. Strictly speaking, this was a debate about the type of policy to be pursued, not whether or not to intervene, but it posed the issue of discretion in monetary policy that came to be associated, in the 20th century, with debates over laissez-faire. Such ideas framed much of the discussions of central bank policy as late as the inter-war period, when the appropriate policy for the US Federal Reserve system was being debated (Laidler, 1999, chs 8–9).

The extent to which such a way of thinking carried over into the 20th century is illustrated by the ‘Austrian’ theories of money. Though in general ardent supporters of laissez-faire, Ludwig von Mises and Friedrich Hayek argued for the implementation of what they considered appropriate monetary policy. Mises (1912, pp. 456–63) supported the gold standard on the grounds that it rendered the value of money independent of political influence. Management of the currency meant inflation, a policy inevitably doomed to eventual failure. Hayek, though theoretically innovative, maintained this emphasis
on sound, or ‘neutral’ money; the problem of the business cycle was caused by the supply of money being too elastic. Despite his otherwise impeccable credentials as a supporter of laissez-faire, it was only in the 1970s that he turned to completely free banking and competition in the supply of currency (Hayek, 1999).

Though his target was the British authorities, this was the mindset that John Maynard Keynes attacked in his *Tract on Monetary Reform* (1923). He argued that to regard the gold standard as a fact of nature was to perpetuate an illusion. ‘There is,’ he wrote, ‘no escape from a “managed” currency, whether we wish it or not’ (Keynes, 1971, p. 136). He continued (1971, p. 138):

> A regulated non-metallic standard has slipped in unnoticed. *It exists.* Whilst the economists dozed, the academic dream of a hundred years, doffing its cap and gown, clad in paper rags, has crept into the real world by means of the bad fairies – always so much more potent than the good – the wicked ministers of finance.

It was but a short step from this to announcing ‘[t]he end of laissez-faire’ (Keynes, 1972, pp. 272–94).

His account of laissez-faire focuses on the philosophical and political rather than the economic, his point being that it cannot rest on ideas of natural liberty, for there is no such thing. It was necessary, he argued, to work out the agenda and non-agenda of the state without the Benthamite prior assumption that interference was likely to be ‘generally pernicious’ (1972, p. 288). The agenda for the state should comprise those things that are otherwise not done, which he identified as regulation of currency and credit, management of investment, and policy in relation to population size (1926, p. 292). His *General Theory of Employment, Interest and Money* (1936) provided a new theoretical justification for such ideas, but the idea that the state's main agenda item was the maintenance of the level of investment, remained.

Most of Keynes's arguments were far from novel. J.A. Hobson and other underconsumptionists had long questioned the ability of unregulated capitalism to produce the appropriate level of saving. Not only had it been argued, even before 1914, that government spending could raise the level of employment, but schemes for doing so had been worked out. The significance of his arguments, which became clear only from the 1940s, lay in the fact that an economist at the heart of the establishment was arguing against laissez-faire from a macroeconomic point of view. Furthermore, his attack on the philosophical foundations of laissez-faire, by someone who was far from being a socialist, indicated a changing climate of opinion towards one in which management of the economy came to be seen as a central role of government.

Planning was also becoming more acceptable in the United States throughout the inter-war period. It has been argued that this marked a radical departure from previous attempts to reform the economy because it was ‘predicated on the assumption that intervention … was necessary for a well-functioning, dynamic economy’ (Balisciano, 1998, p. 154; see also Barber, 1985; 1996). The First World War had shown that planning could raise output above what had been thought possible, and economic fluctuations in the immediate post-war period suggested that government intervention might be desirable. There was a move to create a new economics, appropriate to a new age, exemplified in the White House by Herbert Hoover, an engineer who turned readily to experts. The move towards a scientific economics that could perform this task was represented by institutionalism (see institutionalism, old) but planning took many
forms, from the social planning of Rexford Tugwell and John Maurice Clark to the macroeconomic planning of Laughlin Currie (see Balisciano, 1998). The move towards providing a scientific foundation for policy extended beyond institutionalism: for example, both Wesley Mitchell and Irving Fisher called for quantitative research. These various strands of thought came together in the New Deal, with its mixture of microeconomic planning, macroeconomic management and extensive quantitative research. In continental Europe, planning was observed in the Soviet Union and in Germany under National Socialism. In other countries, corporatist ideas were highly influential. When placed alongside experience of the Great Depression, this raised the question of whether capitalism itself, let alone laissez-faire, was a viable alternative to planning. The socialist calculation debate, initiated by Otto Neurath and von Mises immediately after the First World War, tackled the question of whether a planned economy could be as efficient as a capitalist one. The significance of this controversy is twofold. In making the case that it was theoretically possible to design a socialist economy that was as efficient as a capitalist one, Oskar Lange and the so-called market socialists were shifting the climate of opinion in favour of planning. However, perhaps more significant in the longer term is the fact that planning was defended using arguments about the optimality of a perfectly competitive equilibrium. This took the arguments of Walras and Marshall a stage further, towards the post-war welfare theorems of Kenneth Arrow and Gerard Debreu. A defence of socialism could, with a small twist, be turned into an argument for laissez-faire.

The most theoretically innovative critic of the central planners was Hayek, who developed the idea that the market could be seen as an information-processing mechanism (Hayek, 1937; see also Gamble, 2006). The information possessed by modern societies was necessarily limited, imperfect and dispersed among many individuals, so to assume, as did the market socialists, that this knowledge could be available to central planners was a mistake. Markets enabled prices and economic activities to reflect the knowledge held by millions of distinct individuals and organizations. The significance of this theory is that it reinforces the point that arguments for laissez-faire do not need to rest on any claim that it produces an optimal outcome. If knowledge is imperfect, as Hayek claimed, it is not meaningful to argue in terms of optimality.

The Second World War and after

During the Second World War, planning was widely practised, not just in Germany and the Soviet Union but also in Britain and the United States, perhaps inevitably when military uses accounted for around 40 per cent of national production. Unlike in the First World War, careful attempts were made to plan for the post-war order and although this was to be a liberal world order, based on free trade and free movement of capital, it was to be a planned order, with appropriate national and international institutions to support it. Experience of the First World War was taken as demonstrating that a well-functioning free market economy would not occur spontaneously. The degree and nature of planning and commitment to laissez-faire varied from country to country: the United States may have been at one end of the spectrum, with suspicion that planning might be tainted by Communism, and with government accounting for a lower share of national output than in Europe, but the importance of the defence sector during the Cold War meant that the role of government was far-reaching. Though there was a retreat from the level of planning achieved during the war, and even compared with the New Deal, in favour of a free market economy, government remained very significant.
Economics had also changed, becoming more technical, more mathematical (see, for example, United States, economics in (1945 to present)). However, the relationship of this change to thinking about laissez-faire was complex. Many of the techniques used in this more technical economics had roots in economists’ wartime activities, and were linked with planning. The Cowles Commission, the main centre of mathematical economics in the 1940s, was closely associated with these developments and was also linked, through Oskar Lange, with socialism. A case can be made that microeconomic theory in this period strengthened the case against laissez-faire by developing theories of market failure. General equilibrium theory may have been seen by outsiders as demonstrating rigorously the efficiency of competitive markets, but the restrictive assumptions needed could equally be taken as demonstrating that an efficient allocation of resources required conditions that could never be satisfied in the real world. It was in macroeconomics that the challenge to laissez-faire was strongest, the nearest to a consensus view being the neoclassical synthesis articulated in the third edition of Paul Samuelson's *Economics* (1955). This proposed that if demand management could maintain full employment, the allocation of resources between economic activities could be undertaken by the market. Laissez-faire was rejected at the macroeconomic level in favour of a ‘Keynesian’ policy of demand management (see Keynesianism). At a microeconomic level, laissez-faire was limited by the need to provide public goods, deal with externalities and control monopoly. This left much scope for debate over precisely where the limits to laissez-faire lay, from those who favoured extensive intervention to the Chicago School, which challenged the need for active competition policies and, increasingly, the Keynesian consensus. The pervasiveness of planning in the late 1930s and early 1940s provoked a response from some scholars who believed that classical liberal values were threatened. The most prominent such response was by Hayek, whose *The Road to Serfdom* (1944) became a best seller. In 1947 he helped establish the Mont Pèlerin Society, which became the centre of a network of economists committed to free-market ideas. This network encompassed research institutes aimed at influencing policy and academic economists, of which the most significant was a group centred on Chicago. This offered a much more optimistic, and even radical, view of what could be achieved under laissez-faire than was generally accepted by economists in the 1950s and 1960s. Laissez-faire was as much an end as a means, exemplified in Milton and Rose Friedman's *Free to Choose* (1979).

The 1960s and 1970s saw the beginnings of a major shift in the way that economists approached issues related to laissez-faire. At the heart of this shift was an extension in the scope of the theory of rational choice to the point where it could encompass all aspects of behaviour (see rationality, history of the concept). Two developments were particularly important in moving economists towards laissez-faire. The first was the application of rational choice theory to government and bureaucracies, resulting in the development of a theory of government failure to parallel the earlier theory of market failure. Rent-seeking, legislative vote trading and bureaucratic waste took their places alongside externalities and public goods as phenomena to be taken into account. This was most visible in public choice theory, but spread much more widely. The second was the transformation of macroeconomics associated with the new classical macroeconomics. Rational behaviour was taken to imply that markets would clear and that agents would form expectations rationally, which led to a presumption that attempts to stabilize economic activity would be counterproductive; that laissez-faire applied at the macroeconomic level. This was believed to explain the apparent breakdown of Keynesian policies in the 1970s. This did not go unchallenged, but there was a clear shift in the weight of economists’ opinions on laissez-faire at both
microeconomic and macroeconomic levels. However, other developments worked in the opposite direction. There was much work on the economics of information, which added to the weight of the evidence for why free markets might not be efficient. These involved questioning some of the most basic ideas of supply and demand on which much of the traditional case for laissez-faire rested, a point made most forcefully by Joseph Stiglitz. Market failures can occur in both the production and dissemination of information due to the informational asymmetries and uncertainty that result. A lack of effective futures markets causes intertemporal inefficiencies (for example, on the environmental front), moral hazard and adverse selection problems can cause insurance markets to fail, and the use of education as a signalling and screening device can lead to over-investment in education. At the macroeconomic level, problems associated with risk and information can cause financial markets to react in ways that are destabilizing. Game theory, too, presented problems, showing how strategic behaviour had a propensity to generate market outcomes that departed – sometimes substantially – from the dictates of optimality.

By the new millennium, some of the assumptions underlying this resurgence of laissez-faire thinking were being challenged. A form of Keynesianism re-emerged in the form of inflation targeting through interest rates, a development that reflected both macroeconomic theory and lessons learned from experience. Behavioural economics raised questions about human motivation and opened up the possibility of new ways of analysing economic behaviour. It is, however, too soon to tell what the implications of this will be for attitudes towards laissez-faire.

However, despite the resurgence of laissez-faire thinking, the context is radically different from that prevailing at the beginning of the 20th, let alone the 19th, century. In macroeconomics, the case for central banks operating according to rules so as to stabilize economic activity is, in some sense, almost universally accepted. Debates centre on what those rules should be, not whether there should be rules. At the micro level, there has been a significant expansion in the sphere of market activity since the 1980s, as a result of the deliberate creation of new markets, from financial options to CO2 emissions. These markets are not simply heavily regulated: many of them are designed by government, usually on the basis of economists’ advice. Furthermore, the scale of government is now such that government contracts are an inherent part of the activities of many businesses. In such an environment, it can be questioned whether the traditional distinction between laissez-faire and government intervention has become out of date.

A further complication in discussions of laissez-faire results from the enormous expansion of international organizations, from the International Monetary Fund (IMF) and the World Bank to the World Trade Organisation (WTO) and the United Nations. These have made it meaningful to discuss alternatives to laissez-faire at an international level at the same time that the so-called globalization of economic activity has raised new questions about its benefits and costs to different groups. If trade is to take place within rules laid down by organizations such as the WTO and the IMF, should these rules allow governments to protect industries or workers from what they perceive to be unfair international competition? Does laissez-faire apply to national governments or simply to private organizations? This is a complicated question in a world where many private companies are substantially shaped by their relations with governments.

Conclusions

It has been argued that the developments of recent decades have taken us back to Adam Smith and a laissez-faire welfare economics asserting the efficacy of the market in channelling individual self-interest towards actions that benefit society; and to a pre-Keynesian era when the need for active macroeconomic management was not recognized. But this is not accurate. The 19th- and early 20th-century exponents of laissez-faire, from Mill to Pigou (and perhaps even to Lange or Samuelson), saw an ever-widening range of exceptions to the general rule. Their policy prescriptions reflected well-articulated ideas about market failure and much less completely theorized views about the capacity of government to remedy such problems. As a result of recent developments there is, in general, awareness that neither the market nor government is perfect – that the choice is between two highly imperfect alternatives. Theory cannot settle the matter unless reasons are adduced to play down the importance of market failure (the ‘libertarian’ response) or government failure (the ‘socialist’ response). Because of this, and because of the transformed role of government, there is a strong case for arguing that notions such as ‘laissez-faire’ and ‘state action’, especially if this is seen as an either/or choice, are not particularly helpful. However, there is a reversion to Smithian ideas in one sense: economists increasingly recognize, as did Smith, that markets do not exist apart from an institutional structure that includes the state and its legal system. Discussions of state action are not usually about replacing the market; rather, they are about nudging markets this way or that in order to obtain a more desirable outcome than would obtain otherwise.

Abstract

Kelvin Lancaster made at least three major original contributions to economic theory. The first, together with Richard G. Lipsey, is ‘The General Theory of the Second Best’ in the area of welfare economics. The other was his ‘characteristics’ approach to the pure theory of consumer behaviour. The third, based on this new approach to consumer behavior was a solution to the problem of ‘socially optimal product differentiation’, which showed how to balance the consumer's desire for more variety in the choice of goods to consume against economies of scale in the production of each good.

Article

Kelvin Lancaster was born in Sydney, Australia, on 10 December 1924. He volunteered for the Royal Australian Air Force at the age of 18 and was trained as a bombardier. The war fortunately ended before this kindest and gentlest of men was required to release any bombs using the new Norden bombsight on which he had been trained. He graduated from the University of Sydney with a BSc in mathematics and geology (1948) and a BA (1949) an MA (1953), both in English literature. A growing interest in economics took him to the London School of Economics in 1953, where he obtained the BScEcon degree with First Class Honours as an external student without ever having taken a single course in economics, and his Ph.D. in 1958. He was on the faculty of the LSE from 1954 to 1962, and immediately became one of the brightest stars of the famous seminar led since the early 1930s by Lionel Robbins, whose participants over the years included the likes of Hayek, Hicks, Kaldor, Lerner, Meade and many others of comparable stature.
Lancaster and Richard Lipsey, then also at the LSE, each submitted a paper to the *Review of Economic Studies*, edited by the indefatigable Harry Johnson. Lipsey's on tariffs and customs unions and Lancaster's on monopoly and nationalized industries. Johnson noted that they were both making the same general point, namely, that if one of the necessary conditions for a Pareto optimum failed to hold it was not in general desirable to make the remaining conditions hold. In other words, the Paretian conditions had to be fulfilled in their entirety for a ‘first-best’ optimum to be reached. If one condition failed to hold a ‘second-best’ optimum would in general involve departures from some or all of the others. Johnson suggested that the two papers be merged, making this fundamental general point and giving the customs union and nationalized industry problems as illustrative examples. The result was the celebrated paper on ‘The General Theory of the Second Best’ by Lipsey and Lancaster (1956) that has changed the way economists have since thought about economic policy in every field.

Lancaster moved to the United States in 1962, first to Johns Hopkins (1962–66) and then to Columbia, following his wife Dvora, who had been admitted to Columbia Law School. He remained at Columbia for the rest of his career, becoming the John Bates Clark Professor of Economics in 1978. In 1966 he published ‘A New Approach to Consumer Theory’ in the *Journal of Political Economy*, following it in 1971 with a more detailed treatment in the book *Consumer Demand: A New Approach*. His attempt at a new approach to the classic problem of consumer choice was motivated by the desire to make this most parsimoniously elegant of all economic theories more operational and relevant to the modern industrial world of an almost infinite variety of products. The standard theory involved considering the consumer as maximizing a utility function $U(x)$ subject to a budget constraint $px = I$, where $x$ is an $n$-dimensional vector of goods, $p$ the corresponding vector of prices and $I$ the income of the consumer. The basic idea of the alternative approach he proposed is to regard the arguments of the utility function not as goods but the *characteristics* or attributes of these goods that they provide to the consumer in varying amounts and proportions, the goods themselves being merely the means whereby the consumer satisfies his essential wants. A simple version of the Lancaster approach therefore regards the consumer as maximizing $U(z)$, where $z$ is an $m$-dimensional vector of characteristics, subject to $z = Bx$, where $B$ is an $(m \times n)$ matrix representing the ‘technology of consumption’ or the amount of each characteristic embodied in each good, and the budget constraint $px = I$ as before. Lancaster regards the number of characteristics $m$ as much smaller than the number of goods $n$ in a modern economy.

Suppose, for purposes of illustration, that $n$ is five and $m$ is two. Given $I$ and $p$ we can find how much of each good can be obtained if all of the income is spent on that good alone. The amounts of each of these five goods obtained this way yield a pair of the amounts of the two characteristics that they embody. Number these goods from one to five in descending order of the ratio of the first characteristic to the second that they provide. Each of these five pairs can be plotted as a point in a diagram with the first characteristic on the vertical and the second on the horizontal axis. These points form the five vertices and the straight lines connecting them the four edges or flats of the ‘characteristics-possibility frontier’ or CPF available to the consumer, given his income and the prices of the goods that he is facing. Superimposing the map of convex indifference curves between the two characteristics specified by $U(z)$, we can find the optimal choice of the two characteristics for the consumer by the point at which the highest attainable indifference curve is tangent to the CPF. If the optimal point is on a flat the consumer will demand the convex combination of the two goods spanning the flat yielding that point; the only other possibility is for the optimal point to be at a vertex, in which case only the corresponding good is demanded. Each consumer will therefore demand at most two of the five goods available to him. Any
other consumer will face the same price vector *p* for the goods and the same objective technology of consumption represented by the matrix *B*. Differences in income will result in radial expansions or contractions of the CPF, leaving its structure unchanged. The utility functions *U*(*)z* of the consumers will all in general differ, leading to different choices of the at most two goods that each demands, so that each of the five goods will have a positive demand in the market as a whole if the tastes for characteristics are sufficiently diverse. Adding together the amounts of each good demanded by all the consumers, we obtain a point on the market demand function for that good at the given price vector *p*. Repeating the analysis described for all possible price vectors, we can generate the market demand functions for all five goods by the Lancaster method and then proceed as usual.

The power of this alternative approach is perhaps best revealed by the problem of new goods. In the standard theory we would have to recast the entire utility function *U* as a function of six instead of five arguments in our example, with almost no restrictions capable of being placed on the properties of the new function in comparison with the old. In the Lancaster model, however, the utility function in characteristics space *U*(*)z*) is entirely unaffected by the introduction of the new good. Given its price the new good will appear in the budget constraint with an additional sixth term and in the matrix *B* as an additional sixth column, leading to a sixth vertex and a fifth ‘flat’ for the new CPF. The new good thus leads only to a change in the CPF, which is common for all consumers, with all individual utility functions in the space of characteristics unchanged, instead of each having to be altered in its own particular way in the space of goods. By looking at the CPF we can see exactly which consumers will be affected and which not by the introduction of the new good. If we consider the cases of electric light and candles, automobiles and the horse and buggy, compact discs and vinyl LP records, it is clear that the new goods altered the technology of consumption for all consumers by providing a ‘dominant’ new good that drove out the competing old one on efficiency grounds, rather than leading to a simultaneous subjective shift in tastes by all consumers. Though developed for the analysis of consumer demand, the characteristics approach is also clearly applicable to portfolio selection between alternative financial assets, occupational choice problems in labour economics, provision of public goods and services (see Lancaster, 1991, Part 3) and many other areas.

The characteristics approach also led Lancaster naturally to the problem of ‘socially optimal product differentiation’ that he investigated initially in an article, Lancaster (1975), and with considerably more depth and detail in the 1979 major treatise entitled *Variety, Equity and Efficiency*. To explain the essentials of this problem, consider once again the concept of the CPF introduced earlier. Suppose that we have a unit of ‘resources’, which can be used to produce many alternative goods, each yielding as before a set of characteristics. As the number of potential goods gets increasingly large we can think of the CPF in two dimensions as a continuous curve concave to the origin in characteristics space, like the familiar transformation curve in goods space. Which of these infinitely many alternative goods would be the one most preferred by a particular consumer, given his utility function *U*(*)z* over the two characteristics? This ‘most preferred good’ or MPG would obviously be defined by the point of tangency between the CPF and the highest attainable indifference curve, with the slope of a ray from the origin to the optimal point indicating the ratio of the two characteristics provided by the MPG. Other consumers with different tastes would have different MPGs. What should a social planner do if he wants to attain the objective of putting each consumer at a specified utility level with the minimum use of overall resources? In particular, how many and which goods should be produced? With constant returns to scale it is clear that each consumer should be provided with his MPG, in whatever amount is needed...
to place him at the desired welfare level. With increasing returns to scale, however, we have to trade off the provision of more variety against the sacrifice of less economies of scale. Most of Lancaster (1979) is devoted to a deep and subtle analysis of this fundamental problem under a wide range of alternative technological possibilities, market structures and compensation schemes for the attainment of equitable outcomes, with both first and second-best optima considered. This book, Lancaster's magnum opus, is undoubtedly a major landmark of economic theory that will continue to be an inspiration to the profession for decades to come.

The theory of international trade was another major area that attracted Lancaster's attention and benefited greatly from his application of these novel ideas to it. Early papers on the Heckscher–Ohlin model and the Stolper–Samuelson theorem (see Lancaster, 1996, chs 6 and 7) were followed by a pioneering paper (1980) on ‘Intra-industry Trade under Perfect Monopolistic Competition’, that together with and independently of Paul Krugman (1979; 1980), who was inspired by Dixit and Stiglitz (1977), launched what came to be known as the ‘new trade theory’, supplementing the standard Ricardian and Heckscher–Ohlin models of perfect competition with models involving economies of scale, differentiated products and monopolistic competition. Unlike the standard models it was easy to show that even identical economies could gain from trade and specialization by providing more variety for consumers in both countries and at lower prices for each differentiated product. The use of the convenient but highly restrictive Dixit–Stiglitz ‘love of variety’ utility function enabled Krugman to obtain this key result more easily and compactly than the more general framework used by Lancaster; but the latter offers additional insights not available in the former. Later papers considered tariff protection and monopoly policy in open economies in the context of the new trade theory (see Lancaster, 1996, Part 1).

At Columbia Lancaster regularly taught in the graduate theory sequence, a course built around his Mathematical Economics, an early advanced text published in 1968 the success of which around the world is attested by its translation into Spanish, Japanese, Russian and Rumanian. He also taught a popular undergraduate seminar with the noted philosopher Sidney Morgenbesser. He twice served as chairman of the Economics Department, first from 1973 to 1976 and then from 1989 to 1990. He was elected a Fellow of the Econometric Society, a Distinguished Fellow of the American Economic Association and a Fellow of the American Academy of Arts and Sciences. His death of cancer on 23 July 1999 deprived his university, colleagues, friends and family of a deeply original thinker and a wonderfully warm and compassionate human being. He is survived by his wife Dvora, sons Cliff and Gil, as well as by five grandchildren.

Abstract

While earlier research highlighted the potential market inefficiencies that can result from the particular characteristics of land, recent empirical evidence suggests that these may be small, not always amenable to policy intervention, and outweighed by the contribution of land markets to broader structural transformations, like population movements out of agriculture. High levels of transaction costs pose, however, still considerable obstacles to land market operation, suggesting that measures to reduce them through greater security and formalization of property rights, a streamlined regulatory framework, and ready availability of information may significantly improve functioning of, and enhance benefits from, land markets.

Land rental markets

In a world of perfect information, complete markets and zero transaction costs, the distribution of land ownership will affect welfare but will not matter for efficiency as everyone will operate his or her optimum farm size. However, in most empirical settings, the productivity of land use, and thus the impact of market-mediated transfers of land, will be affected by technology, producers’ ability, potential scale (dis)economies of agricultural production, risk, and imperfections in labour and credit markets. The range of possible contracts will, furthermore, depend on potential tenants’ endowments, their reservation utility, and the transaction costs associated with transferring land. Key questions include whether, with a given ownership distribution of land, rental markets will achieve socially desirable
outcomes, and which factors will enable participants to attain outcomes closer to the optimum. By varying the share and a fixed payment to the tenant, landowners who wish to rent can achieve any combination of contractual forms, from a wage labour contract or a share contract to a fixed-rent contract. While all contracts will lead to equivalent outcomes if output is certain and tenants’ effort can be enforced (Cheung, 1969), relaxation of this assumption gives way to a number of scenarios.

If effort cannot be monitored and agents are risk neutral, only the fixed-rent contract is optimal. The reason is that, in all other cases, equalizing the marginal disutility of effort to their marginal benefit will lead tenants to exert less than the socially optimal amount of effort, thus resulting in lower total production. The optimum outcome will require a trade-off between the risk-reducing properties of the fixed-wage contract, under which the tenant’s residual risk is zero, and the incentive effects of the fixed-rent contract, which would result in optimal effort supply but no insurance. Limited tenant wealth has a similar effect because in case of a negative shock tenants with insufficient wealth are likely to default on rent payments. This implies that landlords will tend to enter into fixed-rent contracts only with tenants who are wealthy enough to pay the rent under all possible output realizations, implying that poorer tenants will be offered only a share contract (Shetty 1988). Finally, a dynamic setting opens up a number of additional perspectives, in addition to the scope for using the repeated game context and the threat of eviction to reduce the efficiency losses of sharecropping. A rental contract that provides tenants with adequate incentives to maximize production in any given time period may lead to over-exploitation of the land if (dis)investment is considered, implying that a share contract with lower-powered incentives and possibly compensation may be more appropriate (Ray, 2005).

A large literature has focused on testing the extent of inefficiency of sharecropping contracts, although often with mixed results and inappropriate methods (Otsuka and Hayami, 1988). Use of within-household variation suggests that, in India, share tenancy is associated with an average loss of productivity of 16 per cent (Shaban, 1987) although part of the losses may have been policy-induced. More recent studies fail to find support for inefficiency of sharecropping (Pender and Fafchamps, 2006), suggesting that agents’ choice of contractual arrangements is rational given the constraints faced in a given situation and that the scope for government to bring about more effective outcomes may be limited.

While potential inefficiencies, if they exist at all, will thus be modest, productivity gains from land rental can be large. Analysis of the same plot before and after being rented in China points towards productivity gains of some 80 per cent, leading to a significant increase in welfare of tenants as well as landlords, in addition to helping the latter to migrate and gain access to non-agricultural income (Deininger and Jin, 2006). Although less direct, empirical analysis of determinants for rental market participation in a large number of countries suggests that the ability of those renting in is generally higher than that of those renting out (Deininger, 2003), implying a positive productivity impact of land rental which, at least in the case of China, is much superior to what is achieved by a social planner (Deininger and Jin, 2005).

The potentially important contribution of land rental to structural change is also illustrated by the fact that rental markets equalize the distribution of per capita operated land area and transfer land to those with lower levels of assets but higher levels of education, and that rental activity increases in settings where wage rates and thus non-agricultural opportunities are higher. Land rental is widespread in developing economies; 71 per cent of farmland is rented in Belgium, and 48 per cent, 47 per cent, and
43 per cent respectively in the Netherlands, France, and the United States (Swinnen and Vranken, 2006). Rental markets can emerge rapidly; for example, in Vietnam the share of participants in land rental increased from 3.8 per cent of rural households in 1992 to 15.8 per cent in 1998. They were also of great importance in the countries of eastern Europe and the former Soviet Union during the initial phases of economic transition, especially where radical individualization of land was pursued, such as in Albania and Moldova. As long as transaction costs arising from fragmentation were not too high, rental was critical where land had been restored to original owners, many of whom had little intention to use it but also did not want to part with their asset. In West Africa, long-term sharing arrangements did historically provide important incentives for long-term investment and, even though increased population density has shifted contractual parameters in favour of landlords, rental continues to be important in providing land access and increasing productivity.

Of course, a high incidence of rental transactions, and the fact that observed transactions had a positive impact, do not imply that the level of rental activity is optimal. Qualitative and quantitative evidence points towards considerable rationing in rental markets. For example in India, farmers are able to realize only about 75 per cent of their desired level of land transactions (Skoufias, 1995), implying that transaction costs or land rental remain high. Two key factors contributing to these are limited security of property rights, which makes renting out too risky, and implicit or explicit restrictions on rental markets in the form of either rent ceilings or the award of property rights to tenants. Even if it leads to only a small decrease of the probability that landlords who rent out their land will get it back upon termination of the contract, insecurity of property rights can significantly reduce the supply of land to the rental market. This is confirmed by econometric studies in countries as diverse as the Dominican Republic, Nicaragua, China, Ethiopia, Vietnam, and Bulgaria. While insecure tenure may not prevent landlords from renting out completely, it often prompts them to rent only to close kin, where enforcement is easier even if, due to the limited pool of renters to choose from, productivity will be lower than from renting to outsiders, as is indeed observed in the case of Vietnam (Deininger and Jin, 2007).

Beyond tenure insecurity, rent ceilings or regulations that aim to confer de facto property rights on tenants by preventing landlords from evicting them and giving heritable use rights to tenants after a certain period of time are a frequent source of inefficiency in rental markets. Although the original intent was to improve equity, such measures led in many cases to self-cultivation by landlords or the adoption of wage labour contracts, both modes of production that are inferior to tenancy in terms of production incentives and outcomes. Analysis shows that, while rent controls can transfer resources to sitting tenants, they tend to make those who are not lucky enough to already sit on tenanted land worse off by restricting the supply of land available to the rental market, undermining tenure security, and reducing investment (Basu and Emerson, 2000). Similarly, conferring heritable (but often non-transferable) use rights on tenants, subject to the requirement that they continue paying rent, can increase welfare in the short term but will – in the medium to long term – reduce investment incentives and supply of land to rental markets in a way that is particularly detrimental to the poor and landless, as in the case of India (Deininger, Jin and Nagarajan, 2006) where such legislation has driven a large number of contracts into informality.

**Land sales markets**
Land sales markets provide an opportunity to obtain land for permanent use which will be associated with higher investment incentives than renting. In addition, markets for land sales are a precondition for using land as collateral in credit markets. If all markets were perfect, the sale price of land would equal the net present value of the stream of profits that can be derived from a given land use, and potential buyers would be indifferent between renting land and purchasing it. However, land sales markets will be affected by a number of factors that include (a) the ability to use land as a collateral in credit markets and thus overcome credit constraints; (b) expectations about future increases in land values due to infrastructure construction or population growth; (c) the risk–return profile and liquidity implications of holding land as compared with other assets; and (d) the level of transaction costs in land sales markets.

In economies where risk is high, land is important as a store of wealth, and access to outside credit is limited, land prices can fluctuate significantly over time (Zimmerman and Carter, 1999). The reason is that, because returns from agricultural production are highly covariate, demand for land, and therefore land prices, will be high in good crop years when savings are high, sellers are few, and potential buyers of land are many. At the same time, households’ need to satisfy basic subsistence needs can give rise to a large supply of land by people who are forced to engage in distress sales of their land in bad years, often to individuals with incomes or assets from outside the local rural economy (Cain, 1981). Such distress sales rarely enhance productivity, and improved functioning of markets for insurance and credit to avoid them will be important.

If covariance of asset prices is observed, those who sell off land during crises will not be able to repurchase it during subsequent periods of recovery, creating a potential for successive decline of asset endowments (Zimmerman and Carter, 2003). In high-risk environments this may lead the poor to prefer assets with a lower but more stable returns to land even if they had access to credit, implying that, in situations where land is very unequally distributed as in Latin America, land sales markets will not be a good way to achieve asset redistribution, and other measures, such as grants, may be needed to increase land access by the poor on a broader scale.

With macroeconomic instability, an expectation of future land price increases, or lack of sufficiently attractive alternative assets, land may be acquired for speculative rather than productive purposes. For example, inflation and changes in real returns on alternative uses of capital were shown to be key factors explaining changes in land prices in the United States. In eastern European countries, the expectation of large capital inflows due to EU accession was a major factor underlying real estate booms that propelled land prices far beyond the net present value of the flow of services that could be derived from the land. Credit or tax preferences, together with weak regulatory oversight, can reinforce such trends which, in the extreme, can lead to bank crises with far-reaching consequences.

Although empirical study of the functioning of land sales markets is more limited than for rental markets, evidence from India over the 1982–99 period supports the notion that distress sales are important, but that options to insure against risk – for example, the presence of safety net programmes or access to bank branches – helped to reduce or eliminate the adverse impact of climatic shocks. Moreover, there is little evidence of a negative impact of land sales markets on productivity or of speculative land accumulation, partly because of land ownership ceilings and partly because of increased availability of other stores of wealth. Although the number of landless who were able to purchase land remained modest, land sales markets constituted the most important avenue to access land by the poor (Nagarajan, Deininger and Jin, 2007).
Well-intended land sales restrictions in a number of countries failed to prevent distress sales but instead drove them into informality. Safety nets and measures to increase access to savings and insurance may be more effective to prevent socially undesirable land loss by the poor. One possible exception is in the transition from customary to more individualized forms of tenure whereby the potential for opportunistic behaviour and land sales by local chiefs is high. To counter this risk, a decision at the local level to maintain a customary land tenure regime that outlaws land transfers outside the community, similar to what was done in the Mexican *ejido* reforms (World Bank, 2002), may be an appropriate second-best solution (Andolfatto, 2002). As long as it results from a conscious choice and there are transparent mechanisms for changing the tenure regime, such a rule is unlikely to be harmful because, once potential advantages exceed the cost at the local level, communities are likely to change the rules to allow sales.

**Policy options to improve the functioning of land markets**

Land registries to make information on property rights available publicly in a cost-effective way have many advantages. They reduce the risk of land loss by landlords renting out, and provide the basis for credit market transactions. While informal rights can provide security within a well-defined and socially cohesive group, they preclude trade and exchange beyond this realm. Once gains from transactions with outsiders became sufficiently high, informal rights are likely to be replaced by formalized property right systems and associated enforcement institutions, leading eventually to abstract representation and the impersonal exchange of rights that allows the emergence of more abstract instruments such as mortgages based on the existing rights system (de Soto, 2000). Making information on private as well as public land ownership widely available would also reduce the potential for opportunistic behaviour and appropriation of public land by powerful interests as resource values rise.

While disputes among private parties can limit the propensity to rent out land, threats of expropriation without (or with only very limited and delayed) compensation and for a very broadly defined public purpose, which in many countries includes transfer of land to private investors, will limit incentives for investment and can prompt informal pre-emptive land transactions at very low prices that improve neither efficiency nor equity. To prevent this, it is critical to have a restrictive definition of public interest, to ensure compensation at market values if expropriation is unavoidable. If for political reasons ceilings cannot be abandoned altogether, they should be limited to preventing speculative land accumulation. Similarly, land use regulations should be used only if needed to avoid undesirable externalities and if capacity for cost-effective implementation is available.

As public investment in infrastructure and other amenities will be capitalized in land values, taxing land comes close to a benefit tax, and is less distorting than taxes on sales or income. It has thus been considered to be an ideal revenue source for local governments. Land taxes that effectively tax resource rents, that is, that are based on the normal potential yield from a certain plot, will discourage speculation and encourage land owners who are not able to make the most efficient use of their land to rent it out to others. Local land taxes are used effectively in the United States where they have been shown to induce land development. Although underexploited in the past, their potential to intensify land use – which is greater than that of other instruments – has provided a motivation for reforms in a number of countries (Bird, 2004).

The often limited ability of the poor to access land through purchase implies that market forces may be
unable to correct highly unequal and often inefficient distribution of land, thereby moving the economy towards an equilibrium with a more equal distribution of opportunities and higher overall output. Land reforms in Asia, such as in Japan, Korea, and Taiwan (China), or the abolition of intermediaries in India, and some of the immediate post-independence efforts in Africa – all of which were accomplished under external pressure or immediately after independence – illustrate that land reform can improve household well-being and productive efficiency. At the same time, in many other countries, including virtually all of Latin America, success often remained elusive because, among other things, such measures were guided by short-term political objectives, insufficient effort was devoted to ensuring access to complementary inputs and the competitiveness of producers, and the mechanisms adopted to implement land reform, like ceilings or rent controls, often undermined the functioning of land markets, thus limiting the potential for synergies. Together with multiple restrictions on beneficiaries’ ability to transfer the land received, this often limited the scope for land reforms to bring about sustained improvement in beneficiaries’ living conditions.

In countries where an unequal distribution of land or incomplete past reforms imply that land reform remains on the agenda, there is broad agreement on a number of common principles (Deininger, 2003). These include (a) the need to have programmes integrated into a broader development strategy that includes training and capacity building, as well as provisions for complementary investment to make the land productive so as to help put households on a viable trajectory of development; (b) a design based on clear and transparent rules that aims to maximize productivity gains; (c) a multiplicity of paths to land access needed to underpin land reform, including, in addition to state-sponsored land transfers, progressive land taxation to increase the supply of underutilized land, divestiture of suitable state land, foreclosure of mortgaged land, and rental and sales markets; (d) secure and unconditional rights for beneficiaries, including the right to rent or sell their land, perhaps after some initial period; and (e) an undistorted policy environment supportive of smallholder agriculture, decentralized implementation, and respect for the rule of law, in particular existing property rights.

Taxation is the form of socialization used in market economies. Choosing what to tax is choosing what to socialize. Rather than socialize labour or repel capital it is possible to tax land. Land holds a unique place in the distributional ethic because it is (by definition) of natural origin. Man did not create Earth with its resources but rather fights over it. Land is also (with exceptions) more nearly permanent than man or his works. Thus, rent as private income neither elicits the supply nor preserves it. Its main function is to allocate the fixed supply among uses, but it is arguable that land taxes, when based on land's capacity-to-serve, are at worst neutral to this function and at best improve on it.

The philosophical rationale for land taxes is strongest under an organic theory of the polity. It is no accident that Henry George (prominent protagonist of land taxes) crystallized his ideas after reading Andrew Bisset's *Strength of Nations* on feudal levies. Landholders have a privilege from the state and in return are liable for taxes in perpetuity.

The entire value of land, now and for ever, is here regarded as a benefit received from government. This is consistent with Alfred Marshall's concept, ‘the public value of land’, where value is the product of three things: nature; government; and spillover values from development of adjoining and linked lands. All these values, being unearned by the individual landholder, are fit to be taxed.

The organic view distinguishes the land from its holder. Land taxes may be paid by income the land earns, not by the holder as a person unless we identify him with the land and regard him as having a prior right to own land free of liabilities to the public from which he holds title. The contractual theory, by contrast, treats government as a kind of business, extending services to specific lands whose holders need pay only for recent benefits received, construed narrowly.

The rationale for land taxes presumes a functional attitude toward distribution, regarding property not as
an end in itself but a means to get things done. A land tax based on market value, not varying with actual use, is a fixed cost that sharpens marginal incentives. Critics today seldom argue otherwise, but oppose land taxes precisely because they do force landholders to respond to the market, which may have its own faults in a world of ‘second-best’.

Land taxes are in rem and so disregard the holder's personal circumstances, a drawback in some opinions. On the other hand landholdings are much more concentrated than the receipt of income or taxable consumption or payrolls, and land taxes are not shifted, making the tax inherently progressive even though but loosely correlated with taxable income. Avoiding land taxes is next to impossible, even though collection enforcement is limited to seizing the land, not the person or any other asset.

The rationale includes a concept of landholder stewardship. A limited number of land titles were issued in order to get land under tenure to assure best use. So far so good, but those not receiving or inheriting land need a counterpoise to assure they receive their share. Land taxes do so in three ways: by supporting government; by pressing landholders to produce goods and services; and pressing them to hire workers to do so. Land taxes act as a kind of social audit and performance standard of stewardship to promote equity towards those excluded.

There is also more equity among landholders, which in turn promotes efficiency. Absent land taxes there is pressure on government to do as much for A's land as for B's. Efficiency, however, calls for specialization and differentiation, meaning high values for some land and low values for other, with windfalls and wipeouts. Land taxes automatically compensate the losers from the gains of the winners, thus freeing land planners to maximize the joint benefits.

The rationale of equity for the excluded says that lands with open general access like parks and roadways should be exempted in whole or in part. But such exemption can lead to overcrowding, to meet which it is clear that some user charges on such land can be construed as special kinds of land taxes. An obvious example is a charge on large trucks in downtown streets. Lacking any such constraint the crowding might in turn lead to indefinite expansion of the exempt land use.

The rationale is only partly consonant with personal ability to pay. Landholding confers potential ability to pay, but that is only realized upon one's using the land well. And earned cash is not tapped at all. A land tax is a fixed periodic charge. It is based on qualities inherent in the land with few concessions to the landholder's personal illiquidity, weakness, setbacks or ageing. ‘Use it or sell it’ is the message, which many consider too harsh.

What is harsh for the distressed holder, however, is accommodating to frustrated buyers, and it boils down to which group shall be accommodated. Since liquidity is known not to increase in step with total wealth, imposing taxes on landed but illiquid holders has a strong progressive effect. The regular flow of land taxes also accommodates governments, especially small local ones needing steady revenues that are not turned on and off at the convenience of others.

It is not always a question of selling complete units. Land around homes and enterprises is subject to sharply diminishing marginal utility or productivity and a function of land taxes is to constrain horizontal extension of holdings, to the end that the nucleus of each holding may be closer to others to facilitate trade, cooperation, linkages, sharing common costs, and other synergies. The ‘highest and best use’ of land is usually that which most relates to and complements its neighbours and trading partners, who must not be held too far distant.

There is also a diminishing return to time as buildings age, and a function of land taxes, in conjunction with building exemption, is to advance (and/or stop retarding) renewal of sites, neighbourhoods, cities,
regions and whole economies.

Locke, Quesnay, Adam Smith and others have shown a tendency to shift all taxes to land, whatever the nominal base or event, assuming elastic supplies of labour and capital. This leads some to conclude that all taxes alike just tap land rent. But one cannot tap rent where there is none. Taxes on other bases simply abort the taxed input or activity at the no-rent margins of land use, both extensive and intensive. This excess burden in turn puts an upper limit on the possible tax rate, thus sparing much rent from being taxed at all while destroying other rent completely. The only way to tap much rent is to tax land directly.

Land value and capital are not convertible into one another (excepting exhaustible minerals, not treated here). From this it follows that efficiency does not require equal tax rates on the two, but only uniformity within each class. Uniformity is impossible with capital because of differential concealability. But land is uniformly non-concealable. The case for neutrality of land taxes is stronger under uniformity, but mainly requires that the tax not be a function of use.

A land tax may be based on the current potential rent, or on value. In practice, it is the latter. Values are not simply proportional to rents because many land values are elevated above that by expected higher future rents. In such cases taxes rise high relative to cash flow, and at a stiff rate may even be higher. This subjects the holders to a cash drain. The extra tax may be shown, however, in general to tax the unrealized increment, in the manner advocated by Haig–Simons, at the time it accrues. There is some recent falling-away from Haig–Simons, and to one school now this is ‘double taxation’, an issue currently mooted.

The most controversial question in land taxation is the effect on appreciating land. Most hands agree the land tax advances conversion to the higher use. To Henry George this ‘sovereign remedy’ would correct a market failure and unlock speculative holdings with profoundly beneficial effects. To several modern writers following Richard T. Ely the advance of conversion is unneutral and somewhat wasteful. Speculation is seen as efficiently keeping land from premature commitments. To this writer it seems mathematically obvious that an efficient adaptation to rising future incomes would result in advancing, not retarding conversion. But the issue is now moot.

Land taxation at the local level has a natural cap in local particularism as expressed in ‘Don’t swamp the lifeboat’. Land taxation by a central national government might go much heavier, and accordingly statesmen like Austen Chamberlain in Britain and James Madison in America have contrived to divert land taxation to local governments. Colin Clark, on the other hand, published a plan to nationalize land through taxation without depriving the poorer localities. He would rank the local jurisdictions in order of land value per capita, and apply a central government surtax starting from zero but graduated upwards according to this ratio. The scheme basically had central government apply to local ones the same principle of direct land taxation that local governments can apply to individuals, tapping the rich rents without destroying marginal rents. Clark, like George, may have been reading Bisset's *Strength of Nations*.

Article

Born on 29 September 1874 in Ajaccio, Corsica, Landry died in Paris on 28 August 1956. A graduate of the Ecole Normale Supérieure, he began as a philosopher, then turned to economics and demography. From 1907 on he held the chair of economic history and history of economics at the Ecole Pratique des Hautes Etudes, Paris. He was elected as a Deputy for Corsica in 1910 for the Radical Socialist party, serving as Minister of Navy in 1920, of Public Instruction in 1924, and of Labour in 1932. As a member of Parliament he was particularly effective in promoting family legislation and family allowances which, intended to stimulate fertility, became quite substantial (subsidies to large families in 1913, the Code de la famille in 1939, and the law on family allowances in 1946).

Very early in his study of economics, Landry revealed himself as a gifted theoretician. His approach was purely literary but analytical and rigorous. He was able to master fully technical arguments and, for instance, early exposed in France the definition and relevance of the new demographic indicators proposed by Lotka and Kuczynski. His culture was quite broad and up to date. He was an explicit proponent of the deductive methodology.

His initial concern was with the theory of income distribution. In his dissertation (1901), which made him known as a socialist, he argued that individual ownership and the subsequent unequal distribution of property rights could not be considered as socially optimal and was responsible for a smaller national output than was feasible. His 1904 book was an excellent presentation of the theory of interest in continuation of Böhm-Bawerk, showing why interest was just an aspect of the general theory of value, paying particular attention to the productivity of capital and criticizing Böhm-Bawerk for his overemphasis on the length of the production process. His two articles on the theory of pure profits (1908b and 1938) discussed the role of uncertainty, the idea of risk aversion being already explicit in 1908. However, Landry refrained from making this the first determinant, arguing that this was rather the

scarcity of entrepreneurs, who must simultaneously have capital, abilities and will. Also interesting are his two long articles. Starting in 1910 from a discussion introduced in 1755 by Cantillon on the demographic impact of a change in landlords’ consumption behaviour, Landry finally explains why the returns to primary factors indeed vary with exogenous shifts of individual preferences. Discussing unemployment in 1935, he explains that it reveals an excess of the wage rate over the marginal productivity of labour but is mainly due to a depression of this productivity and can be cured by measures that will raise it again.

From his first writings, Landry always paid attention to population, which later became his main concern. His 1909 article introduced the distinction between three demographic regimes, population being regulated by mortality and the minimum of subsistence in the first case, by fertility behaviour and the wish to achieve some standard of living in the other two, but whereas in the 18th century the objective was a stationary standard of living, it shifted to a permanently progressive one in the late 19th century, ‘social capillarity’ making this progress feasible for everybody’s children. His 1929 article on the optimal size of the population is interesting since it introduces an objective function that was also preferred in the theory of optimal economic growth in the 1960s: a sum of annual terms in which each term is the product of population size and a utility of average consumption per person. His main thesis, developed in his 1934 book, was that a decreasing population leads to decadence, this thesis being substantiated by a study of Ancient Greece and of the cultural centres of the Roman empire.

Lange, Oskar Ryszard (1904–1965)

Tadeusz Kowalik
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Oskar Lange was a well-known economist, socialist thinker and politician. His special position in economics rested on his profound knowledge of its main currents, of both Marxist economics and Western academic economics (above all the neoclassical) and later of both capitalist and centrally planned eastern European economies. With Abba P. Lerner he was one of the founders of the theory of market socialism. This induced him to make several attempts at a ‘major synthesis’ and to undertake political actions aiming for a rapprochement between the West and the Communist world, for peaceful coexistence, economic cooperation and systemic convergence.

Article

Lange was born on 27 July 1904 in Tomaszow Mazowiecki, near Lodz, Poland, into the family of a German-born, assimilated textile manufacturer, and died on 2 October 1965 in a London hospital following thigh surgery. He studied law and economics in Poznan and Cracow. His main tutor was
Adam Krzyzanowski, liberal and Anglophile. In 1929, Lange studied in London and in 1934–5 in the United States, mostly at Harvard and Berkeley. He lectured in statistics and economics in Cracow (1927–37), Chicago (1938–45) and Warsaw (1948–65). Politically involved since his youth, he was active at the Independent Socialist Youth Union in the interwar period. During the Second World War he pushed the cause of Soviet–American rapprochement and socialist–communist cooperation. He served as the first ambassador of the Polish People's Republic in Washington (1945–6) and as the Polish delegate to the UN Security Council (1946–7). Later he was a member of parliament and a member of the State Council in Poland.

Lange's special position in economic theory rested on his profound knowledge of its main currents, of both Marxist economics and Western academic economics (above all the neoclassical) and later of both capitalist and centrally planned Eastern European socialist economies. This induced him to make several attempts at a ‘major synthesis’ and to undertake political actions for a rapprochement between the West and the Communist world, for peaceful coexistence and economic cooperation.

**Capitalism and economics**

The capitalist economy was Lange's chief research concern from his early youth until the end of the Second World War. His primary interests included the study of business cycles and the evolution of capitalism. His Ph.D. thesis was a study of business cycles in the Polish economy 1923–7 (1928a), and won the title of docent (assistant professor) for a statistical study of the business cycle (1931a). These were among the chief topics of his lectures at US universities, mainly in Chicago. Early in the war he studied, together with L. Hurwicz, ways of empirical verification of business cycle theories. Although he became a leading authority on this subject (see his review, 1941a, of Schumpeter's book and, 1941b, on Kalecki's cycle theory), he never produced a complete theory of his own. His studies of the business cycle led him to econometrics, a discipline he helped create (during the Second World War he edited the quarterly *Econometrica*). His textbook of econometrics (1959), the first of its kind in eastern European countries, recapitulates his studies of business cycle and of market mechanisms, in addition to an outline of programming theory based on Leontief's input–output tables and on Marxian reproduction schemata. The evolution of capitalism was a close interest both as a scholar and as a political writer. Initially he believed that the development of large corporations marked a transition from ‘the anarchical freemarket capitalist economy to a consciously planned economy’ (1929[1973, p. 70]), that is, to an organized capitalism. But with the Great Depression those hopes vanished. Monopolies and government intervention cause chaos and disarray in the economy and led eventually to a collapse of capitalism and the victory of socialism (1931b[1973]). Soon, however, he came to the conclusion that ‘it was not capitalism but the worker movement which collapsed during the crisis’ resulting in a ‘stabilization of capitalism’ (1933[1973, p. 63]).

Just before and during the war, Lange often argued that capitalism cannot possibly be reconciled with economic progress in the long run. But at the same time he looked for ways of reforming capitalist structures to turn them into mixed-type economies – calling for a socialization of the monopolies which he regarded as threats to political democracy and which he blamed for generating unemployment. During his stay in the United States, Lange published a number of contributions exploring and developing, as well as criticizing, the standard economics which was, and continues to be, taught at most universities in the West. Those studies fall roughly into two categories: the first was ‘pre-Keynesian’
from the point of view of general approach, while the other was closely connected with the absorption of
the ‘Keynesian Revolution’ by traditional economics.
In one major study (1936b; 1937b), Lange tried to explore the relationships between interest theory and
the theory of production factor cost. Using a strongly simplified model (one final commodity produced
by labour and one capital good, free competition, ‘neutral’ role of money, risk is neglected), Lange
unfolded a theory of interest which in many of its points came close to that of Frank Knight, even
though in his concept of money capital (‘as a general command over means of production’) he was
influenced more strongly by Schumpeter and Marx.
Lange is regarded as one of the founders of ‘modern welfare economics’ (Graaff, 1957). Following
Bergson's pioneering study (Burk, 1938), Lange listed (1942a) theorems, which do not require
interpersonal comparability of utility as well as those which do. The study of optimal distribution of
incomes must be based on a priori hypotheses concerning marginal utility of incomes for different
persons. For welfare economics propositions it is not necessary that utilities of individuals must be
measurable as long as these utilities can be ordered.
The next and probably most important group of studies concern Keynesian theory's relationship to the
mainstream of Western economic thinking. In a (1938b) study, Lange explores the internal logic of
Keynes's theory investigating the mutual relations between interest rate, propensity to consume,
 marginal efficiency of capital, investment and national income. In Lange's model, elasticity is the all-
decisive concept. Using this concept and some of Walras's ideas, Lange outlined a ‘general theory’ of
which the Keynesian theory was one particular case. That special case occurs when elasticity of liquidity
preference to income is close to zero or when it is infinitely great in relation to the rate of interest. Then,
the rate of interest does not depend on marginal efficiency of capital or on propensity to consume. When
the elasticity of liquidity preference to the rate of interest is close to zero, then the classical and
neoclassical theory, stressing the dependence of money demand on income alone, holds. Keynes
approved Lange's interpretation of his theory as following ‘closely and accurately my line of
thought’ (Keynes, 1973, p. 232n). Lange's exposition of the notion of multiplier (1943a) was more
modest in its intention.
Analysing Say's Law (1942b), Lange made one of the first ever attempts to overcome what was called
the dichotomy of the pricing process. In traditional neoclassical theory, commodity prices were
determined under the assumption that money is just ‘a worthless medium of exchange and a standard of
value’ (1942b, p. 64), and hence of a barter economy. Only later on, prices determined in this way, were
pecuniary prices ‘superimposed’. Accordingly, the substitution of money for commodities and vice
versa was ignored completely. That was the gist of the assumption that total demand is identically equal
to the total supply of commodities. Thus, the theory of money must start with the rejection of this
contention (of Say's Law) and investigate conditions and processes leading to equilibrium of total
demand with total supply. For this purpose, money must be included in the theory of general equilibrium.
These studies prepared the ground for a more ambitious synthesis. In his previous studies, Lange had
already studied questions and problems asked by Keynes (this partly holds also for the theorists of
imperfect competition and for Schumpeter) and tried to resolve them in his own fashion, relying on
mathematical tools of general economic equilibrium as developed and modified by Henry Schultz, R.G.
D. Allen and Paul Samuelson, but especially by J.R. Hicks.
That undertaking found its most complete and systematic exposition in Lange's (1944a) book, which
sums up his theoretical work during his American period. The book is something like a restatement of
the theory of general economic equilibrium in which money is incorporated explicitly as part of this theory. Substitution between money and goods is the key concept for understanding processes of equilibrating and disequilibrating the national economy. As Lange puts it, ‘The interest in the problem and the recognition of the crucial importance of substitution between money and goods were inspired by Lord Keynes. For the tools of analysis the author is heavily indebted to Professor J.R. Hicks’ (1944a, p. vii).

But Lange's book was an outcome as much of theoretical as of practical disputes over general economic policy. His main point of interest was the belief, which survived repeated attacks from Keynesians, that price flexibility – and in particular flexible prices of production factors, mainly of labour – is a condition of full utilization of production factors. Defending the Keynesians’ position on this matter, Lange intended to reach both the general public and sophisticated, mathematically minded economists who refuted Keynes's language of aggregate concepts as too unscientific.

With a view of such different audiences, Lange composed his exposition at two or even three levels of difficulty. The main body of the book is ‘as simple as possible’ and in colloquial non-mathematical language full of socio-political corollaries. Only in the numerous footnotes did he present technical details. The final part of the book, called ‘The Stability of Economic Equilibrium’ and published as an appendix, is in rigid mathematical language and is addressed to the narrower group of specialists.

The book's main message can be summarized in the following way. There are three ways in which money can affect economic equilibrium under flexible prices:

1. 1. If the overall amount of money is constant, the fall in prices of a factor leads at first to a fall in other prices and to a growth in purchasing power of the existing stock of money. An excess supply of money arises. This, in turn, drives up demand for goods and checks prices from falling further. As other prices are falling less quickly than that of the factor under consideration, demand for this factor increases. Along with that, the amount of loanable funds grows, which causes a fall of the interest rate. This, then, encourages investment and results in employment growth. This is the case of the effect of money being positive.

2. 2. When the overall amount of money is determined by credit creation and changes in step with the changing demand for money (cash balances), the effect of money can be said to be neutral. In this case, the mechanism of automatic maintenance and restoration of equilibrium no longer works. The stock of money shrinks in proportion to the falling demand for cash balances and an excess money supply develops. The purchasing power of the stock of money remains unchanged. In consequence, the fall in prices is not checked by a rise in the purchasing power of the stock of money and interest rates do not fall. The excess supply of the production factor under consideration is not being absorbed.

3. 3. Money has a negative effect when its amount shrinks more than proportionately to falling demand for cash balances. Banks, for example, react to the fall in prices by demanding loan repayment. A shortage of money is then felt in the market. Pessimism, growing uncertainty, and so on fosters this development. Then, a fall in the given production factor's price (for example, wages) causes an even more dramatic fall in prices of other goods, which leads to an even larger excess supply of the production factor than was the case originally (for example, to even higher unemployment).
Lange's general conclusion from his analysis was quite pessimistic:

Only under very special conditions does price flexibility result in the automatic maintenance of restoration of equilibrium of demand for and supply of factors of production. These conditions require the combination of such a responsiveness of the monetary system and such elasticities of price expectations as produce a positive monetary effect, sensitivity of intertemporal substitution to changes in interest rates ..., absence of highly specialized factors with demand or supply dependent on strongly elastic price expectations, and finally, absence of oligopolistic or oligopsonistic rigidities of output and input. To a certain extent, the absence of a positive monetary effect may be replaced by the stabilizing influence of foreign trade ... (1944a, p. 83)

On the whole, Lange regarded price flexibility as 'a workable norm' of long-run but not necessarily short-run economic policy during the long period of between the 1840s and 1914. However, the favourable conditions which prevailed during that period belong to the remote past. The oligopolization process, the deteriorating investment opportunities, the tendency towards money supply caused by new technology applications, along with the bad experiences of the two world wars and the Great Depression – all these made any automatic attainment of equilibrium and stability a very unlikely prospect. This conclusion prompts two questions. First, what significance does the general economic equilibrium theory have for economic theory and for economic policy? Several years later, Lange compared that theory, which deals with very unlikely contingencies, to the case of an ape trying to write the Encyclopaedia Britannica. While probability calculus does not preclude such a possibility, we should ask ourselves if dealing with such an unlikely case is not an utterly futile exercise.

Price flexibility was the last fruit of Lange's study of the general equilibrium theory. To what extent his subsequent silence on this subject was due to the fact that, after 1945, he found himself in an entirely different environment, and to what extent due to his disenchantment with the theory, is difficult to say. Anyway, his economic thinking in later years took an unexpected turn. Contrary to his attitude in public life, as a philosopher of science Lange was rather conservative-minded, believing that 'science does not progress ... by the wholesale rejection of old theories and the devising of new ones, but by arduous work of enriching and improving existing scientific achievements' (1970, pp. 80–1). Accordingly, he put a great deal of effort into showing that the so-called Keynesian Revolution was no revolution at all; and that it should be viewed as a contribution merely ‘enriching and improving scientific achievements’. But when he accomplished that job, Lange dropped the synthesis he had worked out with such a great expense of effort only to choose an alternative paradigm.

After the Second World War, however, Lange only sporadically resumed his study of capitalism, mainly to consider whether capitalism is able to resolve economic problems of backward countries (to which his answer was emphatically negative, 1957) or prospects for disarmament and economic cooperation between the Council for Mutual Economic Assistance countries and the capitalist West.

Lange–Breit model of socialist economy

Lange first manifested himself as a socialist writer in his book (1928b) on Edward Abramowski (1868–1918), whose ideology Lange called ‘constructive anarchism’. In those ideas, Lange emphasized
Abramowski's resentment of government interventionism, pitting it against the ideas of English Guild Socialism and of Austro-Marxism, both of which had strongly influenced Lange himself. Lange advocated especially the idea of industrial self-government, of separating the economy from political power, and the decay of the state as an institution of class domination though not of an instrument of coercion.

Together with Marek Breit (1907–42), he wrote the first outline of a socialist economy's functioning in the chapter of a collective book, *Economy–Polity–Tactics–Organization of Socialism* (1934[1973]). It was the product of a group of left-wing socialists, led by Lange, and committed to the revolutionary reconstruction of a system in Poland, which would be different from the Soviet model of polity and economy.

The Lange–Breit model, or the 1934 model (see Kowalik, 1970; 1974; Chilosi, 1986, 2005; Toporowski, 2003) is one version of a corporate market economy under socialism. It rests on the following rules. Plants should go public, or be ‘socialized’, in his terminology, by transferring private ownership titles to a Public Bank and by organizing the national economy into public trusts by industrial branches. Trusts would be the basic units of the economy and endowed with a great deal of autonomy. The decisive say in their boards would belong to workers, who would be organized into ‘an appropriate system of worker councils’. Trusts autonomy is limited by the Public Bank's supervision and coordination functions or, more exactly, by the functions performed by a uniform and monopolistic bank system. Basic planning instruments would include accumulation fund management and trust financing. The Public Bank would also watch if trusts and companies subordinate to them abided by management rules, in particular by rules of ‘rigorous’ price and cost accounting. Plants run at a loss would be closed down. Plants failing to record an average surplus would forfeit their right to get loans not only for expansion but even for ordinary capital replacement, and hence they would decline. Both trusts and plants would be obliged not only to remit their production costs but also to achieve a certain accumulation, the rate of which would be established by the Public Bank and subsequently redistributed for investment and for subsidizing public utilities (which may be run at a loss).

Since trusts would hold virtually monopoly power in the market, as all public plants would by law belong to some trust, Lange and Breit perceived the danger of charging excessive prices and cutting output rates. They realized that such a policy might become quite popular among employees of any given trust, who might hope to get their wages increased. To forestall monopoly practices, they therefore proposed to oblige trusts to take on all job-seekers applying to them. If price increases resulted in higher wages in any given trust, employees from other trusts would swarm to it so that the increased wage fund would have to be redistributed among a larger number of employees. The underlying purpose of that obligation, then, was to deter trusts from driving up prices.

As the two authors did not consider the question of inflation, they did not say why excessive wage increases by one trust should not set off an avalanche of price increases if other trusts attempted to forestall an exodus of their own workforce. Nor did they envisage possible consequences of the indivisible nature of means of production and of possible consequences of delays in market adaptation. Moreover, the Public Bank's investment policy would be based on workforce migration in reaction to changing demand, price fluctuations and subsequently price changes. This was to be something like an automatic indicator of demand intensity for individual goods.

The Public Bank would further control capital imports and exports, whereas a ‘foreign trade office’ created by the trusts concerned would be in charge of goods sales and purchases abroad. The Public
Bank would also be authorized to transfer capital assets from trust to trust. The private sector, which is consistently referred to as the ‘non-socialized’, that is, non-public, sector of the economy, was to remain ‘broad’, consisting of private farms holding less than 20 hectares of land, crafts shops, business enterprises with less than 20 people on their payrolls, as well as retail trade shops. However, because economies of scale were expected to impart higher efficiency to larger companies, the private sector would be ‘a relic on the way out’. The two authors said nothing about credit policies towards this sector, but the Public Bank would conduct a discriminatory kind of policy towards profit-making small capitalist businesses (up to 20 employees) designed eventually to bring about their demise through taxes. Lange and Breit recommended that the Public Bank should levy taxes equal to the accumulation rate, which was supposed to reduce owners’ incomes to the level of manager's salaries. The two authors failed to take account of the role of risk and innovation.

Nor is it clear how the two authors thought plants (which they preferred not to call enterprises) would be managed, or how trusts would be organized and what prerogatives the latter would have. They merely said workers organized in a system of worker councils would have the decisive say and that trade unions and worker cooperatives were best suited to create trusts. Nor did they propose any clear procedure for appointing the Public Bank's board of management, which was expected to make the socialist economy a planned economy. Designed as an alternative model to the command–planning system then existing in the Soviet Union, the Lange–Breit concept was largely reminiscent of Bolshevik concepts from before the period of wartime communism or right after it (trusts, worker councils, a single state-owned bank, a long-run policy of farm collectivization), modified by an emphasis on separating political authority from economic organization, on impartial economic criteria, and on recognizing consumer preferences as the foundation of investment policies.

The theory of market socialism

The next model of socialist economy, which I propose to call the classical, Lange presented in a study (originally published as two articles, 1936a; 1937a), and in a book form (with Taylor, 1938b). It was devised only two or three years after publishing Lange–Breit model. But this period brought an immense improvement of Lange's analytical expertise. On a Rockefeller Foundation Grant, Lange studied at Harvard, Berkeley and Chicago, and at the London School of Economics. He was strongly influenced by Schumpeter, under whose tutorship he worked at Harvard during most of his two-year scholarship, and he took part in a famous seminar (The Economics Club) led by the Austrian-American economist. That influence surfaces in many of Lange's studies, including his study *On the Economic Theory of Socialism*, especially in the economic justification of socialism. That study, or at least its main body, was written at Harvard and must have been heatedly discussed there. At that time he also became intellectually involved with the brothers Alan and Paul Sweezy, economists and socialists of a similar orientation to that of the visitor from Poland. He also had working contact with W. Leontief.

*On the Economic Theory of Socialism* expresses Lange's long-lasting conviction that neoclassical economics, especially welfare economics, is best suited to serve as a foundation of a theory of socialist economy. The classical model, of course, is theoretically more sophisticated and more accurate in its purely
economic aspect, but perhaps at the cost of giving less specific treatment to institutional aspects than the 1934 model. That was probably due to the chief purpose of that study, namely, to disprove Mises’ argument about a theoretical and practical (practical, according to Hayek and Robbins) infeasibility of economic calculus in socialism because of the absence of a genuine market (prices) for capital. Many formulations in that classical study indicate that a socialist society's general outlines of economic organization were similar or identical in both the early and classical models. In particular, this is true of the separation of political power from economic management, of its three-level structure – the centre, the branches organized in trusts, individual plants – and of the similar powers of the Central Planning Board (CPB) and the Public Bank. In both models, the centre is expected to react to changes in market factors (prices and wages) and, correspondingly, to changes in employment in the early model or to changing inventories and emerging shortages in the classical one. The CPB, basically, is to imitate the market. The early model was clearly more ‘market-oriented’ because all prices of goods and services were to be determined by the market. Accordingly, there would be no difference between actual market prices and calculated prices as set by the CPB.

**Lange–Lerner mechanism**

This is a designation commonly used to denote a market-oriented socialism model devised by Lange, who later amended it after public discussion with Lerner. The first, fundamental part of Lange's study was published together with A.P. Lerner's (1936) critical remarks in the same issue of the *Review of Economic Studies*, while the second part appeared together with Lange's reply to Lerner (1937). Later on, Lange made the changes necessary to publish his study (together with F.M. Taylor's essay) in book form (1938b). The term is occasionally used in a less restricted sense, to bring out the similarity of Lange's and Lerner's views on other matters concerning socialist economy.

The mechanism of socialist economy in the Lange–Lerner blueprint was based on the following assumptions. It has its institutional framework in the public ownership of means of production (for simplicity, the private sector is omitted) and in the free choice of consumption and employment (job and workplace), while consumer preferences – ‘through demand prices’ – are the all-decisive criterion of both production and resource allocation. Under these assumptions, an authentic market (in the institutional sense) exists for consumer goods and labour services. But prices of capital goods and ‘all other productive resources except labour’ are set by a CPB as indicators of existing alternatives established for the purpose of economic calculation. So, apart from market prices, there are also ‘accounting prices’. In order to make their choices, both categories of prices are used by enterprise and industry managers, who are public officials.

Production managers in charge of individual enterprises or entire industries make autonomous decisions about what and how much should be produced and how it should be done, while prices are set as parameters outside the enterprises or industries. But since profit maximization has by definition ceased to be a direct goal of economic activity, to ensure that they can achieve effects close to those achieved in free-market economy, production managers must obey two rules. First, they must pick a combination of production factors under which average cost is minimized; and second, they must determine a given industry's total output at a level at which marginal cost is equal to product price. The first rule was expected to eliminate all less efficient alternatives. In combination with the second rule, in so far as it concerns plant managers, it performs the same function as the free-market economy desire to maximize
profit. This leads to minimization of production costs. The second rule compels production managers to increase or cut the output of a whole industry in accordance with consumer preferences, which is a substitute for free entry in a free competitive economy.

These rules lead to an economic equilibrium by the trial-and-error method first described by Fred M. Taylor (1929). The CPB acts like an auctioneer, initially watching the behaviour of economic actors in reaction to a price system it picks at random or – perhaps the best solution – to the historically inherited prices. The behaviour of the system is measured by the movement of inventories of goods. If there is too much of some product at a given price, then its inventory grows, and vice versa. This is regarded as information that the product price should be cut or increased, respectively. This procedure is applied as many times as is necessary to reach equilibrium, providing that this process does in fact converge to the system of equilibrium prices. Accounting prices, then, are objective in character, just like market prices in a competitive system, the difference being that in this case the CPB performs the role of the market.

The same trial-and-error way towards equilibrium could also be applied in two other models of socialist economy, one providing for a decreased consumer influence on production programme, the other presupposing none at all.

In its extreme version, which for sociopolitical reasons Lange deems untenable, the model might provide no freedom of choice for either consumption or employment. Production plans would be decided by the CPB officials’ scale of preferences. In such a version all prices are basically accounting prices. Consumer goods are rationed, while the place and kind of employment are imposed by command. If production managers keep to the above-mentioned rules, and if the CPB keeps to the parametric price system, then economic calculus is possible even in this version, while prices are not arbitrary but reflect the relative scarcity of factors of production.

There is an intermediate model, which provides for freedom of consumption decisions but only within a production plan established on the ground of CPB preferences. In this case, accounting prices of producer and consumer goods reflect the CPB’s preference scale, while production managers would rely on them in their decision-making. Market prices for consumer goods would be set by supply and demand. But Lange rejects even this system as undemocratic, saying that the dual system of prices could be applied only when there is widespread agreement that checking the consumption of some products (say, alcohol) while promoting the consumption of other goods (say, cultural services) is in the public interest.

But the CPB might conceal its preferences and resort to rationing production goods and resources. Society can defend itself against such practices by creating a supreme economic court, which would be entitled to declare any unconstitutional CPB decision as null and void. In Lange's view, any decision introducing rationing would be unconstitutional.

Interestingly, Lange rejects these two versions of socialist economy on account of the potential hazards they carry for democracy, and says not a word about democracy's possible link with economic efficiency. Lange considers the distribution of national income in three aspects.

Wages would be differentiated by seeking a distribution of labour services that would maximize society's wealth in general. This happens when differences in marginal disutility of work in different trades and workplaces are offset by wage differences. Wage differentials can be treated as converses of prices paid by employees for differing work conditions, as a simplified form of buying free time, safety or pleasant work (which is easy to imagine assuming that all employees get the same earnings but pay different prices for doing different jobs; the easier and safer a given job, the more one has to pay for it).
In this sense, the wage differentiation rule can be brought into harmony with egalitarianism. Apart from wages paid by employees, each consumer is paid a public dividend as his or her share of capital and natural resources. At first Lange was inclined to distribute such dividends proportionally to wages. But as Lerner pointed out that such a policy would impart added attractiveness to the hardest jobs, Lange changed his mind, saying there should be no link between procedures for public dividend distribution and wage differentials.

The distribution of national income between consumption and accumulation, said Lange, would not be arbitrary when only consumers’ individual savings decide the rate of accumulation. But if savings are ‘corporately’ determined – and Lange at first thought that was typical of a socialist economy – then there would be no way of preventing the CPB from being at least partly arbitrary in its decisions.

Emphasizing that resource allocation is guided by formally analogous rules in both socialist and free competitive economies, Lange argued that real allocation in socialism would be different from and more rational than that in capitalism. In his static analysis, he considered the following factors as decisive in judging the relative performance of the two systems. Greater equality of income distribution enhances society's well-being (in the subjective sense, that is, as a sum total of individual satisfactions). Second, socialist economy makes allowances in its calculus for all the services rendered by producers and for all the costs involved, while a private entrepreneur does not care for benefits that do not flow into his own pocket nor for costs he does not have to pay: ‘Most important alternatives, like life, security, and health of the workers, are sacrificed without being accounted for as a cost of production’ (1938b, p. 104).

Even the possible flaws that Lange conceded might appear in a socialist economy, such as the arbitrary setting of the rate of accumulation or the danger of bureaucratization of economic life, would be milder than under capitalism, he argued.

But the ultimately decisive economic argument in favour of socialism, Lange believed, was the general waste and endogenous tendency towards stagnation generated by modern capitalism's monopolistic tendencies. This question, though, goes beyond the scope of the often-criticized static analysis underlying Lange's classical model. Leaving aside the now enormous critical literature, let us try to answer the question of what Lange himself saw as his model's limitations.

Lange anticipated possible charges by critics in the second part of his study, in his discussion of ‘The Economist's Case for Socialism’:

The really important point in discussing the economic merits of socialism is not that of comparing the equilibrium position of a socialist and of a capitalist economy with respect to social welfare. Interesting as such a comparison is for the economic theorist, it is not the real issue in the discussion of socialism. The real issue is whether the further maintenance of the capitalist system is compatible with economic progress. (1938b, p. 110)

But as he develops this general idea, Lange clearly uses an asymmetrical kind of argument. Having presented free competitive capitalism as the system that generated ‘the greatest economic progress in human history’, Lange proceeds to show (among other things, by referring to Keynes) that the source of that progress is drying up because of the progressive concentration and monopolization of production. His main point is that corporations, which are capable of controlling the market, attempt to avoid losses due to capital depreciation caused by innovation, and hence they try to check progress in technology.
Neither a return to free competition nor government control can effectively eliminate this tendency. The only effective solution, then, is the socialization of big capital, the introduction of socialism. But will socialism ensure rapid technical progress? Will the abolition, via socialization, of capitalist monopolies’ well-known tendency to check technological progress automatically dismantle all the barriers to innovation? Or will it amount to substituting new barriers for old? Will the two rules for managers be sufficient to guarantee the adoption of state-of-the-art production techniques? In his classic study, Lange never even asked such questions and only much later did he become aware of them. Towards the end of his life (in a letter to the present writer dated 14 August 1964), Lange wrote:

What is called optimal allocation is a second-rate matter, what is really of prime importance is that of incentives for the growth of productive forces (accumulation and progress in technology). This is the true meaning of, so to say, ‘rationality’.

It seems that he must have lacked the indispensable tools to solve this question or even to present it in detail.

**Towards a mixed economy**

Perhaps, the most important difference between the early (Lange–Breit) and the classical models was his new emphasis that ‘the real danger of socialism is that of a bureaucratization of economic life, and not the impossibility of coping with the problem of allocation of resources’. He reassured himself by pointing out that the same danger existed in monopolistic capitalism and that ‘officials subject to democratic control seem preferable to private corporation executives who practically are responsible to nobody’ (Lange, 1938b, pp. 127–8). When he became aware of that danger, which would exist even in a market-dominated brand of socialism, he embarked on a long quest for what he called in the title of one article (1943b), ‘The Economic Foundations of Democracy in Poland’. In the classical study he had already put forward the idea of a Supreme Economic Court whose function would be to safeguard the use of the nation's productive resources in accordance with the public interest, in particular to declare as null and void any CPB decision which was incompatible with adopted management rules. During the Second World War, Lange suggested a number of ideas for better safeguards for democracy, either by substantiating the injunction to take account of consumer preferences (and hence limiting the central economic authority’s prerogatives) or by devising institutional guarantees for democratic control of decision-making bodies, or by indicating limits to the socialization of property. There were a number of highlights of the evolution of Lange's views during that period. In his letter to Hayek in 1940 (Kowalik, 1984) Lange gave a more accurate, and perhaps slightly different, description of the CPB's prerogatives for pricing goods and services:

Practically, I should, of course, recommend the determination of prices by a thorough market process whenever this is feasible, i.e. whenever the number of selling and purchasing units is sufficiently large. Only where the number of these units is so small that a situation of oligopoly, oligopsony, or bilateral monopoly would obtain, would I

advocate price fixing by public agency•••.

Accordingly, he recommends socialization of industries only in areas where there is not automatic competitive market process. Later in 1942–3, he departed even further from his classical model towards a mixed economy. In his review of Dickinson's book (1942c), he had the following idea of how to prevent the central authority's arbitrariness in determining the accumulation rate. With reference to Lerner's observation of the dependence of interest rates not only on the quantity of capital involved but also on investment rates, Lange thought that, if saving was ceded to individual consumers, accumulation rates could be made to reflect consumers' preference. His 1936–8 model should be improved in this way, he said.

In his two public lectures delivered in Chicago in 1942 on 'The Economic Operation of a Socialist Society' (1975), Lange tacitly dropped what was perhaps the chief feature of his classical model, namely, the central authority's prerogative of setting and reviewing prices as a road towards equilibrium. He made only a passing remark about such a possibility, and only in reference to future prices the centre may impose on production managers in order to ensure stable forecasting (which is as a rule erratic in capitalist economy).

But perhaps the greatest change in his concept of the desired shape of socialism can be found in his above-mentioned article on economic foundations of democracy in Poland (1943b). The title alone shows that a commitment to furnish solid economic foundations for 'Poland's democratic order' was the point of departure in designing future political transformations. In that article, Lange envisaged the socialization only of key industries (which necessarily include banks and transport). This would put an end to the power of 'the socially irresponsible monopolistic capitalism'. Having said this, he cautions that care should be taken to prevent the socialized key industries from becoming a foundation for 'an equally dangerous' threat to democracy in the form of too much economic power being concentrated in the state bureaucracy along with privileges arising from this.

But private farms, crafts shops and minor but also medium-sized industries were all to remain areas of private initiative and enterprise. So broad a field of action for private entrepreneurship was, on the one hand, to be one foundation of democracy, and, on the other, it was to preserve 'the kind of flexibility, pliability and adaptiveness that private initiative alone can achieve'. This is the reason for which the development of private sector is to be one of the chief guidelines for the socialized financial policy. The private sector then appears to have been a permanent element of the new model Lange proposed for Poland.

This proposal had its counterpart for the United States in the lengthy essay written with Abba P. Lerner on a democratic programme for full employment (1944b).

The changes in Lange's views of socialist economy during the war years were evidently so substantial that they could be used to compose from them an alternative version of a market socialism, compared with which his classical model can indeed be described as 'quasi-centralistic' (Pryor, 1985). The extent of those changes may have been the reason why he dropped his previous plan to revise his classical study:

The essay is so far removed from what I would write on the subject today that I am afraid that any revision would produce a very poor compromise, unrepresentative of my thoughts. Thus, I am becoming inclined to let the essay go out of print and express my

present views in entirely new form. I am writing a book on economic theory in which a chapter will be devoted to this subject. This may be better than trying to rehash old stuff. (Letter to M. Harding, 25 May 1945: 1986, p. 553)

Towards a major synthesis

Lange's lifelong ambition to produce a synthesis can be seen to have differed in scope, so that a ‘minor’ and a ‘major’ synthesis can be distinguished in it. His earliest endeavours included an attempt to incorporate the Marshall's method of partial equilibrium into the general equilibrium theory developed by the mathematical school (1932). In later years, he wrote a series of studies commenting on various aspects of the Keynesian theory to include it in and reduce to a particular case of general equilibrium theory.

Several times during his life Lange prepared himself to create his major synthesis. He did have the indispensable background for such a job, not only on account of his economic versatility (he was intimately familiar with all the main currents and schools in economic theory, and with the ‘three economic worlds’) but also because he felt at home in several other disciplines such as statistics and econometrics, history and sociology, praxeology and cybernetics.

The first outline for a major synthesis came in his article ‘Marxian Economics and Modern Economic Theory’ (1935). His chief argument was that these two currents are in fact complementary. Their advantages and drawbacks arose from the different specific tasks each of them was supposed to do. Marxian economics was designed to furnish the revolutionary movement with guidance for rational policies, defining as it did the lines and limitations of the evolution of capitalism. Modern economic theory, for its part, was expected to provide a foundation for capitalist management. But equilibrium theory, which was designed to serve precisely this purpose, was actually universal in character, so after some adaptation it could be used for day-to-day management of a socialist economy, a job Marxist economics was ill-suited to do. For some time Lange thought his synthesis should be based on marginalist economics, the categories of which seemed even useful for presenting problems of class structure. Clinging to ‘Marxist semantics’ was to him a sign of traditionalism and conservative attitudes.

In the late 1950s, he began to work on a three-volume treatise on political economy that would rest on two tiers – historical materialism and the principle of rationality. On a lower level of abstraction he attempted, rather unsuccessfully, to synthesize Marxian political economy with the neoclassical economics. He managed to finish the first volume (1959; 1963) on scope and method of economics and half of the second one (1966; 1971a). However, Poland was at that time only at the beginning of shedding its isolation straitjackets and thus of rapidly changing political, ideological and scientific perspectives and possibilities. That is why, only four years after the publication of the first volume, Lange came to a conclusion that, after having written the two next ones, it would need a substantial reworking.

From idea to reality

Having returned to Poland after the Second World War Lange gave an entirely new expression to his view of socialist economy. But by an ironic twist of history (to which he was fond of referring) he articulated his new approach only when his views changed in an entirely different direction from what
he was pursuing during the wartime: namely, Lange embarked on the search for a rationale for the command-type economy and subsequently for ways of reforming it.

The evolution of Lange's views of socialism in the post-war years is much harder to follow because he became so deeply involved in political activity. Not only the form but also the substance of his views was often influenced by tactical considerations and by the changing scope of freedom of expression accorded to scholars in social science. The freedom was broad prior to 1948, virtually extinct in the early 1950s, considerable in the latter half of the 1950s, and gradually curtailed later on.

The main change in Lange's theoretical approach was that he switched over from a micro to a macroeconomic approach. Whereas he had previously based his argument on the general equilibrium theory, after 1945 he relied on a Marxian reproduction model. The new approach was first presented in the report he submitted to the International Statistical Conference (1947) on practical economic planning and optimal resource allocation. In this report he tried to confront eastern European economic practices with welfare economics. His point was that the centre's main decisions resulted from a desire to industrialize the country as rapidly as possible. The economic successes those countries had scored up to then were due to full employment and to the liquidation of private monopolies, which worked as powerful checks on their national economies in the past. Economic choices were a second-rate matter in the period of reconstruction, but as those countries were moving into a phase of development more sophisticated choices may have to be made. Marginal analysis may in such events prove useful, provided it is carried out in categories adequately reflecting reality. Although, Lange talked about practical planning in descriptive rather than theoretical terms and although he did not reject marginal analysis, F. Perroux said:

Je note que le théoricien socialiste a complétement changé de méthode. Il a autrefois essayé de montrer qu'une économie socialiste peut fonctionner à peu près comme isolée des unités économie de marché, sur la base de calcul. ... Il fonde aujourd'hui sa thèse sur les macro-décisions de l'Etat. Il le fait paradoxalement au moment précisément où tout le monde est d'accord sur la nécessité du 'breakdown of the aggregate quantities'. (1947, p. 172)

The new theoretical approach was given more clear-cut contours in a booklet (1953) in which Lange commented on Stalin's famous work on socialist economy in the USSR. The reasons for which Lange wrote that book, in which he extolled the Stalin work as 'a momentous event in the history of science with far-reaching practical consequences', are somewhat puzzling. He did it, probably, for two reasons. First, he was convinced that the Stalin work marked a turn from economic voluntarism towards respect for the inexorable laws governing economic life, towards a rehabilitation of efficiency and greater consideration of social needs. Indeed, the first studies written by Polish theorists who later became known as revisionists did find some support in Stalin's work.

The second reason that prompted him to write this booklet must have been his view of the evolution the Communist economies were undergoing due to industrialization. He believed that not only the Stalinist terror but also the main body of practical devices applied then, as well as the functioning of the economy itself at that time, were all determined by political considerations, specifically by militarization and the forceful industrialization bid (1943c). Lange often defined the centralistic command model as wartime economy. But he hoped that industrialization, with the subsequent emergence of an educated working
class and socialist intelligentsia, creates a good social base for democracy and decentralization of management. Presuming that industrialization entailed democratization, he believed the future of the ‘Polish economic model’ depended on how mature and experienced society will be. This is why he was unwilling ‘to design any new model from behind the desk’. In 1956–7 he refused to give his permission for the publication of an already finished translation of his classical work of 1936–8 because he did not want to lend his support to the ‘socialist free-marketers’. But it is unclear whether he regarded the market-oriented model of socialism as premature or as invalidated by the progress made in economic theory and practice (1967).

Late in his life, cybernetics and mathematical programming became his fascination. Using the theory of systems self-regulation and self-control, Lange gave an interpretation of the chief categories, wholes and parts, of dialectical materialism ([1962] 1965a). He also wrote an introduction to economic cybernetics (1965b), and to the theory of optimal decisions (1971b). This fascination was born from a belief in a great role of the computer as a most powerful device for central planning (sometimes called ‘computopia’). The strongest expression of this fascination contains his last publication on *The Computer and the Market* (1967). Recalling his polemics with Hayek and Mises, he confesses, that:

> Were I to rewrite my essay today my task would be much simpler. My answer to Hayek and Robbins would be: so what’s the trouble? Let us put the simultaneous equations on an electronic computer and we shall obtain the solution in less than a second. The market process with its cumbersome *tatonnements* appears old-fashioned. Indeed, it may be considered as a computing device of the pre-electronic age.

It is rather obvious that such a view sharply contradicts his strong attachment to Marxian economics as economic sociology regarded by him as a seminal step in explaining a structure and evolution of capitalism.

This was, however, one side of his views. The other one, expressed rather in private communications, stems from his everyday observation and was truly pessimistic. Above we mentioned his opinion about the prime importance of incentives for the growth of productive forces termed by him as a true meaning of rationality. A couple of months before his death he did appreciate sociological factors of economic development: ‘Poland became a completely parochial country. It is going to become the Portugal of the socialist block. The sociological setting generates an enduring stagnation, while an “explosive” solution of her problems stands no chance of success (nor does it seem really desirable). A change, if it comes, may be touched off by external developments, namely when Poland falls too far behind the capitalist world and the socialist world’ (O. Lange's letter to T. Kowalik of 19 February 1965, in his possession). Even if a comparison of Poland with the Salazar-time Portugal may be shocking, Lange's prophecy has proved to be quite realistic. Fifteen years later an ‘explosive solution’ in a form of a ten-million mass movement, ‘Solidarity’, brought first a lot of hopes, ended with martial law, but in another ten years Poland entered upon a track of peaceful dismantling of a Communist system. Theoretically, this could have opened a freedom for a democratic choice of socio-economic system, based if not on Lange's classical model literally then on his general democratic and egalitarian principles. It happened to the contrary. A wild form of capitalism emerged. Ronald Reagan, Margaret Thatcher, Milton Friedman and F.A. Hayek became prophets. The works of Oskar Lange and another eminent economist, Michał Kalecki, were rejected, their followers marginalized. At least five Polish politically engaged historians.
accused Lange of being a secret agent for the Soviet Union during his stay in the USA, although 13 volumes of declassified FBI documents clearly contradict this slander.

**The post-Langean concepts of market socialism**

Not all Western intellectuals have treated the sudden collapse of the Soviet bloc as a final victory of liberal capitalism. Even the *Washington Post* published (on 14 January 1990) an article entitled ‘In Eastern Europe Social Democracy – not Capitalism of “1984” is winning’. Some of them saw the possibility of creating a new economic system, which would not simply emulate Western-type capitalism, and elaborated proposals using some of Lange's ideas as a starting point.

One of the first of them was Joseph Stiglitz, who as early as spring 1990 sent the following remarkable message to the post-Communist countries:

> The answer that socialism provided to the age-old question of the proper balance between the public and the private can now (...) be seen to have been wrong. But if it was based on wrong, or at least incomplete, economic theories (...) it was also based on ideals and values many of which are eternal. It represented a quest for a more humane and a more egalitarian society (...). As the former socialist countries embark on their journey, they see many paths diverging. There are not just two roads. Among these there are many that are less traveled by – where they end up no one yet knows. One of the large costs of the socialist experiment of the past seventy years is that it seemed to foreclose exploring many of the other roads. As the former socialist economies set off on this journey, let us hope that they keep in mind not only the narrower set of economic questions that I have raised (...) but the broader set of social ideals that motivated many of the founders of the socialist tradition. Perhaps some of them will take the road less traveled by, and perhaps that will make all the difference, not only for them, but for the rest of us as well. (Stiglitz, 1990, p. 70; 1994, p. 279, emphasis added)

Stiglitz was very critical about the Lange–Lerner model of market socialism as based on wrong premises of the neoclassical paradigm. However, inspired by more general ideas of Lange, Michał Kalecki and the experience of Chinese gradual reforms, he suggested to the post-Communist countries several (for an American mainstream economist) very unconventional recommendations: not shock therapy as favoured by the IMF experts and particularly by Jeffrey Sachs, but evolutionary systemic changes; not market versus the state, but a search for the proper balance between market and government, the private and the state sector; not imitation of Anglo-Saxon capitalism, but a search for people's capitalism. He stressed that the post-Communist countries had most probably a chance to create a more egalitarian socio-economic system than any Western country. It was to be a mixed (market-cum-state) economy striving for social justice.

The efforts of a British philosopher and political scientist David Miller (1989) went in a different direction. Trying to create the theoretical foundations of market socialism, he explicitly says that his model would involve even ‘more extensive use of markets’ than the classical model of Oskar Lange. Several economists also presented different concepts as alternatives to capitalism directly referring to
some of Lange's ideas. The best known among them is John E. Roemer's (1994) proposal. Searching for an alternative system, which would be at least as efficient as present-day capitalism, he proposes to organize corporations in groups, operated according to the rules of the Japanese corporations called keiretsu with main banks crediting and monitoring them. Corporations would have to transfer after-tax profits to a state agency which would distribute it among all citizens as social dividend. This idea of a social dividend borrowed from Lange would be the main socialist feature of Roemer's model, which was nevertheless criticized as closer to capitalism than to socialist ideas.

Another American economist, James A. Yunker (1992), declared himself to be an enthusiast of Lange, not so much as an author of a classical model of socialism, but rather as a socialist thinker and particularly as a pioneer of reconciliation of conflicting theories. In this vein, he was arguing at the beginning of the 1990s for 'East–West ideological convergence' (Yunker, 1993) based on his ‘pragmatic market socialism’ presented in many publications. He took over from his master only certain ideas, such as the social dividend, the interest rate as the main regulator of investment, and the scope of public ownership to be limited to firms where management was separated from ownership. But in other respects Yunker's model was quite far from its original inspiration. The institutional crux of his concept was to be – as he writes – the Bureau of Public Ownership, which would take over all rights inherent in stocks, bonds and other financial instruments owned by private households. The operation of this public sector would be based on institutional investing, which would proceed much as it does in present-day capitalism.

Contrary to Stiglitz, both Roemer's and Yunker's models are based on fully fledged market mechanism and the neoclassical paradigm.

Different character of a book is that by W·odzimierz Brus (Oxford) and Kazimierz •aski (Vienna) (1989), both Polish emigrants as a result of the anti-Semitic campaign of March 1968. Earlier, while in Poland, Brus was a close collaborator of Lange and an eminent and very influential reform economist in the central European debates. Already in the beginning of the 1980s he became sceptical about the viability of market socialism. As a result of the analysis of its theoretical foundations and particularly a summary of the outcomes of reforms in the Soviet bloc, Yugoslavia and China, Brus and •aski are inclined to abandon the very concept of socialism meant as an economic organization radically different from capitalism. They do not reject, however, socialist ideals, but see them as possibly realized rather in Scandinavian-type reforms of capitalism. After the collapse of Communism they saw some sort of market socialism rather as a necessary stage of transition to a new socio-economic system, when a coexistence of public and private ownership will be tolerated.

Needless to say, in all countries of central and eastern Europe the above-mentioned concepts, even as cautious and moderate as that of Brus and •aski, fell on deaf ears.

Lardner, Dionysius (1793–1859)

Robert B. Ekelund, Jr.
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Jevons, W. S.; Lardner, D.; mathematical economics; price discrimination; profit maximization; spatial economics

Article

Scientific popularizer and railway economist, Lardner was born in Dublin on 3 April 1793 and died on 29 April 1859. He was educated at Trinity College, Dublin, between 1817 and 1827 and is probably best known for his Cabinet Cyclopaedia of 133 volumes, published between 1829 and 1849. Although Lardner's series was graced by a number of distinguished contributors, he was satirized in the scientific community as 'Dionysius Diddler'. An astronomer as well as an essayist on numerous scientific topics, Lardner often took side trips into other fields. He studied railway engineering in Paris, and was probably well acquainted with the econo-engineering work at the Ecole des Ponts et Chaussées at a time when Jules Dupuit was actively pursuing economic topics. His sole work relating to economics, Railway Economy (1850), was filled with the kind of factual work and analysis being undertaken by the French engineers and by an American pupil of the Ecole, Charles Ellet. Lardner's work caught the eye of W.S. Jevons, who claimed that a reading of Railway Economy in 1857 led him to investigate economics in mathematical terms.

There is little doubt that Lardner's book contains important and creative insights into economic theory. An authority on Belgian railroads of the time, Lardner drew up a vast array of facts to develop a theory of the railway firm's costs and revenues. His theory of profit maximization derived from 'empirical' firm's costs and revenues may be set out graphically (see Figure 1).

Figure 1

[Diagram of profit maximization]
The railway tariff, which Lardner identified as the independent variable, is displayed on the horizontal axis of the figure while total cost and receipts are measured on the horizontal. The total cost curve shows costs increasing as the tariff is lowered. At a prohibitive tariff $Ox$, that is, where no traffic would be transported, costs are some positive amount. Fixed costs, which exist whether traffic is carried or not, are an amount $xL$. As the tariff is lowered, increases in traffic carried cause total costs to increase until they reach maximum at a zero tariff. Both fixed and variable components of cost, then, are considered by Lardner.

Lardner formalized his conception of total receipts in the following terms. If, with Lardner, we let $r = \text{the tariff imposed per mile on each ton of goods carried}$, $D = \text{the average distance in miles to which each ton of goods is carried}$, $N = \text{the number of tons booked}$, and $R = \text{the gross receipts from goods transport}$, then total receipts may be expressed as

$$R = NDr.$$
As the tariff is lowered from Ox, the average distance of each ton carried, D, and the number of tons booked, N, increase. With reference to Figure 1, lowering the tariff from Ox causes receipts, R in Lardner's equation, to increase to some maximum mp. Tariff reductions below Om, however, cause total receipts to fall, so that at a tariff of zero, total receipts are zero (demand is inelastic for tariffs below Om).

Tariffs On′ and On are ‘break even’ tariffs in Figure 1 and, significantly, Lardner argued that the profit-maximizing tariff would fall somewhere between the break-even tariff On′ and the revenue-maximizing tariff Om. In modern terminology Lardner identified, if implicitly, the profit maximizing quantity as being where marginal cost equals marginal revenue.

It is noteworthy that Lardner's analysis of profit maximization, which so impressed Jevons, is nowhere to be found in Jevons's writings.

In addition to a fine model of the profit-maximizing firm, Lardner presented a fairly complete theory of price discrimination related to location in his Railway Economy. Specifically, Lardner called for a reduction in long-haul rail rates and for the increase in short-haul rates in order to increase the aggregate profits of the railroad. The differing elasticities of demand for transport which made this discriminatory pricing structure possible were explained on the basis of spatially distributed demanders.

Economists have often claimed that our theories were never intended to describe individual behaviour in all its idiosyncrasies. Instead, in this view, economic theory is supposed to explain only general patterns across large populations. The prime example is the theory of competitive markets, which is designed to deal with situations in which the influence of any individual agent on price formation is ‘negligible’. As in so many aspects of economics, Cournot (1838) was the first to make the role of large numbers explicit in his analysis. Cournot provided a theory of price and output which, as the number of competing suppliers increases without bound, asymptotically yields the competitive solution of price equals marginal and average cost. However, for any given finite number of competitors, an imperfectly competitive outcome results.

It took over a century for Cournot's insights on the role of large numbers to be fully appreciated. Edgeworth (1881) argued the convergence of his contract curve as the economy grew, and increasing numbers of authors assumed that the number of agents was ‘sufficiently large’ that each one's influence on quantity choices was negligible, but it was not until the contributions of Shubik (1959) and Debreu and Scarf (1963) to the study of the asymptotic properties of the core that the number of agents took a central role in economic analysis.

The crucial step in this line of analysis was taken by Aumann (1964). Arguing that, in terms of standard models of behaviour, an individual agent's actions could be considered to be negligible only if the individual were himself arbitrarily small relative to the collectivity, Aumann modelled the set of agents as being (indexed by) an atomless measure space. In this context, an individual agent corresponds to a set of measure zero, while aggregate quantities are represented as integrals (average, per capita amounts). Then changing the actions of a single individual (or any finite number) actually has no...
large economies: The New Palgrave Dictionary of Economics

influence on aggregates. The non-atomic measure space formulation brings three mathematical properties that have proven important. The first is that it provides a consistent modelling of the notion of individual negligibility: only in such a context is an individual truly able to exert no influence on prices. Thus, this model correctly represents the primary reason for appealing to ‘large numbers’: in it, competitive price-taking behaviour is rational. Moreover, this individual negligibility, when combined with an assumption that individual characteristics are sufficiently ‘diffuse’, means that discontinuities in individual demand disappear under aggregation (Sondermann, 1975).

The second property is that a (non-negligible) subset of agents drawn from an economy with a non-atomic continuum of agents is essentially sure to be a representative sample of the whole population. This property has proven crucial in the literature relating the core and competitive equilibrium. (See Hildenbrand, 1974, for a broad-ranging treatment of these issues.) It is also used in showing equivalence of core and value allocations (Aumann, 1975).

The other important property of the non-atomic continuum model is the convexifying effect. Even though individual entities (demand correspondences, upper-contour sets, production sets) may not be convex, Richter's theorem implies that the aggregates of these are convex sets when the set of agents is a non-atomic continuum. This property yields existence of competitive equilibrium in large economies even when the individual entities are ill behaved and no ‘diffuseness’ is assumed.

In the non-atomic continuum modelling, the individual agent formally disappears. Instead, one has coalitions (measurable sets of agents), and an individual is formally indistinguishable from any set of measure zero. The irrelevance of individuals is made very clear in the model of Vind (1964), where only coalitions are defined and individual agents play no part. Debreu (1967) showed the equivalence of Vind's and Aumann's approaches. A further extension of this line is to consider economies in terms only of the distributions of individual characteristics and allocations in terms of distributions of commodities. The strengths of this approach are shown in Hildenbrand (1974).

This disappearance of the individual is intuitively bothersome: economists are used to thinking about individual agents being negligible, but not about individuals having no existence whatsoever. Brown and Robinson (1972) provided an escape from this dilemma by their modelling of a large set of agents via non-standard analysis. This approach gives formal meaning to such notions as an infinitesimal that had been swept out of mathematics and replaced by ‘epsilon-delta’ arguments. In interpreting non-standard models, one distinguishes between how things appear from ‘inside the model’ and what they look like from ‘outside’. From outside, these models may have an infinity of (individually negligible, infinitesimal) agents, yet from inside each agent is a well-defined, identifiable entity. Using this mathematical modelling eases the interpretation of large economies and also allows formalization of some very intuitive arguments that otherwise could not be made. Unfortunately, the difficulties of mastering the mathematics of non-standard analysis have limited the number of economists using this approach.

While these formal models capture the essential intuition about the nature of economic behaviour of large economies, results obtained in this context should be of interest only to the extent that these models provide a good approximation to large but finite economies. This point was first emphasized by Kannai (1970), and its elaboration was the central issue confronting mathematical general equilibrium theory through the 1960s and early 1970s. The issue is one of continuity: in what sense are infinite
economy models the limits of finite economies as the economy grows, and do the various constructs of interest (competitive or Lindahl allocations, cores, value allocations, and so on) of the finite economies approach those of the limit, infinite economies? These questions are extremely subtle. A good introduction to them is Hildenbrand (1974).

The study of the limiting, asymptotic properties of various economic concepts represents an alternative, more direct (but often less tractable) approach to large economy questions than does working with infinite economies. This line begins with Cournot's (1838) treatment of the convergence of oligopoly to perfect competition, the general equilibrium development of which has been a major focus of recent activity (see Mas-Colell, 1982 and the references there). The work growing out of Edgeworth (1881) and Debreu and Scarf (1963) on the core-competitive equilibrium equivalence noted above also follows this line.

Once such convergence is established, the crucial question becomes that of the rate of convergence because asymptotic results are of limited interest if convergence is too slow. This question was first addressed for the core by Debreu (1975), who showed convergence at a rate of at least 1 over the number of agents.

A more direct approach to this issue of how large a market must be for its outcomes to be approximately competitive is to employ a model in which price formation is explicitly modelled. (Note that this is not a property of the Cournot or Arrow–Debreu analyses.) In a partial equilibrium context the Bertrand (1883) model of price-setting homogeneous oligopoly indicates that ‘two is large’, in that duopoly can yield price equal to marginal cost. Recent striking results in the same line for the double auction are due to Gresik and Satterthwaite (1985), who show that, even with individual reservation prices being private information, equilibrium under this institution can yield essentially competitive, welfare-maximizing volumes of trade with as few as six sellers and buyers.

This work is very heartening, for it tends to justify the profession's traditional reliance on competitive models which make formal sense only with an infinite set of agents. Another basis for optimism on this count comes from experimental work which shows strong tendencies for essentially competitive outcomes to be attained with quite small numbers. The further study of such institutions is clearly indicated.

large games (structural robustness)

Ehud Kalai

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In strategic games with many semi-anonymous players all the equilibria are structurally robust. The equilibria survive under structural alterations of the rules of the game and its information structure, even when the game is embedded in bigger games. Structural robustness implies *ex post* Nash conditions and a stronger condition of information-proofness. It also implies fast learning, self-purification and strong rational expectations in market games. Structurally robust equilibria may be used to model games with highly unspecified structures, such as games played on the web.

Keywords

herding; large games; mixed-strategy equilibrium; pure-strategy equilibrium; purification; rational expectations equilibrium; structural robustness

Article

Earlier literature on large (many players) cooperative games is surveyed in Aumann and Shapley (1974). For large strategic games, see Schmeidler (1973) and the follow-up literature on the purification of Nash equilibria. There is also substantial literature on large games with special structures, for example large auctions as reported in Rustichini, Satterthwaite, and Williams (1994).

Unlike the above, this survey concentrates on the structural robustness of (general) Bayesian games with many semi-anonymous players, as developed in Kalai (2004; 2005). (For additional notions of robustness in game theory, see Bergemann and Morris, 2005.)

Main message and examples

In simultaneous-move Bayesian games with many semi-anonymous players, all Nash equilibria are structurally robust. The equilibria survive under structural alterations that relax the simultaneous-play

Large economic and political systems and distributive systems such as the Web are examples of environments that give rise to such games. Immunity to alterations means that Nash equilibrium predictions are valid even in games whose structure is largely unknown to modellers or to players. The next example illustrates immunity of equilibrium to revisions, or being \textit{ex post} Nash, see Cremer and McLean (1985), Green and Laffont (1987) and Wilson (1987) for early examples.

\textbf{Example 1: Ex post stability illustrated in match pennies}\n
Simultaneously, each of $k$ males and $k$ females chooses one of two options, $H$ or $T$. The payoff of every male is the proportion of females his choice matches and the payoff of every female is the proportion of males her choice mismatches. (When $k=1$ this is the familiar match-pennies game.) Consider the mixed-strategy equilibrium where every player chooses $H$ or $T$ with equal probabilities. Structural robustness implies that the equilibrium must be \textit{ex post} Nash: it should survive in alterations that allow players to revise their choices after observing their opponents’ choices. Clearly this is not the case when $k$ is small. But as $k$ becomes large, the equilibrium becomes arbitrarily close to being \textit{ex post} Nash. More precisely, the Prob[some player can improve his payoff by more than $\epsilon$ \textit{ex post}] decreases to zero at an exponential rate as $k$ becomes large.

\textbf{Example 2: Invariance to sequential play illustrated in a computer choice game}\n
